In 2022–2023 an outbreak of Mpox spread in men who have sex with men (MSM) and caused over 95 000 cases globally due to clade II of Mpox. The incubation period was 5–24 days. A prodrome of fever, headache, malaise and sore throat was common. Lymphadenopathy frequently occurs and individuals are infectious during the prodrome. The skin lesions of Mpox are firm or rubbery and may demonstrate umbilication. Skin lesions evolve from papules or macules to vesicles and pustules and then scab over. Lesions are often painful and are infectious until the scab has fallen off and new skin has formed. During the outbreak in MSM, lesions could be few in number and were often concentrated in the anogenital region and mouth. Skin scars and bacterial superinfections were complications. The illness typically lasts 2–4 weeks. In the 2022 outbreak, there was a high prevalence of PWH. In general, clinical manifestations with PWH were similar to individuals without HIV but a detectable HIV viral load or CD4 count <100 cells/mm^3 was associated with complications. Diagnosis involves detection of Mpox DNA by PCR in a skin swab or skin lesion material. There are no licensed antivirals, but tecovirimat was used under exceptional cases for severe or complicated disease during the 2022 outbreak. Vaccination with the modified vaccinia Ankara-Bavarian Nordic vaccine (MVA-BN (UK) or JYNNEOS (USA)), which is a replication defective smallpox vaccine, reduced the incidence of Mpox during the 2022 outbreak. The vaccine was safe in PWH even with lower CD4 T-cell counts.

Cowpox

Humans in contact with infected cows develop large vesicles, usually on the hands or arms and associated with fever and regional lymphadenitis. The reservoir is thought to be wild rodents.

Vaccinia virus

This laboratory strain is used as the smallpox vaccine. Widespread vaccination is no longer recommended due to the likelihood of local spread from the vaccination site (potentially life-threatening in those with eczema (eczema vaccinatum) or immune deficiency) and of encephalitis. However, vaccination may still be recommended for key medical staff or for Mpox prevention in outbreaks.

Other poxviruses: orf and molluscum contagiosum

See page 1121 and Figure 14.30.

Gastrointestinal viral infections

Norovirus

Norovirus is the most common UK cause of infectious gastroenteritis and causes outbreaks in hospital wards, cruise ships and military camps. Food handlers may transmit this virus, which is relatively resistant to decontamination procedures. The incubation period is 24–48 hours. High attack rates and prominent vomiting are characteristic. Diagnosis may be achieved by antigen or DNA detection (PCR) in stool samples, although the characteristic clinical and epidemiological features mean that microbiological confirmation is not always necessary. The virus is highly infectious and cases should be isolated and environmental surfaces cleaned with detergents and disinfected with bleach.

Astrovirus

Astroviruses cause diarrhoea in small children and occasionally in immunocompromised adults.

Rotavirus

Rotaviruses infect enterocytes and are a major cause of diarrhoeal illness in young children worldwide. Winter epidemics are common in high-income countries, particularly in nurseries. Adults in close contact with cases may develop disease. The incubation period is 48 hours and patients present with watery diarrhoea, vomiting, fever and abdominal pain. Dehydration is prominent. Diagnosis is aided by commercially available enzyme immunoassay kits, which require fresh or refrigerated stool samples. Immunity develops to natural infection. Monovalent and multivalent vaccines have been licensed in many countries and have now demonstrated efficacy in large trials in Africa and the Americas.

Hepatitis viruses (A–E)

See Chapter 23.

Other viruses

Adenoviruses are frequently identified from stool culture and implicated as a cause of diarrhoea in children. They have also been linked to cases of intussusception.

Respiratory viral infections

These infections are described further on page 550.

Respiratory syncytial virus

Respiratory syncytial virus (RSV) is a major cause of lower respiratory tract infection in children but also in the elderly and immunocompromised. RSV is spread by droplets. It is a orthopneumonovirus, an enveloped RNA virus. The G protein aids attachment to the respiratory epithelium and the F protein enables host cell fusion. RSV causes seasonal outbreaks in the UK, but there is less seasonality in tropical climates. Most children are infected in the first years of life. Natural acquired immunity is not fully protective so recurrent infections occur throughout life.

Clinical features

In infants and young children 30%–70% of infections lead to lower respiratory tract infection, primarily bronchiolitis, characterised by wheezing and hypoxaemia or by pneumonia. Fever and acute otitis media are other features. Prematurity, chronic lung disease, congenital heart disease or immunocompromise are risk factors for more severe disease. In older children and adults, re-infections can be asymptomatic but typically result in upper respiratory tract infection with fever and cough. Compared to other causes of coryza, RSV symptoms last longer and can be more severe. Tracheobronchitis may occur and RSV can cause prolonged cough. Pneumonia or other lower airway complications may occur and wheezing is common. RSV can also cause lower respiratory tract infection in the elderly and can be associated with nursing home outbreaks or nosocomial transmission. It also causes lower respiratory tract infection in immunocompromised hosts, in particular allogeneic haematopoietic stem cell transplant recipients prior to engraftment or with graft-versus-host-disease. Patients with chronic medical conditions including chronic obstructive pulmonary disease may be more likely to experience lower respiratory tract infections or exacerbations of the underlying condition.

Diagnosis

When compared with influenza, productive cough, sinus pain or earache are more often reported in older children or healthy adults with RSV. Fever may be less marked than with influenza. RSV is detected by RT-PCR, often as part of a respiratory panel, but antigen detection point-of-care tests are often used to aid rapid diagnosis. Antigen testing is sometimes used in children but is less sensitive in adults.

Management

To prevent RSV in infants, one of two strategies are recommended: either maternal vaccination in pregnancy at 32–36 weeks' gestation with one approved recombinant protein subunit vaccine; or use of a long-acting monoclonal antibody against RSV, nirsevimab. Nirsevimab is used for infants up to 8 months whose mothers have not received vaccination, or whose mothers are at risk of not responding to vaccination. It is also recommended for certain infants entering their second RSV season with a high risk of severe RSV due to conditions such as immunocompromise, chronic lung disease of prematurity, manifestations of severe cystic fibrosis (CF) or severe congenital heart disease. Nirsevimab is preferred because of its efficacy and duration (administration provides protection for one RSV season) over another monoclonal antibody, palivizumab, which was recommended before nirsevimab was licensed. In older adults vaccines are also licensed to prevent RSV. Licensed vaccines are protein subunit vaccines (using the F protein) or an mRNA vaccine. In the United Kingdom vaccination is recommended at 75 years and older and in the United States at 60 years. The antiviral ribavirin has been used in nebulised formulation against RSV in severely immunocompromised patients, e.g. allogeneic haematopoietic stem cell transplant recipients with RSV, but there are concerns about efficacy and there are challenges to administration.

Coronaviruses

Coronaviruses are single-strand positive-sense RNA viruses that cause widespread infection in animals and humans.

Coronaviruses HCoV-229E, HCoV-NL63, HCoVH-KU1 and HCoV-OC43 have a worldwide distribution. They usually cause mild upper respiratory tract infection, but occasionally more serious respiratory infection at extremes of age or in immunocompromised hosts.

Three coronaviruses within the genus *Betacoronavirus* have emerged in recent years that cause more serious infections. These are SARS-CoV (severe acute respiratory syndrome coronavirus), MERS-CoV (Middle East respiratory syndrome coronavirus) and SARS-CoV-2 (the cause of coronavirus disease 2019; COVID-19). These coronaviruses have emerged as zoonoses from bats and potentially intermediate hosts. The intermediate hosts for SARS-CoV and MERS-CoV include palm civets and camels, respectively, but the identity of the intermediate host(s) for SARS-CoV-2 remains elusive.

Pathogenesis

The coronaviruses contain non-structural proteins including RNA-polymerases and proteases and structural proteins including the envelope, spike (S) glycoprotein and nucleocapsid protein. The coronaviruses infect a range of cells, including respiratory and gastrointestinal epithelial cells. Initial interactions involve the S glycoprotein, which binds to the surface receptor. For SARS, SARS-CoV-2 and HCoV-NL63, the receptor is the human angiotensin-converting enzyme 2 (hACE2). The receptor-binding domain of the S glycoprotein undergoes mutation to allow adaptation during cross-species transmission from bats to other species, including man.

Coronaviruses induce suboptimal early interferon responses. Antiviral immunity requires production of neutralising antibody and effective CD4$^+$ and CD8$^+$ T-cell responses. In SARS-CoV and SARS-CoV-2 infection, pulmonary complications typically emerge after 1–2 weeks and are thought to result from dysregulation of immune responses and recruitment of pro-inflammatory CCR2$^+$ monocytes in the lung contribute to inflammation. Disease is more severe in older individuals and it is thought this may correlate with suboptimal T-cell responses and enhanced pro-inflammatory responses with ageing. For SARS-CoV-2, activation of the clotting cascade in association with marked inflammation appears to be a distinct feature. Microthrombi occur around the body and both venous thromboembolism and arterial clots in the heart and brain may be prominent features.

SARS coronavirus (SARS-CoV)

SARS-CoV emerged as a major respiratory pathogen during an outbreak of SARS in 2002–2003, in which there were approximately 8000 cases. The virus originated in China, and spread to several other countries, with secondary transmission reported. SARS presented as a flu-like illness with non-specific symptoms, including fever, malaise, myalgia, headache, diarrhoea and shivering. In severe cases these progressed to pneumonia, requiring intensive care admission. The case fatality rate was approximately 11%.

Middle East respiratory syndrome coronavirus (MERS-CoV)

In 2012, a novel coronavirus, distantly related to SARS-CoV, caused several deaths connected with pneumonia in patients originating from the Middle East. The Middle East respiratory syndrome coronavirus (MERS-CoV) appears to be a zoonosis, involving transmission from bats to camels and then to humans. Over 20 countries have reported cases, although most cases have a history of travel to Saudi Arabia or other countries in the Arabian Peninsula. By 2024 there had been over 2620 reported cases including hospital acquired. MERS-CoV remains an important but still geographically restricted coronavirus.

Clinical features

The incubation period in person-to-person transmission is 2–14 (average 5) days. Any age may be infected but patients over 50 with medical comorbidities are particularly susceptible to severe disease. Initial symptoms are fever, chills, headache, myalgia, dry cough and dyspnoea. Abdominal pain and diarrhoea may be prominent. The mean period from symptom onset to hospitalisation is 4 days, and 5 days to intensive care unit admission. Illness is complicated by rapid development of respiratory failure and features of ARDS and multi-organ failure. Mortality is 35%.

Diagnosis and management

Laboratory features include lymphopenia, thrombocytopenia and raised lactate dehydrogenase (LDH). Diagnosis is confirmed by detection of virus RNA (PCR) in serum, nasopharyngeal or other respiratory samples. Antibody detection may also be useful. Treatment is supportive. Strict infection control measures should be implemented for anyone with fever, severe respiratory illness and epidemiological risk factors. Patients should be managed in an airborne infection isolation room with contact and airborne infection control measures, including personal protective equipment for health-care workers.

SARS-CoV-2

SARS-CoV-2 was first identified in December 2019 in Wuhan, China, and spread globally. The virus is believed to have been transmitted to humans via horseshoe bats (*Rhinolophus sinicus*) and potentially other intermediate hosts, to whom individuals may have been exposed at wild food markets.

SARS-CoV-2 appears to be more transmissible than SARS-CoV and MERS-CoV. The World Health Organization declared COVID-19 to be a pandemic in March 2020, just 3 months after it was first identified. By late 2020 new variants had emerged carrying several amino acid substitutions. In May 2021, to both simplify the nomenclature and avoid the pejorative connotations of geographic associations, the WHO started to assign Greek characters to the variants, for example Omicron (e.g. B.1.1.529). The variants have higher R numbers than the ancestral virus and are more transmissible due to mutations in the receptor-binding domain of the S protein. Mutations modify interactions with antibodies generated after natural infection or vaccination, necessitating adjustment of seasonal vaccines. SARS-CoV-2 is therefore very much a ‘moving target’ with respect to disease prevention strategies.

Infection prevention and control in health-care settings

SARS-CoV-2 is believed to be predominantly transmitted by droplet spread in most circumstances (short-range airborne transmission, e.g.

14.55 Infection prevention and control strategies used for COVID-19 in the health-care setting*

‘Standard’ precautions	• Hand hygiene • Use of personal protective equipment (PPE), e.g. masks, gloves, aprons, gowns and eye protection, according to the clinical circumstances • Spillage, sharps, laundry and clinical waste management • Environmental cleaning and disinfection
Transmission-based precautions	• A combination of airborne, contact and droplet precautions (see Box 7.9) with airborne precautions often reserved for situations in which aerosol-generating procedures (AGPs) are carried out • Different precautions may be applied depending on the level of patient risk (e.g. confirmed vs. suspected COVID-19)
Isolation, cohorting and quarantining	• Isolation or cohorting to minimise the risk of onward transmission (cohorting should be reserved for confirmed cases, or it carries the risk of uninfected patients being exposed to infected patients) • Quarantining patients prior to elective procedures • Quarantining staff who test positive for SARS-CoV-2
Screening	• Admission screening to identify asymptomatic infected patients • Interval screening of inpatients to identify and prevent health care–acquired COVID-19 • Pre-procedure screening for patients having elective procedures • Staff screening to identify asymptomatic infected staff
Visitor restriction	• To minimise the possibility of uninfected patients being infected by visitors, and vice versa
Contact tracing	• Detection (and subsequent isolation) of uninfected patients who have been exposed to infected patients (e.g. in a bay/hospital ward) and staff

*Infection prevention and control measures vary with time, in different countries and according to resource availability.

when an infected patient is breathing rapidly or coughing). It can also be transmitted when a patient is subjected to an ‘aerosol-generating procedure’ (AGP). AGPs include (but are not limited to) tracheal intubation, manual ventilation, non-invasive ventilation and the use of certain high flow oxygenation treatments.

The control of COVID-19 in health-care settings therefore requires a combination of measures, as shown in Box 14.55.

Public health measures

A major strategy for limiting spread of SARS-CoV-2 has been the introduction of non-pharmacological interventions (NPI) such as physical distancing measures, the most wide-reaching of which have been termed ‘lockdowns’. The components have typically included: the closure of schools, workplaces, non-essential shops, sporting and entertainment venues; a move to remote (i.e. computer-based) working where possible; banning mass gatherings; curfews; stay-at-home orders; and other local, national and international travel restrictions. Not all countries employed lockdowns. Physical distancing measures are designed to slow the spread of the virus and limit the burden of serious illness on overstretched health services, rather than to eradicate the virus.

Other important measures in limiting virus spread are ensuring high levels of case identification, ramping up testing to identify cases, ensuring public health follow-up of potential cases and enforcing quarantine measures for cases, contacts and travellers from high-incidence countries. Novel approaches to ‘test, trace and isolate’ (TTI) have been developed, including the use of mobile phone apps.

Social distancing strategies employed when lockdown is not considered necessary have included keeping people physically separate (a target of ≥ 2 metres has been used in the UK), promoting frequent hand hygiene and enforcing the use of face coverings in places where close contact is likely.

Vulnerable adults, including older and immunocompromised people, have been advised to limit social interactions, a strategy termed ‘shielding’ in the UK.

Clinical features

The incubation period for COVID-19 is 5–6 days on average but can range from 2 to 14 days. Many infections, approximately 40%, are asymptomatic. Where patients do experience symptoms, these are very variable and depend on the vaccination status of the patient and the SARS-CoV-2 variant with which they are infected.

In unvaccinated patients features include high fever, persistent cough, shortness of breath and loss of taste or smell. Myalgia, fatigue, dizziness or headache are also frequent, as are chest pain, vomiting and diarrhoea. Vomiting and diarrhoea may be prominent features and may precede fever, and gastrointestinal symptoms are often also prominent in children. Confusion or delirium occur, particularly in older people. In vaccinated individuals with variant strains that have evolved since the pandemic onset, a greater range of symptoms, for example cough, sore throat, coryzal symptoms fatigue, myalgia and headaches, which resemble other upper respiratory tract infections, are observed. Delirium and confusion in the elderly remain common.

Before the introduction of vaccination, approximately 15% of symptomatic patients would develop severe symptoms and 5% critical illness. These are now less frequent. Physical examination of such patients may reveal tachycardia, hypotension, cyanosis, hypoxia or bilateral crackles in the lung fields. Bronchial breath sounds and focal consolidation are a frequent feature of COVID-19. These usually are the response to the viral infection alone, and only in a minority of cases suggest bacterial superinfection. Skin lesions are occasionally noted and include maculopapular lesions, vesicles, pustules and urticarial lesions.

If complications occur, they usually develop in the second week. These are most commonly due to acute respiratory distress syndrome (ARDS). Bacterial pneumonia complicates a minority of infections, and sepsis may occur. Superinfections occur, in particular in those receiving invasive mechanical ventilation. Disseminated intravascular coagulation (DIC) may occur and is associated with severe disease and multi-organ failure. Venous thromboembolism occurs in 20%–30% of critically ill patients but may occur in any patients with microthrombi in the lung distinct from conventional pulmonary emboli.

A specific but rare manifestation in children was the ‘paediatric inflammatory multisystem syndrome: temporally associated with SARS-CoV-2’ (PIMS-TS), also referred to as multisystem inflammatory syndrome in children (MIS-C). This severe complication consisted of fever, abdominal symptoms, rash, conjunctivitis and markers of a high inflammatory response. Myocardial dysfunction, shock and respiratory failure were complications, and some children met a clinical definition of Kawasaki disease with features such as coronary artery dilatation or vascular aneurysms. This syndrome appeared distinct from Kawasaki disease; however, since it involves an older age group with more marked elevation of inflammatory biomarkers, and is associated with COVID-19. There was also a variant of MIS in adults. As the pandemic evolved, this syndrome became much less common.

The true case fatality rate for SARS-CoV-2 infection is hard to accurately predict. By 2024 global estimates suggested over 700 million infections and 7 million deaths, suggesting case fatality has now fallen to approximately 1%.

Virus is shed in respiratory secretions for approximately 7–24 days. Infection rates appear higher in urban or socially deprived areas. Mortality is higher with male gender, age and frailty (Box 14.56) and medical comorbidity (e.g. diabetes, heart disease, hypertension, chronic lung disease). Immunocompromised patients may have atypical presentations and prolonged viral shedding.

Features of COVID-19 in comparison to influenza are highlighted in Box 14.57.

Long COVID

In the UK, the National Institute for Health and Care Excellence (NICE) has defined acute COVID-19 as 'signs and symptoms of COVID-19 for up to 4 weeks', ongoing symptomatic COVID-19 as 'signs and symptoms of COVID-19 from 4 to 12 weeks' and the post-COVID-19 syndrome as 'signs and symptoms that develop during or after an infection consistent with COVID-19, continue for more than 12 weeks and are not explained by an alternative diagnosis'. 'Long COVID' and post-COVID-19 terms are often used interchangeably and can involve any part of the body. The World Health Organization has developed a definition for 'post COVID-19 condition' that specifies a symptom duration of at least two months, with symptoms being either a continuation of the initial infection or new symptoms after initial recovery. Common features of long-COVID include fatigue, memory problems and poor concentration ('brain fog'), myalgia, arthralgia, shortness of breath, palpitations and dizziness. Persistent headache, insomnia and mental health symptoms such as depression are frequently reported. Optimal management strategies for long COVID are still evolving.

14.56 Features of COVID-19 in older age and frailty

- **Pathogenesis:** reduced expression of hACE2 may predispose to more severe respiratory presentation.
- **Immunity:** increased inflammatory responses in general and reduced antiviral responses may reduce viral clearance and increase complications.
- **Clinical features:** atypical presentations with confusion, delirium and falls.
- **Complications:** increased complication rates.
- **Mortality:** case fatality rate increased in those > 65 years and increases with age.
- **Treatment:** may be less likely to be admitted to intensive care.
- **Preventative strategies:** older adults are associated with lower vaccine responses.

(hACE2 = human angiotensin-converting enzyme 2)

14.57 Influenza versus COVID-19

Characteristic	Influenza	COVID-19
Time to symptoms	1–4 days	2–14 days
Transmission	Mainly when symptomatic Onset a day before symptoms start Duration approximately 4 days Less transmissible than SARS-CoV-2	Frequently when asymptomatic Onset 2–3 days before symptoms start Duration approximately 10–11 days More transmissible than influenza A viruses
Symptoms	Similar but diarrhoea mainly in young children not adults Loss of taste and smell less common	Diarrhoea at all ages Loss of taste and smell commonly seen with early strains but now less common
Complications	Super-infections more common Blood clots less common than in COVID-19 Multisystem inflammatory syndrome (MIS) not observed Direct pathological features of viral replication	Super-infections less common Blood clots more common MIS in children and adults Inflammatory complications after viral peak

Investigations

Acute laboratory abnormalities can include an increased neutrophil to lymphocyte ratio; elevated ALT, D-dimer and inflammatory markers, including C-reactive protein (CRP) and ferritin; hypoalbuminaemia and lymphopenia. Acute kidney injury is common in severe disease. Hyperglycaemia is common and may be observed in patients not known to be diabetic. Hypoxia may be accompanied by hypocapnia so that it appears inappropriately well tolerated with a mismatch between hypoxia and respiratory rate during severe disease.

Chest radiology shows bilateral predominantly basal and peripheral infiltrates, or in a minority, unilateral infiltrates. CT scan of the chest shows 'ground-glass' abnormalities, consolidation, septal thickening or crazy-pavement patterning (Fig. 14.31).

Microbiological diagnosis is by nasopharyngeal or oropharyngeal swab and RT-PCR to detect viral RNA. Detection is now combined as part of respiratory panels, and rapid point-of-care tests are often employed. Lateral flow immunochromatography (p. 131) is also used to detect SARS-CoV-2 antigens. It is rapid (around 30 minutes) and can be used at home but is less sensitive and specific than PCR.

Management

In severe illness respiratory failure is managed with high flow oxygen and 'awake' proning. Non-invasive ventilation or mechanical ventilation are required for those with more severe respiratory failure. Shock and organ dysfunction are treated as per critical care guidelines. Antimicrobials are added only if there are signs or symptoms suggestive of secondary infection and antifungals only if there is evidence of COVID-19-associated pulmonary aspergillosis. Anticoagulation is used as in other groups where there is documented evidence of venous thromboembolism. For prevention it is recommended to use therapeutic levels of anticoagulation when treating patients with moderate COVID-19, due to increased risks

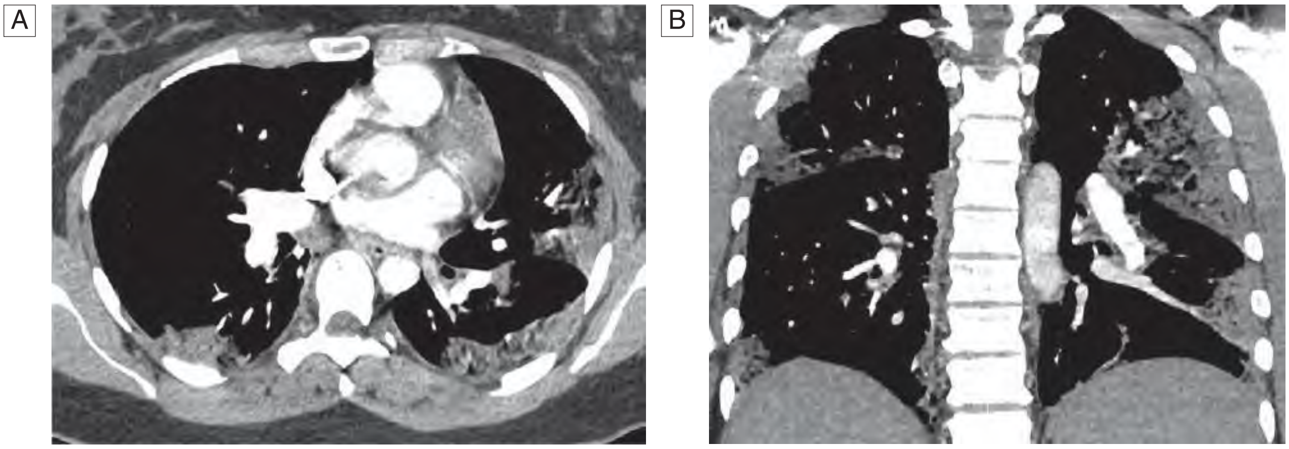

Fig. 14.31 Axial A and coronal B CT scans in a patient with COVID-19 showing multiple focal areas of consolidation in both lungs.

of thromboembolism, but to use prophylactic doses when treating patients with critical or severe COVID-19. Dexamethasone (6 mg once a day orally for 10 days) improves survival and is recommended for all hospitalised patients requiring supplemental oxygen or mechanical ventilation. Where dexamethasone cannot be given, alternative corticosteroids can be used. Anti-interleukin (IL)-6 monoclonal antibodies (e.g. tocilizumab) or oral baricitinib (a Janus kinase inhibitor) may be added to reduce mortality in hospitalised patients on supplemental oxygen or mechanical ventilation, who are receiving dexamethasone and do not have evidence of a super-infection complicating COVID-19 but have a CRP > 75 mg/L.

An initial randomised clinical trial of the nucleotide analogue remdesivir (Ch. 7) found that it decreased the time to recovery when used within 10 days of symptom onset in patients requiring supplemental oxygen but not mechanical ventilation. However, it has not been found to significantly improve survival and is not currently recommended by the WHO. It may be used for patients hospitalised with COVID pneumonia. In the UK, NICE guidelines emphasise that its use is likely only cost-effective in patients who are at high risk of progression to severe COVID-19, such as immunocompromised groups. For hospitalised patients it is administered intravenously as a 200 mg loading dose and as 100 mg daily for up to 5 days.

For patients at high risk of progression to severe COVID-19, antivirals may also be used. Two oral antivirals are available: Paxlovid (nirmatrelvir with ritonavir) and molnupiravir. Paxlovid is a combination of two protease inhibitors: nirmatrelvir inhibits the SARS-CoV-2 3CL protease and ritonavir inhibits the breakdown of nirmatrelvir. It is the preferred agent, but the presence of ritonavir means there are many drug–drug interactions which can limit use, particularly in immunocompromised (e.g. solid organ transplant), comorbid or elderly patients at high risk of progression. It is dosed as 300 mg nirmatrelvir/100 mg ritonavir orally twice a day for 5 days. Molnupiravir is a prodrug, which is metabolised into a form that causes viral RNA-dependent RNA polymerase to introduce fatal mutations into nascent RNA strands. Although it represents an alternative, there is uncertainty about its efficacy since initial trial data involved unvaccinated patients and has not included more recent viral strains. Both agents should only be used in the community for individuals with mild COVID-19 symptoms, but at high risk of progression to severe disease. Both should be used within 5 days of symptom onset. Remdesivir can also be used in high-risk patients at risk of progression to severe COVID. It is administered intravenously with a 200 mg load and then at 100 mg a day for 3 days. It should only be used when the oral agents are unsuitable or not available and must be started within 7 days of symptom onset.

An alternative antiviral strategy is to use antibodies against the virus. The use of single monoclonal antibodies to variable regions of the S protein is limited by rapid emergence of viral resistance, and they have not demonstrated sustained efficacy even in combination. Currently only sotrovimab is available for use against mild COVID-19 in patients at high risk of progression to severe disease and in whom other oral agents such as Paxlovid are not suitable. Its role in the future is uncertain. Trials using convalescent serum have not shown efficacy.

Vaccination

Currently available vaccines are updated each year on the basis of recently circulating SARS-CoV-2 variants. Individuals should get an annual updated vaccine if they are older than 75, nursing home residents or immunocompromised. In addition, people who live in care homes or who are health workers should receive an annual vaccine. The SARS-CoV-2 vaccines induce T-cell immunity in addition to neutralising antibody. Vaccines have a more dramatic effect on reduction of hospitalised cases than they do on reduction of overall infection, but they still play a major role in reducing community transmission. Reported severe complications have occurred at incidences approximating 1 per million or less. At least two of the adenoviral vector COVID-19 vaccines have been linked to very rare cases of thrombosis with thrombocytopenia (vaccine-induced thrombosis with thrombocytopenia syndrome (TTS)), a condition with some similarities to heparin-induced thrombocytopenia (p. 970). Guillain–Barré syndrome is also reported after the adenoviral vaccines. The RNA vaccines have been linked to rare cases of myocarditis and pericarditis. The need to maintain the 'cold chain' from manufacture to administration is a particular challenge for the pure RNA SARS-CoV-2 vaccines, as they need to be stored at either −20°C or −70°C at all times.

'Vaccine hesitancy' refers to a heterogeneous process in which individuals may refuse or delay vaccination. Vaccine hesitancy has been encountered in many countries and may be more prominent in populations with demographics that vary in different regions. This can represent a major challenge to ensuring high levels of vaccine uptake in a population.

Other respiratory viruses

Adenoviruses, rhinoviruses and enteroviruses (coxsackieviruses and echoviruses) often produce non-specific upper respiratory tract symptoms but may cause viral pneumonia. Parainfluenza causes upper respiratory tract disease and croup in small children and pneumonia, particularly in the immunocompromised. Metapneumovirus and bocavirus cause upper and occasionally lower respiratory tract infection, especially in immunosuppressed individuals.

Viral infections with neurological involvement

See also page 1220. For rabies and for polio, see page 1221.

Japanese encephalitis virus (JEV)

This flavivirus is an important cause of endemic encephalitis in Japan, China, Russia, South-east Asia, India and Pakistan; outbreaks also occur elsewhere. There are 10 000–20 000 cases reported to the WHO annually. Pigs and aquatic birds are the reservoirs and transmission is by *Culex* mosquitoes. Exposure to rice paddies is a recognised risk factor.

Clinical features

The incubation period is 4–21 days. Most infections are subclinical in childhood and 1% or less of infections lead to encephalitis. Initial systemic illness with fever, malaise and anorexia is followed by headache, photophobia, vomiting and changes in brainstem function. Other neurological features include meningism, seizures, cranial nerve palsies, flaccid or spastic paralysis and extrapyramidal syndromes. Mortality with neurological disease is 25%. Some 50% of survivors have neurological sequelae.

Investigations, management and prevention

Other infectious causes of encephalitis should be excluded. There is neutrophilia and often hyponatraemia. CSF analysis reveals lymphocytosis and elevated protein. Serological testing of serum and CSF aids diagnosis but may cross-react with dengue and other flaviviruses.

Treatment is supportive. Vaccination is recommended for travellers to endemic areas during the monsoon. Some endemic countries include vaccination in their childhood schedules.

Tick-borne encephalitis virus

This flavivirus is endemic in an area from northern Europe (including the UK) that extends across Siberia to China and Japan. Its incidence is increasing, and it is transmitted from domestic or wild animals by *Ixodes* ticks or sometimes by unpasteurised dairy products. The incubation period is up to 28 days but averages 7 days. A third of cases cause symptoms, with fever, myalgia and headache followed by an interval of up to a month before meningitis, encephalitis or radiculitis occur. The Far

Eastern subtype tends to be more severe. Diagnosis is by IgM ELISA or detection of viral RNA by RT-PCR of blood or CSF. IgG serology cross-reacts with other flaviviruses. Treatment is supportive. Prevention is by avoidance of tick bites. A vaccine is also available.

West Nile virus

This flavivirus is an important cause of neurological disease throughout Australia, India and Russia through Africa and southern Europe and across to North America. The disease has an avian reservoir and a *Culex* mosquito vector. Older people are at increased risk of neurological disease.

Clinical features

Most infections are asymptomatic. After 2–6 days' incubation, a mild febrile illness and arthralgia may occur. A prolonged incubation may be seen in immunocompromised individuals. Children may develop a maculopapular rash. Neurological disease is seen in 1% and is characterised by encephalitis, meningitis or asymmetric flaccid paralysis with 10% mortality.

Diagnosis and management

Diagnosis is by serology or detection of viral RNA in blood or CSF. Serological tests may show cross-reactivity with other flaviviruses, including vaccine strains. Treatment is supportive.

Nipah virus encephalitis

Nipah virus is a paramyxovirus in the *Henipavirus* genus, which caused an epidemic of encephalitis in Malaysia and subsequent outbreaks in Bangladesh and India. It is carried by fruit bats and infects humans usually by consumption of unpasteurised date palm sap. Human-to-human spread occurs to health-care workers. Mortality is around 70%. Diagnosis is by PCR or serology.

JC virus

JC virus (polyomavirus 2) is a DNA polyoma virus. After initial asymptomatic infection, the virus remains latent. It can cross the blood–brain barrier and can reactivate in people with significant T-cell immunosuppression. These include patients with AIDS, organ transplants or those who have received certain monoclonal antibodies e.g. anti-CD20 (rituximab) and anti-alpha4 integrin cell adhesion molecule (natalizumab, used in multiple sclerosis and Crohn disease). Reactivation in the brain leads to loss of oligodendrocytes, white matter inflammation and characteristic white matter space-occupying lesions on MRI scan of the head, a condition termed progressive multifocal leukoencephalopathy (PML) (p. 330). Diagnosis involves detection of JC virus by PCR in the cerebrospinal fluid. There is no specific antiviral therapy, and despite withdrawal of immunosuppressant agents or administration of ART for PWH, mortality is high.

BK virus is a related polyoma virus (polyoma virus 1), which can reactivate in the kidney of renal transplant recipients causing BK virus–associated nephropathy, leading to graft rejection. It also causes interstitial nephritis and bladder fibrosis in patients after haematopoietic stem cell transplant. Diagnosis is on biopsy material or PCR of blood or urine. Treatment involves reduction of immunosuppression. Leflunomide can be used as second-line therapy.

Human T-cell lymphotropic virus type I

Human T-cell lymphotropic virus type I (HTLV-1) is a retrovirus that causes chronic infection with development of adult T-cell leukaemia/lymphoma (ATL) or HTLV-1-associated myelopathy (HAM) in a subset of those infected (see Box 24.60). It is found mainly in Japan, the Caribbean, Central and South America, and the Seychelles. The lifetime risk of ATL in those with chronic HTLV-1 infection is estimated at 2.5%–4%. HAM or tropical spastic paraparesis occurs in less than 5% of those with chronic infection, and presents with gait disturbance, spasticity of the lower extremities, urinary incontinence, impotence and sensory disturbance. Myositis and uveitis may also occur with HTLV-1 infection. Serology, sometimes confirmed with PCR, establishes the diagnosis. Treatment is supportive.

Viral infections with rheumatological involvement

Rheumatological syndromes characterise a variety of viral infections ranging from exanthems, such as rubella and parvovirus B19, to blood-borne viruses, such as HBV and HIV-1 and the sequelae of EVD.

Chikungunya virus

Chikungunya is an alphavirus that causes fever, rash and arthropathy. The disease occurs mainly in Africa and throughout Asia, but is becoming commoner in other areas, including South America and the Caribbean. Cases occur sporadically or in epidemics, with notable epidemics occurring in Réunion and Mauritius (> 272 000 cases in 2005–2006) and India (1 400 000 cases in 2006). Humans and non-human primates are the main reservoir. The vectors are *Aedes* mosquitoes including *Ae. aegyptii* and *Ae. albopictus*.

The incubation period is 2–12 days. A period of fever may be followed by an afebrile phase and then recrudescence of fever. Children may develop a maculopapular rash. Adults are susceptible to arthritis, which causes early morning pain and swelling, most often in the small joints. Arthritis can persist for months and may become chronic in individuals who are positive for human leucocyte antigen (HLA)-B27. A live attenuated vaccine, Ixchiq, has recently been licensed.

Related alphaviruses causing similar syndromes include Sindbis virus (Scandinavia and Africa), O'nyong-nyong virus (Central Africa), Ross River virus (Australia) and Mayaro virus (Caribbean and South America).

Diagnosis is by serology, but cross-reactivity between alphaviruses occurs. Treatment is symptomatic. The disease may be debilitating but is rarely fatal.

Prion diseases

Prions cause transmissible spongiform encephalopathies and are discussed in Chapter 27.

Bacterial infections

Bacterial infections of the skin, soft tissues and bones

Most infections of the skin, soft tissues and bone are caused by either *Staphylococcus aureus* or streptococci (mainly *Streptococcus pyogenes* (group A Strep)) (see pp. 1050 and 1119).

Staphylococcal infections

Staphylococci are usually found colonising the anterior nares and skin. Some staphylococci produce coagulase, an enzyme that converts fibrinogen to fibrin in rabbit plasma, causing it to clot. *Staphylococcus aureus* is coagulase-positive, and most other species are coagulase-negative.

Staphylococcus aureus is the main cause of staphylococcal infections. *Staphylococcus intermedius* is another coagulase-positive staphylococcus, which causes infection following dog bites. Among coagulase-negative organisms, *Staphylococcus epidermidis* is the predominant commensal organism of the skin and can cause severe infections in those with central venous catheters or implanted prosthetic materials. *Staphylococcus saprophyticus* is part of the normal vaginal flora and causes urinary tract infections in sexually active women. *Staphylococcus*

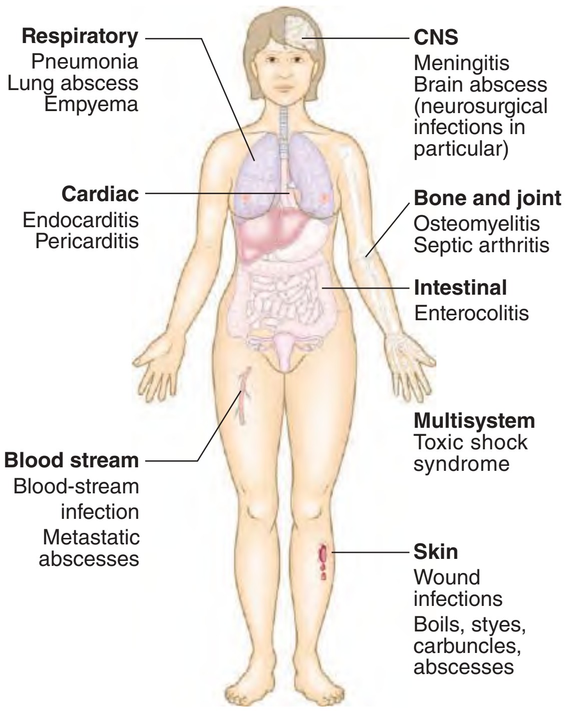

Fig. 14.32 **Infections caused by *Staphylococcus aureus*.** (CNS = central nervous system)

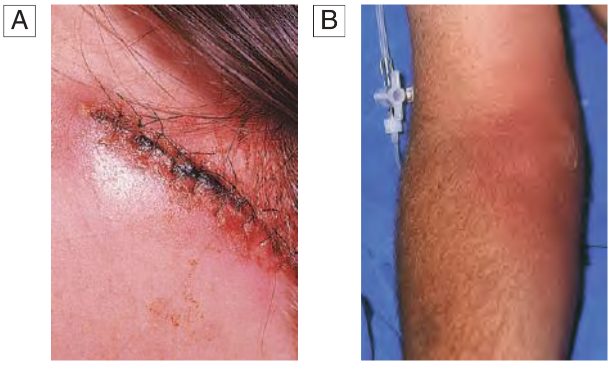

Fig. 14.33 **Manifestations of skin infection with *Staphylococcus aureus*.** **A** Wound infection. **B** Cannula-related infection.

lugdunensis, *Staphylococcus schleiferi*, *Staphylococcus haemolyticus* and *Staphylococcus caprae* are also human pathogens.

Staphylococcal blood-stream infections can disseminate widely (Fig. 14.32). In any patient with staphylococcal bacteraemia, especially injection drug-users, the possibility of endocarditis must be considered (see p. 498). Growth of *Staphylococcus aureus* in blood cultures should not be dismissed as a 'contaminant'. Spreading cellulitis mandates the urgent need for an antistaphylococcal antibiotic, such as flucloxacillin, cefazolin or a glycopeptide if MRSA is suspected. This is particularly true for mid-facial cellulitis, which can result in cavernous sinus thrombophlebitis, and for which assessment should include consideration of the need to employ an agent that achieves adequate cerebrospinal penetration to ensure the antimicrobial achieves satisfactory levels in the cavernous sinus.

In addition, *Staphylococcus aureus* can cause severe systemic disease due to the effects of toxin produced at superficial sites in the absence of tissue invasion by bacteria.

Skin infections

Staphylococci cause ecthyma, folliculitis, furuncles, carbuncles, bullous impetigo and the scalded skin syndrome, which are discussed in Chapter 26. They may also be involved in necrotising infections of the skin and subcutaneous tissues.

Wound infections

Many wound infections, which prolong post-operative care, are caused by staphylococci (Fig. 14.33A). Prevention involves careful attention to hand hygiene, skin preparation and aseptic technique, and the use of topical and systemic antibiotic prophylaxis.

Treatment is by early drainage of any abscesses, removal of prosthetic materials if possible, plus adequate dosage of antistaphylococcal antibiotics.

Cannula-related infection

Staphylococcal infection associated with cannula sepsis (Fig. 14.33B) and thrombophlebitis is an important and common reason for morbidity following hospital admission. The visual infusion phlebitis (VIP) score aids cannula evaluation (see Box 14.6). Staphylococci have a predilection for plastic, rapidly forming a biofilm on cannulae, which is a source of bacteraemia. Local poultice application may relieve symptoms, but cannula removal and antibiotic treatment with flucloxacillin (or a glycopeptide) are necessary if there is spreading infection.

Meticillin-resistant Staphylococcus aureus

Resistance to meticillin (methicillin) is due to a penicillin-binding protein mutation in *Staphylococcus aureus*, which confers resistance to almost all β-lactam antibiotics. Resistance to vancomycin/teicoplanin (glycopeptides) in either glycopeptide intermediate *Staph. aureus* (GISA) or, rarely, vancomycin-resistant (VRSA) strains threatens management of serious staphylococcal infections. Meticillin-resistant *Staph. aureus* (MRSA) is now a major worldwide health care–acquired pathogen, accounting for up to 40% of staphylococcal bacteraemia in high-income countries. Community-acquired MRSA (c-MRSA) currently accounts for 50% of all MRSA infections in the USA. These organisms have also acquired other toxins, such as Panton–Valentine leukocidin (PVL), and can cause rapidly fatal infection in young people. Clinicians must be aware of the potential danger of these infections and implement appropriate locally approved infection control measures.

Treatment options for MRSA are shown in Box 7.17. Treatment should always be based on the results of antimicrobial susceptibility testing, since resistance to all these agents occurs. Milder MRSA infections may be treated with clindamycin, tetracyclines or co-trimoxazole. Glycopeptides, linezolid and daptomycin are reserved for treatment of more severe infections. Toxin-producing MRSA infections should be treated with the addition of protein-inhibiting antibiotics (clindamycin, linezolid).

Staphylococcal toxic shock syndrome

Staphylococcal toxic shock syndrome (TSS) is a life-threatening disease associated with infection by *Staph. aureus* producing a specific toxin (toxic shock syndrome toxin 1, TSST1). Formerly seen in young women in association with the use of highly absorbent intravaginal tampons, it can occur with any infection involving a TSST1-producing *Staph. aureus* strain. The toxin acts as a 'super-antigen', triggering significant T-cell activation and massive cytokine release.

TSS has an abrupt onset with high fever, generalised systemic upset (myalgia, headache, sore throat and vomiting), a widespread erythematous blanching rash resembling scarlet fever, and hypotension. It rapidly progresses over a few hours to multi-organ failure, leading to death in 10%–20%. Recovery is accompanied at 7–10 days by desquamation (Fig. 14.34).

The diagnosis is clinical and may be confirmed in menstrual cases by finding a retained tampon with staphylococci on Gram stain. Subsequent culture and demonstration of toxin production are confirmatory.

Management

Treatment is with immediate and aggressive fluid resuscitation and an intravenous antistaphylococcal antimicrobial, usually with the addition of

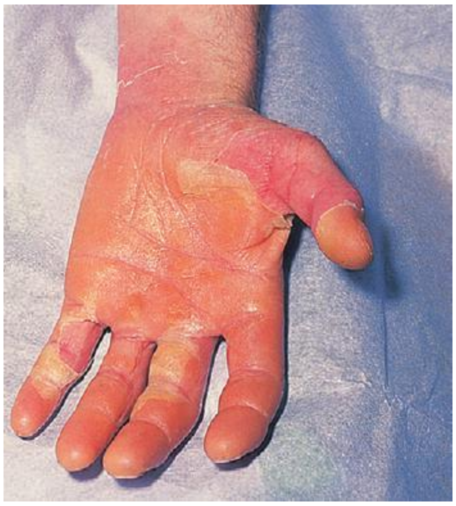

Fig. 14.34 Full-thickness desquamation after staphylococcal toxic shock syndrome.

a protein synthesis inhibitor (e.g. clindamycin) to inhibit toxin production. Intravenous immunoglobulin is occasionally added in the most severe cases. Women who recover from tampon-associated TSS should avoid tampons for at least 1 year and they should be advised that the condition can recur.

Streptococcal infections

Streptococci are oropharyngeal and gut commensals, which appear as gram-positive cocci in chains (see Fig. 7.3). They were classified by the pattern of haemolysis they produce on blood agar (see Fig. 7.4), by their 'Lancefield serogroups' (Box 14.58) but are now usually identified and classified by matrix-assisted laser desorption/ionisation time-of-flight (MALDI-TOF) mass spectrometry. Some streptococci (e.g. *Streptococcus milleri* group) defy simple classification.

Streptococcus pyogenes (group A streptococcus, GAS) is the leading cause of bacterial pharyngitis. Although the presence of fever, tender anterior lymphadenopathy and purulent tonsillar exudate and the absence of cough make streptococcal pharyngitis more likely than viral infection, clinical features alone are unreliable for diagnosing streptococcal pharyngitis. GAS are the major cause of cellulitis, erysipelas and impetigo. They also cause the post-streptococcal syndromes of glomerulonephritis and rheumatic fever, which are described in Chapters 18 and 16, respectively. The closely related *Streptococcus dysgalactiae* subsp. *equisimilis* (SDSE) (formerly groups C and G) cause cellulitis, particularly in older people, diabetic or immunocompromised patients. *Streptococcus agalactiae* (group B streptococci, GBS) colonise the gut and vagina. They cause post-partum and neonatal sepsis, as well as other deep infections (infective endocarditis, septic arthritis, osteomyelitis etc.), especially in older people.

Streptococcal scarlet fever

Streptococcus pyogenes (or occasionally SDSE) causing pharyngitis, tonsillitis or other infection may lead to scarlet fever if the infecting strain produces a streptococcal pyogenic exotoxin. Scarlet fever is most common in school-age children but can also occur in young adults who have contact with young children. A diffuse erythematous rash occurs, which blanches on pressure (Fig. 14.35A), classically with circumoral pallor. The tongue, initially coated, becomes red and swollen ('strawberry tongue', Fig. 14.35B). The disease lasts about 7 days, the rash disappearing in 7–10 days, followed by a fine desquamation. Residual petechial lesions in the antecubital fossa, 'Pastia sign', can occur (Fig. 14.35C).

14.58 Streptococcal and related infections

β-haemolytic group A (*Streptococcus pyogenes*)

- Skin and soft tissue infection (including erysipelas, impetigo, necrotising fasciitis)
- Streptococcal toxic shock syndrome
- Glomerulonephritis
- Rheumatic fever
- Bone and joint infection
- Tonsillitis

β-haemolytic streptococci group B (*Strep. agalactiae*)

- Neonatal infections, including meningitis
- Female pelvic infections
- Cellulitis

β-haemolytic streptococci groups C and G

- Cellulitis
- Endocarditis
- Pharyngitis
- Septic arthritis

α-, β- or non-haemolytic group D (*Enterococcus faecalis, E. faecium*)

- Endocarditis
- Intra-abdominal infections
- Urinary tract infection

α- or non-haemolytic group D (*Strep. gallolyticus* subsp. *gallolyticus/ S. bovis* biotype I)

- Bacteraemia/endocarditis associated with large bowel malignancy

α-haemolytic optochin-resistant (viridans streptococci – *Strep. mitis, Strep. sanguis, Strep. mutans, Strep. salivarius*)

- Sepsis in immunosuppressed
- Endocarditis

α-haemolytic optochin-sensitive (*Strep. pneumoniae*)

- Pneumonia
- Meningitis
- Endocarditis
- Otitis media
- Sepsis
- Spontaneous bacterial peritonitis
- Sinusitis

Variable haemolysis (*Strep. milleri* group – *Strep. anginosus, Strep. intermedius, Strep. constellatus*)

- Endocarditis
- Intra-abdominal infections
- Urinary tract infection

Anaerobic streptococci (*Peptostreptococcus* spp.)

- Sepsis in immunosuppressed
- Endocarditis

N.B. All streptococci can cause sepsis. Enterococci are no longer classified as streptococci.

Treatment involves intravenous benzylpenicillin or an oral penicillin plus symptomatic measures.

Streptococcal toxic shock syndrome

Strep. pyogenes and SDSE can produce one of a variety of toxins, such as streptococcal pyrogenic exotoxin A. Like staphylococcal TSST1 (see above), these act as super-antigens. Initially, an influenza-like illness occurs, with signs of localised infection in 50% of cases, most often involving the skin and soft tissues. A faint erythematous rash, mainly on the chest, rapidly progresses to circulatory shock. Skin desquamation occurs later during infection. Without aggressive management, multi-organ failure will develop.

Judicious fluid resuscitation is combined with parenteral antistreptococcal antibiotic therapy, usually with benzylpenicillin and clindamycin, to inhibit toxin production. Intravenous immunoglobulin is often administered. If necrotising fasciitis is present, it should be treated as described on page 307 with urgent débridement.

Treponematoses

Syphilis

This disease is described in Chapter 15.

Endemic treponematoses

Yaws

Yaws is a granulomatous disease, mainly involving the skin and bones, caused by *Treponema pertenue*. It is morphologically and serologically

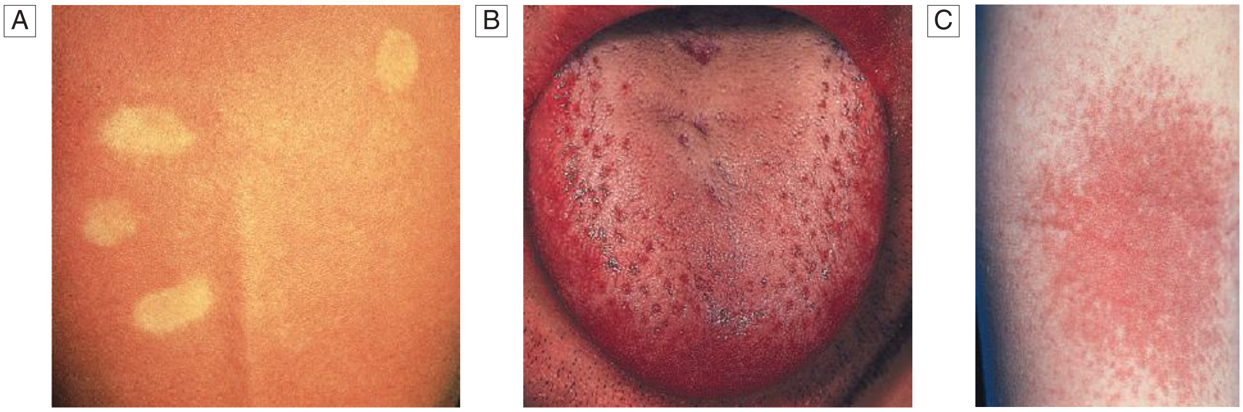

Fig. 14.35 Clinical features of scarlet fever. A Characteristic rash with blanching on pressure. B 'Strawberry tongue'. C Pastia sign: a petechial rash in the cubital fossa.

14.59 Diagnosis and treatment of yaws, pinta and bejel

Diagnosis of early stages

- Detection of spirochaetes in exudate of lesions by dark-ground microscopy

Diagnosis of latent and early stages

- Positive serological tests, as for syphilis (see Box 15.8)

Treatment of all stages

- Single intramuscular injection of 1.2 g long-acting penicillin, e.g. benzathine benzylpenicillin

indistinguishable from the microorganisms causing syphilis and pinta. The geographical origin and sexual history of patients helps exclude false-positive syphilis serology due to endemic treponemal infections. Between 1950 and 1960, WHO campaigns treated over 60 million people and eradicated yaws from many areas, but the disease has persisted throughout the tropics. A resurgence occurred in the 1980s and 1990s in West and Central Africa and the South Pacific.

Organisms are transmitted by bodily contact from a patient with infectious yaws through minor skin abrasions of the recipient, usually a child. After 3–4 weeks' incubation, a proliferative granuloma containing numerous treponemes develops at the inoculation site. This primary lesion is followed by secondary eruptions. In addition, there may be hypertrophic periosteal bone lesions, with underlying cortical rarefaction. Lesions of late yaws are characterised by destructive changes that closely resemble the osteitis and gummas of tertiary syphilis. These heal with scarring and deformity. Investigations and management are outlined in Box 14.59. Improved housing and hygiene, combined with mass chemotherapy programmes, have achieved dramatic success in the control of yaws.

Pinta and bejel

These two treponemal infections occur in poor rural populations with low standards of domestic hygiene but are found in separate parts of the world. They have features in common, notably that they are transmitted by contact, usually within the family and not sexually, and in the case of bejel, through common eating and drinking utensils. Their diagnosis and management are as for yaws (see Box 14.59).

- *Pinta*. Pinta is found only in South and Central America, where its incidence is declining. The infection is confined to the skin. The early lesions are scaly papules or dyschromic patches on the skin. The late lesions are often depigmented and disfiguring.
- *Bejel*. Bejel is the Middle Eastern name for non-venereal syphilis, which has a patchy distribution across sub-Saharan Africa, the Middle East, Central Asia and Australia. It has been eradicated from Eastern Europe. Transmission is most commonly from the mouth of the mother or child and the primary mucosal lesion is seldom seen. The early and late lesions resemble those of secondary and tertiary syphilis, but cardiovascular and neurological disease is rare.

Tropical ulcer

Tropical ulcer is due to a synergistic bacterial infection caused by a fusobacterium (*Fusobacterium ulcerans*, an anaerobe) and *Treponema vincentii*. It is common in hot, humid regions. The ulcer commonly involves the lower legs, developing as a papule that rapidly breaks down to form a sharply defined, painful ulcer. The ulcer base has a foul slough. Penicillin and metronidazole are useful in the early stages, but rest, elevation and dressings are the mainstays of treatment.

Buruli ulcer

Mycobacterium ulcerans causes Buruli ulcer in tropical rainforests. Cases were declining until 2016 but have risen since. In 2022 there were over 2000 cases reported. Outside West and Central Africa, occasional cases have been reported in Australia.

The initial lesion is a small subcutaneous nodule on the arm or leg. This breaks down to form a shallow, necrotic ulcer with deeply undermined edges, which extends rapidly. Healing may occur after 6 months but granuloma formation and the accompanying fibrosis cause contractures and deformity. Clumps of acid-fast bacilli are detected in the ulcer floor.

A combination of rifampicin and clarithromycin can cure the infection. Infected tissue should be removed surgically. Wound and lymphoedema management, surgery, including skin grafting, and physiotherapy all play a role in management and prevention of disability.

Systemic bacterial infections

Brucellosis

Brucellosis is an enzootic infection (i.e. endemic in animals) caused by a gram-negative coccobacilli. The four species causing human disease and their animal hosts are: *Brucella melitensis* (goats, sheep and camels in Europe, especially the Mediterranean basin, the Middle East, Africa, India, Central Asia and South America), *B. abortus* (cattle, mainly in Africa, Asia and South America), *B. suis* (pigs in South Asia) and *B. canis* (dogs). *B. melitensis* causes the most severe disease; *B. suis* is often associated with abscess formation.

Infected animals may excrete *Brucella* spp. in their milk for prolonged periods and human infection is acquired by ingesting contaminated dairy products (especially unpasteurised milk), uncooked meat or offal. Animal urine, faeces, vaginal discharge and uterine products may transmit infection through abraded skin or via splashes and aerosols to the respiratory tract and conjunctiva.

Clinical features

Brucella spp. are intracellular organisms that survive for long periods within the reticulo-endothelial system. This favours chronicity and relapse, even after antimicrobial therapy.

Acute illness is characterised by a high swinging temperature, rigors, lethargy, headache, arthralgia, myalgia and scrotal pain. Occasionally, there is delirium, abdominal pain and constipation. Physical signs are non-specific, e.g. enlarged lymph nodes. Splenomegaly may cause thrombocytopenia.

Localised infection (Fig. 14.36) occurs in approximately 30% of patients, particularly if treatment is delayed.

Diagnosis

Definitive diagnosis depends on culture of the organism. Blood cultures are positive in 75%–80% of *B. melitensis* and 50% of *B. abortus* infections. Bone marrow culture is not routine but may increase the diagnostic yield if antibiotics have been used prior to culture. CSF culture in neurobrucellosis is positive in about 30% of cases. The laboratory should be informed of suspected brucellosis, to allow appropriate laboratory steps to prevent laboratory worker infection.

Serology may aid diagnosis. In endemic areas, a single high antibody titre of more than 1/320 or a fourfold rise in titre supports a diagnosis of acute infection. The test usually takes several weeks to become positive but should eventually detect 95% of acute infections.

Management

Aminoglycosides show synergistic activity with tetracyclines, and treatment regimens for different forms of brucellosis are outlined in Box 14.60.

Borrelia infections

Borrelia are flagellated spirochaetal bacteria that infect humans after bites from ticks or lice. They cause a variety of human infections worldwide (Box 14.61).

Lyme disease

Lyme disease is caused by *B. burgdorferi*, which occurs in the USA, Europe, Russia, China, Japan and Australia. In Europe, two additional genospecies are also encountered, *B. afzelii* and *B. garinii*. The reservoir

14.60 Treatment of brucellosis

Adults with non-localised disease

- Doxycycline 100 mg twice daily orally for 6 weeks *plus* gentamicin 5 mg/kg IV once daily for 7 days
  or
- Doxycycline 100 mg twice daily *plus* rifampicin 600–900 mg orally once daily for 6 weeks

Bone disease

- Doxycycline 100 mg twice daily *plus* rifampicin 600–900 mg once daily orally for 6 weeks *plus* gentamicin 5 mg/kg IV once daily for 7 days
  or
- Ciprofloxacin 750 mg twice daily orally *plus* rifampicin 600–900 mg orally once daily for 3 months

Neurobrucellosis

- Doxycycline 100 mg twice daily *plus* rifampicin 600–900 mg orally once daily for 6 weeks *plus* ceftriaxone 2 g IV twice daily until the cerebrospinal fluid is clear (though susceptibility should be confirmed because sensitivity to third-generation cephalosporins varies among strains)

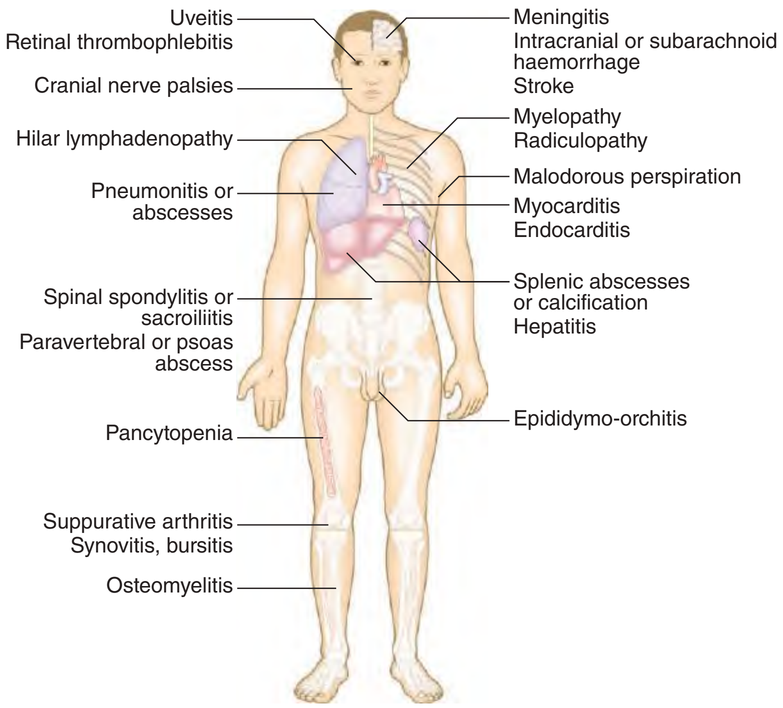
Endocarditis

- Almost always needs surgical intervention
  plus
- Doxycycline 100 mg twice daily, rifampicin 600–900 mg orally once daily and co-trimoxazole 5 mg/kg of trimethoprim component for 6 months *plus* gentamicin 5 mg/kg IV once daily for 2–4 weeks

Pregnancy

- Rifampicin 600–900 mg orally once daily and co-trimoxazole 5 mg/kg of trimethoprim component for 4 weeks, but caution in last week of pregnancy due to displacement of bilirubin from albumin by drugs and risk of kernicterus to the fetus

(IV = intravenous)



Uveitis
Retinal thrombophlebitis
Cranial nerve palsies
Hilar lymphadenopathy
Pneumonitis or abscesses
Spinal spondylitis or sacroiliitis
Paravertebral or psoas abscess
Pancytopenia
Suppurative arthritis
Synovitis, bursitis
Osteomyelitis
Meningitis
Intracranial or subarachnoid haemorrhage
Stroke
Myelopathy
Radiculopathy
Malodorous perspiration
Myocarditis
Endocarditis
Splenic abscesses or calcification
Hepatitis
Epididymo-orchitis

Fig. 14.36 Clinical features of brucellosis.

14.61 Clinical diseases caused by *Borrelia* spp.

Species	Vector	Geographical distribution
Lyme disease		
B. burgdorferi sensu stricto	Tick: *Ixodes scapularis* *I. pacificus*	Northern and eastern USA Western USA
B. afzelii	*I. ricinus* *I. persulcatus*	Europe Asia
B. garinii	*I. ricinus* *I. persulcatus*	Europe Asia
Louse-borne relapsing fever		
B. recurrentis	Human louse: *Pediculus humanus corporis*	Worldwide
Tick-borne relapsing fever		
B. hermsii	Tick: *Ornithodoros hermsii*	Western North America
B. turicatae	*O. turicatae*	South-western North America and northern Mexico
B. venezuelensis	*O. rudis*	Central America and northern South America
B. hispanica	*O. erraticus*	Iberian peninsula and north-western Africa
B. crocidurae	*O. erraticus*	North Africa and Mediterranean region
B. duttonii	*O. moubata*	Central, eastern and southern Africa
B. persica	*O. tholozani*	Western China, India, Central Asia, Middle East
B. latyschewii	*O. tartakovskyi*	Tajikistan, Uzbekistan

of infection is ixodid (hard) ticks that feed on a variety of large mammals, particularly deer. Birds spread ticks over a wide area. The organism is transmitted to humans via the bite of larval, nymphal or adult ticks.

Ehrlichiosis is a common co-infection with Lyme disease. Two forms occur: *Anaplasma phagocytophilum*, human granulocytic anaplasmosis (HGA); and *Ehrlichia chaffeensis*, human monocytic ehrlichiosis (HME). Symptoms involve fever, chills, headache and myalgia. Complications include meningo-encephalitis, disseminated intravascular coagulopathy and multi-organ failure. Rash may occur with ehrlichiosis. Diagnosis is with PCR or serology using indirect fluorescent antibody (IFA). Treatment is with doxycycline.

Clinical features

There are three stages of disease. Progression may be arrested at any stage.

- *Early localised disease*. The characteristic feature is a skin reaction around the site of the tick bite, known as erythema migrans (Fig. 14.37). Initially, a red 'bull's eye' macule or papule appears 2–30 days after the bite. It then enlarges peripherally with central clearing and may persist for months. Atypical forms are common. The lesion is not pathognomonic of Lyme disease since similar lesions can occur after tick bites. Acute manifestations, such as fever, headache and regional lymphadenopathy, may develop with or without the rash.
- *Early disseminated disease*. Dissemination occurs via the blood stream and lymphatics. There may be a systemic reaction with malaise, arthralgia and, occasionally, metastatic areas of erythema migrans (see Fig. 14.37). Neurological involvement may follow weeks or months after infection. Common features include lymphocytic meningitis, cranial nerve palsies (especially unilateral or bilateral facial nerve palsy) and peripheral neuropathy. Radiculopathy, often painful, may present a year or more after initial infection. Carditis, sometimes accompanied by atrioventricular conduction defects, occurs in the USA but is rare in Europe.

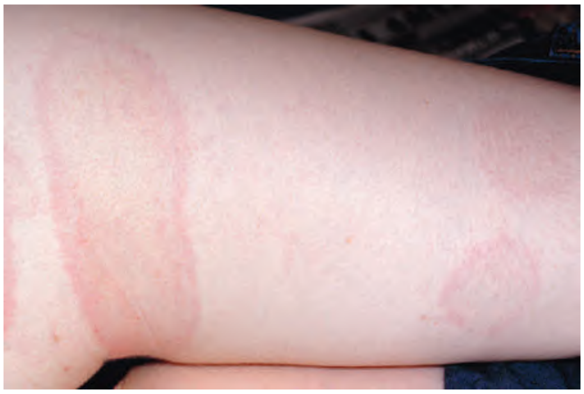


Fig. 14.37 Rash of erythema migrans in Lyme disease with metastatic secondary lesions. *Courtesy of Dr Ravi Gowda, Royal Hallamshire Hospital, Sheffield.*

- *Late disease*. Late manifestations include arthritis, polyneuritis and encephalopathy. Prolonged arthritis, particularly affecting large joints, and brain parenchymal involvement, causing neuropsychiatric abnormalities, may occur but are rare in the UK. Acrodermatitis chronica atrophicans is an uncommon late complication seen more frequently in Europe than North America. Doughy, patchy discoloration occurs on the peripheries, eventually leading to shiny atrophic skin. The lesions are mistaken for those of peripheral vascular disease. In patients with facial nerve palsy coming from an endemic area or having risk factors, Lyme disease should be excluded.

Diagnosis

The diagnosis of early Lyme borreliosis is clinical. Culture from biopsy material is rarely available, has a low yield and may take over 6 weeks. Antibody detection is frequently negative early in the course of the disease but sensitivity increases to 90%–100% in disseminated or late disease. Immunofluorescence or ELISA can give false-positive reactions in a number of conditions, including other spirochaetal infections, infectious mononucleosis, rheumatoid arthritis and systemic lupus erythematosus (SLE). Immunoblot (Western blot) techniques are more specific and should be used to confirm the diagnosis. Microorganism DNA detection by PCR has been applied to blood, urine, CSF and biopsies of skin and synovium.

Management

Asymptomatic patients with positive antibody tests do not require treatment. However, erythema migrans always requires therapy because organisms may persist and cause progressive disease, even if the skin lesions resolve. Standard therapy consists of a 14-day course of doxycycline (200 mg daily) or amoxicillin (500 mg 3 times daily). Some 15% of patients with early disease will develop a mild febrile reaction (Jarisch–Herxheimer, JHR) during the first 24 hours of therapy. In pregnant women and small children with penicillin allergy, or in those allergic to amoxicillin and doxycycline, 14-day treatment with cefuroxime axetil (500 mg twice daily) or azithromycin (500 mg once daily) may be used.

Disseminated disease and arthritis require therapy for up to 28 days. Arthritis may respond poorly, but after one to two courses of therapy, including one of IV therapy, referral to a rheumatologist is recommended rather than further courses of antimicrobials. Neuroborreliosis is treated with parenteral β-lactam antibiotics for 3–4 weeks; third-generation cephalosporins such as ceftriaxone are preferred.

Prevention

Protective clothing and insect repellents should be used in tick-infested areas. Since the risk of borrelial transmission is lower in the first few hours of a blood feed, prompt removal of ticks is advisable. Unfortunately, larval and nymphal ticks are tiny and may not be noticed. Where risk of transmission is high, a single 200 mg dose of doxycycline, given within 72 hours of exposure, has been shown to prevent erythema migrans.

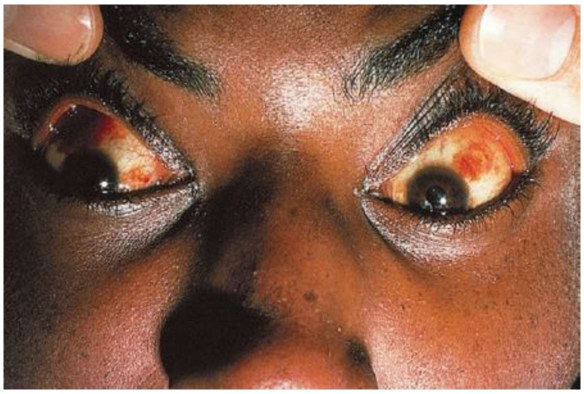

Fig. 14.38 **Louse-borne relapsing fever.** Injected conjunctivae.

Louse-borne relapsing fever

The human body louse, *Pediculus humanus*, causes itching. Borreliae (*B. recurrentis*) are released from infected lice when they are crushed during scratching, inoculating borreliae into the skin. The disease occurs worldwide, with epidemic relapsing fever most often seen in Central/East Africa and South America.

The borreliae multiply in the blood, where they are abundant in the febrile phases, and invade most tissues, especially the liver, spleen and meninges.

Clinical features

Onset is sudden with fever. The temperature rises to 39.5–40.5°C, accompanied by a tachycardia, headache, generalised aching, injected conjunctivae (Fig. 14.38) and herpes labialis. Thrombocytopenia is associated with a petechial rash and epistaxis. As the disease progresses, tender hepatosplenomegaly, jaundice and elevated transaminases are common. There may be severe serosal and intestinal haemorrhage, delirium and meningism. The fever ends in crisis between the fourth and tenth days, often associated with profuse sweating, hypotension and circulatory and cardiac failure. Fever may resolve but, in a proportion of patients, after an afebrile period of about 7 days, there are one or more febrile relapses, which are usually milder and less prolonged. Without specific treatment, the mortality rate is up to 40%, especially among older and malnourished patients.

Investigations and management

Dark-ground microscopy of a wet film or Wright–Giemsa-stained thick and thin films demonstrate the organism in blood from a febrile patient.

Treatment aims to eradicate the organism and prevent relapses, while minimising the severe JHR that inevitably follows successful chemotherapy. The safest treatment is procaine penicillin 300 mg intramuscularly, followed the next day by 0.5 g tetracycline. Tetracycline alone is effective and prevents relapse but may give rise to a worse reaction. Doxycycline 200 mg once orally in place of tetracycline has the advantage of also being curative for typhus, which often accompanies epidemics of relapsing fever. JHR is best managed in a high-dependency unit with expert nursing and medical care.

The patient, clothing and all contacts must be freed from lice, as in epidemic typhus.

Tick-borne relapsing fever

Soft ticks (*Ornithodoros* spp.) transmit *B. duttonii* (and other *Borrelia* species) through saliva while feeding on their host. People sleeping in mud houses are at risk, as the tick hides in crevices during the day and feeds on humans during the night. Rodents are the reservoir except in East Africa, where humans are the reservoir. Clinical manifestations are similar to those seen with the louse-borne disease, but microorganisms are detected in fewer patients on dark-field microscopy. A 7-day course (due to a higher relapse rate than in louse-borne relapsing fever) of treatment with either tetracycline (500 mg 4 times daily) or erythromycin (500 mg 4 times daily) is needed.

Leptospirosis

Microbiology and epidemiology

Leptospirosis is one of the most common zoonotic diseases, favoured by a tropical climate and flooding during the monsoon but occurring worldwide. Leptospires are tightly coiled, thread-like organisms about 5–7 μm in length, which are actively motile; each end is bent into a hook. *Leptospira interrogans* is pathogenic for humans. The genus can be separated into more than 200 serovars (subtypes) belonging to 23 serogroups.

Leptospirosis is ubiquitous in wildlife and in many domestic animals. The organisms persist indefinitely in the convoluted tubules of the kidney and are shed into the urine in massive numbers, but infection is asymptomatic in the host. The most frequent hosts are rodents, especially the common rat (*Rattus norvegicus*). Particular leptospiral serogroups are associated with characteristic animal hosts; for example, *L. icterohaemorrhagiae* is the classical parasite of rats and *L. canicola* of dogs. There is nevertheless considerable overlap in host–serogroup associations.

Leptospires can penetrate intact skin or mucous membranes but human infection is facilitated by cuts and abrasions. Prolonged immersion in contaminated water facilitates invasion, as the spirochaete survives in water for months. Leptospirosis is common in the tropics and also in freshwater sports enthusiasts.

Clinical features

After a relatively brief bacteraemia, invading organisms are distributed throughout the body, mainly in kidneys, liver, meninges and brain. The incubation period averages 1–2 weeks. Four main clinical syndromes can be discerned and clinical features can involve multiple different organ systems (Fig. 14.39).

Bacteraemic leptospirosis

Bacteraemia with any serogroup can produce a non-specific illness with high fever, weakness, muscle pain and tenderness (especially of the calf and back), intense headache and photophobia, and sometimes diarrhoea and vomiting. Conjunctival congestion is the only notable physical sign. The illness comes to an end after about 1 week, or else merges into one of the other forms of infection.

Aseptic meningitis

Classically associated with *L. canicola* infection, this illness is very difficult to distinguish from viral meningitis. The conjunctivae may be congested, but there are no other differentiating signs. Laboratory clues include a neutrophil leucocytosis, abnormal LFTs and the occasional presence of albumin and casts in the urine.

Icteric leptospirosis (Weil disease)

Fewer than 10% of symptomatic infections result in severe icteric illness. Weil disease is a dramatic life-threatening event, characterised by fever, haemorrhages, jaundice and acute kidney injury. Conjunctival hyperaemia is a frequent feature. The patient may have a transient macular erythematous rash, but the characteristic skin changes are purpura and large areas of bruising. In severe cases there may be epistaxis, haematemesis and melaena, or bleeding into the pleural, pericardial or subarachnoid spaces. Thrombocytopenia, probably related to activation of endothelial cells with platelet adhesion and aggregation, is present in 50% of cases. Jaundice and hepatomegaly usually occur without hepatic failure or encephalopathy. Acute kidney injury, primarily caused by impaired renal perfusion and acute tubular necrosis, causes oliguria or anuria, with albumin, blood and casts in the urine.

Weil disease may also be associated with myocarditis, encephalitis and aseptic meningitis. Uveitis and iritis may appear months after apparent clinical recovery.

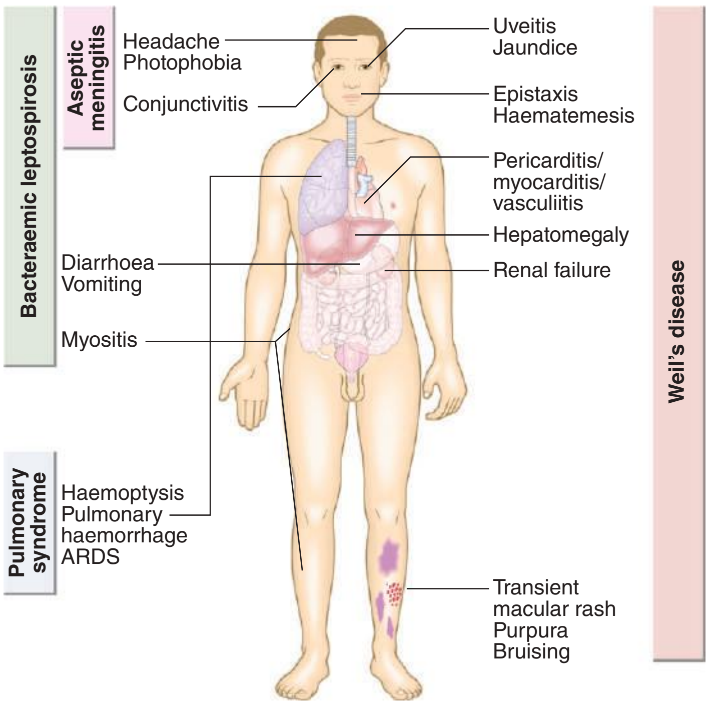

Fig. 14.39 **Clinical syndromes of leptospirosis.** (ARDS = acute respiratory distress syndrome)

Pulmonary syndrome

This syndrome has long been recognised in the Far East and has been described during an outbreak of leptospirosis in Nicaragua. It is characterised by haemoptysis, patchy lung infiltrates on CXR, and respiratory failure. Total bilateral lung consolidation and ARDS with multi-organ dysfunction may develop, with a high mortality (over 50%).

Diagnosis

A polymorphonuclear leucocytosis is accompanied in severe infection by thrombocytopenia and elevated blood levels of creatine kinase. In jaundiced patients, there is hepatitis and the prothrombin time may be prolonged. The CSF in leptospiral meningitis shows a variable cellular response, a moderately elevated protein level and normal glucose content. Acute kidney injury due to interstitial nephritis is common.

In the tropics, dengue, malaria, typhoid fever, scrub typhus and hantavirus infection are important differential diagnoses.

Definitive diagnosis of leptospirosis depends on isolation of the organism, serological tests or detection of specific DNA. In general, however, it is probably under-diagnosed.

- Blood cultures are most likely to be positive if taken before day 10 of illness. Special media are required and cultures may have to be incubated for several weeks.
- Leptospires appear in the urine during the second week of illness, and in untreated patients may be recovered on culture for several months.
- Serological tests are diagnostic if seroconversion or a fourfold increase in titre is demonstrated. The microscopic agglutination test (MAT) is the investigation of choice and can become positive by the end of the first week. IgM ELISA and immunofluorescent techniques are easier to perform but are of lower specificity than MAT; however, while rapid immunochromatographic tests are specific they are of only moderate sensitivity in the first week of illness.
- Detection of leptospiral DNA by PCR is possible in blood in early symptomatic disease, and in urine from day 8 of illness and for many months thereafter.

Management and prevention

The general care of the patient is critically important. Blood transfusion for haemorrhage and careful attention to renal function, the usual cause of death, are especially important. Acute kidney injury is potentially reversible with adequate support, such as dialysis. Most infections are self-limiting. Therapy with either oral doxycycline (100 mg twice daily for 1 week) or intravenous penicillin (900 mg 4 times daily for 1 week) is effective but may not prevent the development of renal failure. Parenteral ceftriaxone (1 g daily) is as effective as penicillin. JHR may occur but is usually mild. Uveitis is treated with a combination of systemic antibiotics and local glucocorticoids. There is no role for the routine use of glucocorticoids in the management of leptospirosis.

Trials in military personnel have shown that infection with *L. interrogans* can be prevented by taking prophylactic doxycycline 200 mg weekly.

Plague

Plague is caused by *Yersinia pestis*, a small gram-negative bacillus that is spread between rodents by their fleas. If domestic rats become infected, infected fleas may bite humans. Hunters and trappers can contract plague from handling rodents. In the late stages of human plague, *Y. pestis* may be expectorated and spread between humans by droplets, causing 'pneumonic plague'.

Epidemics of plague, such as the 'Black Death', have occurred since ancient times. It is often said that the first sign of plague is the appearance of dead rats. Plague foci are widely distributed throughout the world, including the USA; human cases are reported from about 10 countries per year (Fig. 14.40).

Y. pestis is a potential bioweapon because of the possibility of person-to-person spread and the high fatality rate associated with pneumonic plague.

Clinical features

Organisms inoculated through the skin are transported rapidly to the draining lymph nodes, where they elicit a severe inflammatory response that may be haemorrhagic. If the infection is not contained, sepsis ensues and necrotic, purulent or haemorrhagic lesions develop in many

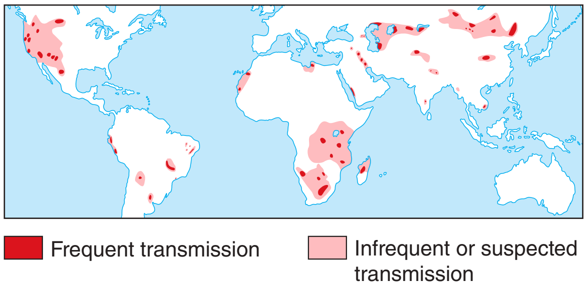

Fig. 14.40 Foci of the transmission of plague. Map lines delineate study areas and do not necessarily depict accepted national boundaries. *Reproduced by permission of the World Health Organization.*

organs. Oliguria and shock follow and disseminated intravascular coagulation may result in widespread haemorrhage. Inhalation of *Y. pestis* causes alveolitis. The incubation period is 3–6 days but shorter in pneumonic plague.

Bubonic plague

In this, the most common form of the disease, onset is usually sudden, with a rigor, high fever, dry skin and severe headache. Soon, aching and swelling at the site of the affected lymph nodes begin. The groin is the most common site of the 'bubo', a collection of swollen lymph nodes and surrounding tissue. Some infections are relatively mild but, in the majority, toxaemia quickly increases, with a rapid pulse, hypotension and delirium. The spleen is usually palpable.

Septicaemic plague

Those without a bubo usually deteriorate rapidly, with high associated mortality. Older people are more prone to septicaemic plague. The patient is toxic and may have gastrointestinal symptoms, such as nausea, vomiting, abdominal pain and diarrhoea. DIC may occur, manifested by bleeding from various orifices or puncture sites, along with ecchymoses. Hypotension, shock, renal failure and ARDS may develop. Meningitis, pneumonia and expectoration of blood-stained sputum containing *Y. pestis* may complicate septicaemic, or occasionally bubonic, plague.

Pneumonic plague

Following primary infection in the lung, the onset of disease is very sudden, with cough and dyspnoea. The patient expectorates copious blood-stained, frothy, highly infective sputum, becomes cyanosed and dies. Chest radiology reveals bilateral infiltrates, which may be nodular and progress to an ARDS-like picture.

Investigations

The organism may be cultured from blood, sputum and bubo aspirates. It should be noted that automated biochemical identification systems and matrix-assisted laser desorption ionization–time of flight mass spectrometry (MALDI-TOF MS) may not include *Y. pestis* in their databases, resulting in misidentification as *Y. pseudotuberculosis*. For rapid diagnosis, Gram, Giemsa and Wayson stains (the latter containing methylene blue) are applied to smears from these sites. *Y. pestis* is seen as bipolar staining coccobacilli, sometimes referred to as having a 'safety pin' appearance. Smears are also subjected to antigen detection by immunofluorescence, using *Y. pestis* F1 antigen-specific antibodies. The diagnosis may be confirmed by seroconversion or a single high titre (> 128) of anti-F1 antibodies in serum. DNA detection by PCR is under evaluation.

Plague is a notifiable disease under international health regulations.

Management

If the diagnosis is suspected on clinical and epidemiological grounds, treatment must be started as soon as, or even before, samples have been collected for laboratory diagnosis. Streptomycin (1 g twice daily) or gentamicin (1 mg/kg 3 times daily) is the drug of choice. Tetracycline (500 mg 4 times daily) and chloramphenicol (12.5 mg/kg 4 times daily) are alternatives. Fluoroquinolones (ciprofloxacin and levofloxacin) may be as effective, but there is less clinical experience. Treatment may also be needed for acute circulatory failure, disseminated intravascular coagulopathy and hypoxia.

Prevention and infection control

Rats and fleas should be controlled. In endemic areas, people should avoid handling and skinning wild animals. The patient should be isolated for the first 48 hours or until clinical improvement begins. Attendants must wear gowns, masks and gloves. Symptomatic or asymptomatic close contacts of cases of pneumonic plague should receive post-exposure antibiotic prophylaxis (doxycycline 100 mg or ciprofloxacin 500 mg twice daily) for 7 days.

A recombinant subunit vaccine (protein antigens F1 + V) is in development.

Listeriosis

Listeria monocytogenes is an environmental gram-positive bacillus that can contaminate food. Outbreaks have been associated with raw vegetables, soft cheeses, under-cooked chicken, fish, meat and pâtés. The bacterium demonstrates 'cold enrichment', outgrowing other contaminating bacteria during refrigeration. Although food-borne outbreaks of gastroenteritis have been reported in immunocompetent individuals, *Listeria* causes more significant invasive infection, especially in pregnant women, older adults (over 55 years) and the immunocompromised.

In pregnancy, in addition to systemic symptoms of fever and myalgia, listeriosis causes chorioamnionitis, fetal deaths, abortions and neonatal infection. In other susceptible individuals, it causes systemic illness due to bacteraemia without focal symptoms. Meningitis especially affecting the base of the brain and often involving cranial nerves, similar to other bacterial meningitis but with normal CSF glucose, is the next most common presentation; CSF usually shows increased neutrophils but occasionally only the mononuclear cells are increased (see Box 27.6).

Investigations and management

Diagnosis is made by blood and CSF culture. The organism grows readily in culture media.

The most effective regimen consists of a combination of intravenous amoxicillin or ampicillin plus an aminoglycoside. A sulfamethoxazole/trimethoprim combination can be used in those with penicillin allergy. The organism is inherently resistant to cephalosporins, an important consideration when treating meningitis empirically where high-dose amoxicillin should be added to at-risk groups.

Proper treatment of foods before eating is the key to preventing listeriosis. Pregnant women are advised to avoid high-risk products, including soft cheeses.

Enteric fevers (typhoid and paratyphoid)

Typhoid and paratyphoid fevers, which are transmitted by the faecal–oral route, are important causes of fever in South Asia, sub-Saharan Africa and Latin America. Elsewhere, they are relatively rare. Enteric fevers are caused by infection with *Salmonella enterica* serotypes Typhi and Paratyphi A, B and C, but invasive disease is occasionally observed with non-typhoidal *Salmonella* spp. After a few days of bacteraemia, the bacilli localise, mainly in the lymphoid tissue of the small intestine, resulting in typical lesions in the Peyer patches and follicles. These swell at first, then ulcerate and usually heal. After clinical recovery, about 5% of patients become chronic carriers (i.e. continue to excrete the bacteria after 1 year); the bacilli may live in the gallbladder for months or years and pass intermittently in the stool and, less commonly, in the urine.

Clinical features

Typhoid fever

Clinical features are outlined in Box 14.62. The incubation period is typically about 10–14 days but can be longer, and the onset may be

14.62 Clinical features of typhoid fever

First week

- Fever
- Headache
- Myalgia
- Relative bradycardia
- Constipation
- Diarrhoea and vomiting in children

End of first week

- Rose spots on trunk
- Splenomegaly
- Cough
- Abdominal distension
- Diarrhoea

End of second week

- Delirium, complications, then coma and death (if untreated)

14.63 Complications of typhoid fever

Bowel

- Perforation
- Haemorrhage

Septic foci

- Bone and joint infection
- Meningitis
- Cholecystitis

Toxic phenomena

- Myocarditis
- Nephritis

Chronic carriage

- Persistent gallbladder carriage

insidious. The temperature rises in a stepladder fashion for 4 or 5 days with malaise, increasing headache, drowsiness and aching in the limbs. Constipation may be caused by swelling of lymphoid tissue around the ileocaecal junction, although in children diarrhoea and vomiting may be prominent early in the illness. The pulse is often slower than would be expected from the height of the temperature, i.e. a relative bradycardia.

At the end of the first week, a rash may appear on the upper abdomen and on the back as sparse, slightly raised, rose-red spots, which fade on pressure. Cough and epistaxis occur. Around the 7th–10th day, the spleen becomes palpable. Constipation is followed by diarrhoea and abdominal distension with tenderness. Bronchitis and delirium may develop. If untreated, by the end of the second week the patient may be profoundly ill.

Paratyphoid fever

The course tends to be shorter than that of typhoid fever and the onset is often more abrupt, with acute enteritis. The rash may be more abundant and the intestinal complications less frequent.

Complications

These are given in Box 14.63. Haemorrhage from, or a perforation of, the ulcerated Peyer patches may occur at the end of the second week or during the third week of the illness. A drop in temperature to normal or subnormal levels may be falsely reassuring in patients with intestinal haemorrhage. Additional complications may involve almost any viscus or system because of the bacteraemia present during the first week. Bone and joint infection is common in children with sickle-cell disorder.

Investigations

In the first week, diagnosis may be difficult because, in this invasive stage with bacteraemia, the symptoms are those of a generalised infection without localising features. Typically, there is a leucopenia. Blood culture establishes the diagnosis and multiple cultures increase the yield. Stool cultures are often positive in the second and third weeks. The Widal test detects antibodies to the O and H antigens but is not specific.

Management

Antibiotic therapy must be guided by in vitro sensitivity testing. Chloramphenicol (500 mg 4 times daily), ampicillin (750 mg 4 times daily) and co-trimoxazole (960 mg PO or IV twice daily) are losing their effect due to resistance in many areas of the world, especially in South and South-east Asia but also in Africa and Latin America. Multidrug-resistant (MDR) strains are resistant to these three antimicrobials. Fluoroquinolones are the drugs of choice (e.g. ciprofloxacin 500 mg twice daily) if nalidixic acid screening predicts susceptibility, but resistance is common, especially in South Asia and also in the UK. Extended-spectrum cephalosporins (ceftriaxone and cefotaxime) are useful alternatives but have a slightly increased treatment failure rate. Azithromycin (500 mg once daily) is an alternative when fluoroquinolone resistance is present but has not been validated in severe disease. Treatment should be continued for 14 days. Extensively drug-resistant ('XDR') typhoid is resistant to chloramphenicol, ampicillin, co-trimoxazole, ciprofloxacin and ceftriaxone. XDR strains have been causing an ongoing outbreak in Pakistan since 2016, spreading from the Sindh province, accounting for over 60% of infections. They have spread to a range of other countries. Azithromycin is the only currently reliable oral therapy, but resistance to azithromycin is now also reported. In this case meropenem or tigecycline may be required. Pyrexia may persist for up to 5 days after the start of specific therapy. Even with effective chemotherapy, there is still a danger of complications, recrudescence of the disease and the development of a carrier state.

Chronic carriers were formerly treated for 4 weeks with ciprofloxacin but may require an alternative agent and duration, as guided by antimicrobial sensitivity testing. Cholecystectomy may be necessary.

Prevention

Improved sanitation and living conditions reduce the incidence of typhoid. Travellers to countries where enteric infections are endemic should receive typhoid vaccination. In young children a tetanus conjugate vaccine containing Vi polysaccharide conjugated to tetanus toxoid has over 80% efficacy and is superior to older inactivated injectable or oral live attenuated vaccinesused for travellers. The typhoid conjugate vaccine induces T-cell immunity and can be used from 6 months of age, making it the preferred vaccine in endemic areas.

Tularaemia

Tularaemia is primarily a zoonotic disease of the northern hemisphere. It is caused by a highly infectious gram-negative bacillus, *Francisella tularensis*. *F. tularensis* is passed transovarially (ensuring transmission from parent to progeny) in ticks, which allows persistence in nature without the absolute requirement for an infected animal reservoir. It is a potential bioweapon. Wild rabbits, rodents and domestic dogs or cats are potential reservoirs, and ticks, mosquitoes or other biting flies are the vectors.

Infection is introduced either through an arthropod or animal bite or via contact with infected animals, soil or water through skin abrasions. The most common 'ulceroglandular' variety of the disease (70%–80%) is characterised by skin ulceration with regional lymphadenopathy. There is also a purely 'glandular' form. Alternatively, inhalation of the infected aerosols may result in pulmonary tularaemia, presenting as pneumonia. Rarely, the portal of entry of infection may be the conjunctiva, leading to a nodular, ulcerated conjunctivitis with regional lymphadenopathy (an 'oculoglandular' form). Typhoidal tularaemia is a rare and serious form of tularaemia with vomiting, diarrhoea and hepatosplenomegaly, which may be complicated by pneumonia and meningitis.

Investigations and management

Demonstration of a single high titre (≥ 1:160) or a fourfold rise in 2–3 weeks in the tularaemia tube agglutination test confirms the diagnosis. Bacterial yield from the lesions is extremely poor. DNA detection methods to enable rapid diagnosis are still in development.

Treatment consists of a 10- to 21-day course of parenteral aminoglycosides, streptomycin (7.5–10 mg/kg twice daily) or gentamicin (1.7 mg/kg 3 times daily), with doxycycline or ciprofloxacin offered as alternatives.

Melioidosis

Melioidosis is caused by *Burkholderia pseudomallei*, a saprophyte found in soil and water (rice paddy fields). Infection is by inoculation or inhalation, leading to bacteraemia, which is followed by the formation of abscesses in the lungs, liver and spleen. Patients with diabetes, renal stones, thalassaemia or severe burns are particularly susceptible. The disease is most common in South-east Asia and northern Australia and carries a significant mortality. Disease may present years or decades after the initial exposure.

Clinical features

Pneumonia is the most common feature but localised skin nodules and abscesses, or sepsis, especially in diabetics, may occur. Diarrhoea and hepatosplenomegaly may be observed. The chest X-ray can resemble cavitary tuberculosis. In chronic forms, multiple abscesses occur in subcutaneous tissue, liver, spleen ('Swiss cheese' appearance) and bone, accompanied by profound weight loss.

Investigations and management

Culture of blood, sputum or pus on selective media, e.g. Ashdown agar, may yield *B. pseudomallei*. Latex agglutination has been developed as a rapid diagnostic test in Thailand and PCR-based tests are also available. Indirect haemagglutination testing can be helpful in travellers; however, most people in endemic areas are seropositive.

In the acute illness, prompt initiation of empirical therapy is life-saving. Ceftazidime 100 mg/kg (2 g 3 times daily) or meropenem (0.5–1 g 3 times daily) is given for 3–4 weeks. Meropenem is preferred for critical illness, central nervous system disease or persistent bacteraemia. The longer duration of four weeks is preferred for multi-lobar or bacteraemic cases. Co-trimoxazole may be added during induction therapy for severe disease. Induction therapy is followed by maintenance therapy of co-trimoxazole (sulfamethoxazole 1600 mg plus trimethoprim 320 mg twice daily) or doxycycline 200 mg daily, typically for 20 weeks. Co-trimoxazole resistance is reported in Thailand but difficulties with laboratory testing means resistance should be confirmed by E-test for sulfamethoxazole. Abscesses should be drained surgically.

Actinomycete infections

Nocardiosis

Nocardiosis is caused by aerobic Actinomycetes of the genus *Nocardia*, found in the soil. Infection occurs following direct traumatic inoculation or occasionally inhalation or ingestion. Nocardiosis can result in localised cutaneous ulcers or nodules, most often in the lower limbs. Chronic destructive infection in tropical countries can result in actinomycetoma, involving soft tissues with occasional penetration to the bone. Actinomycetoma may also be caused by other aerobic Actinomycetes, and a similar clinical syndrome, eumycetoma, is caused by filamentous fungi. Both conditions are discussed on page 399. Systemic *Nocardia* infection occurs most commonly in immunocompromised individuals, resulting in suppurative disease with lung and brain abscesses.

On microscopy, *Nocardia* spp. appear as long, filamentous, branching gram-positive rods, which are also weakly acid-fast. They are easily grown in culture but require prolonged incubation.

Treatment of systemic infection is guided by sensitivity testing and typically requires combinations of imipenem with ceftriaxone, amikacin or co-trimoxazole, often for 6–12 months or longer. Meropenem, tigecycline, linezolid and minocycline may also be used with severe disease or with allergy, or when intolerance prevents use of the preferred agents. Abscesses are drained surgically when this is feasible. Localised cutaneous infection is usually treated with a single agent for 1–3 months. Treatment of actinomycetoma is discussed on page 399.

Actinomyces *spp.*

Actinomyces are anaerobic Actinomycetes, which are predominantly commensals of the oral cavity. They are capable of causing deep, suppurating infection in the head and neck (cervicofacial actinomycosis), the lungs (thoracic actinomycosis) and gall bladder. They also cause suppurating disease in the pelvis, associated with intrauterine contraceptive devices (IUCDs). Modern diagnostic techniques demonstrate that actinomycosis is caused by many different *Actinomyces* species, the most common of which is *Actinomyces israelii*. Treatment of established disease requires approximately 6–12 months of penicillin or doxycycline. Early disease may respond to shorter antibiotic courses.

Gastrointestinal bacterial infections

The approach to patients presenting with acute gastroenteritis is described on page 308.

Staphylococcal food poisoning

Staphylococcus aureus is transmitted via cuts on the hands of food handlers to foodstuffs such as dairy products, including cheese, and cooked meats. Inappropriate storage of these foods allows growth of the organism and production of one or more heat-stable enterotoxins.

Nausea and profuse vomiting develop within 1–6 hours. Diarrhoea may not be marked. The toxins that cause the syndrome act as 'super-antigens' and induce a significant neutrophil leucocytosis that may be clinically misleading. Most cases settle rapidly but severe dehydration can occasionally be life-threatening.

Antiemetics and appropriate fluid replacement are the mainstays of treatment. Suspect food should be cultured for staphylococci and demonstration of toxin production. Public health authorities should be notified if food vending is involved.

Bacillus cereus food poisoning

Ingestion of pre-formed heat-stable exotoxins of *B. cereus* causes rapid onset of vomiting and some diarrhoea within hours of food consumption, which resolves within 24 hours. Fried rice and freshly made sauces are frequent sources; the organism grows and produces enterotoxin during storage (Fig. 14.41). If viable bacteria are ingested and toxin formation takes place within the gut lumen, then the incubation period is longer (12–24 hours) and watery diarrhoea and cramps are the predominant symptoms. The disease is self-limiting but can be severe.

Appropriate fluid replacement and notification of the public health authorities are indicated.

Clostridium perfringens food poisoning

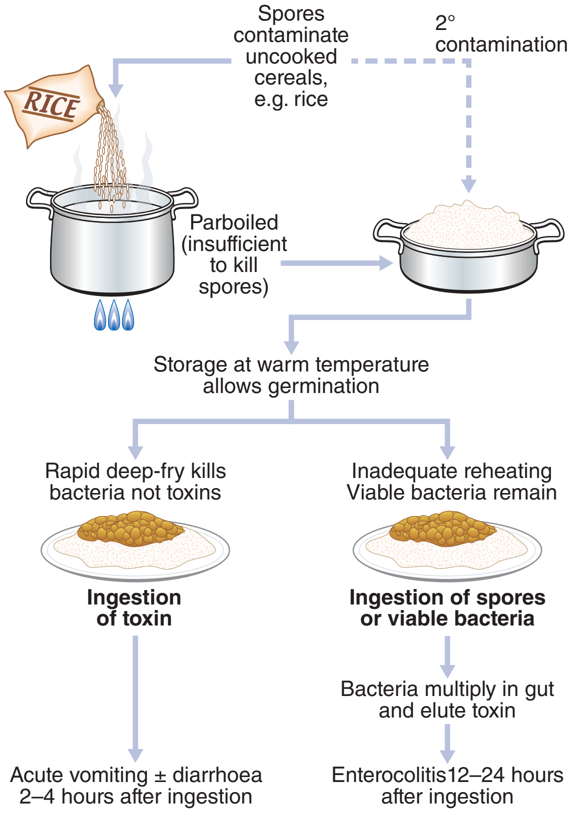
Spores of *C. perfringens* are widespread in the guts of large animals and in soil. If contaminated meat products are incompletely cooked and stored in anaerobic conditions, *C. perfringens* spores germinate and viable organisms multiply. Subsequent reheating of the food causes release of enterotoxin. Symptoms (diarrhoea and cramps) occur 6–12 hours following ingestion. The illness is usually self-limiting.

Clostridial enterotoxins are potent and most people who ingest them will be symptomatic. 'Point source' outbreaks, in which a number of cases all become symptomatic following ingestion, classically occur after school or canteen lunches where meat stews are served.

Clostridial necrotising enteritis (CNE) or pigbel is an often-fatal type of food poisoning caused by a β-toxin of *C. perfringens*, type C. The toxin is normally inactivated by certain proteases or by normal cooking. Pigbel is more likely in protein malnutrition or in the presence of trypsin inhibitors, either in foods such as sweet potatoes or during infection with *Ascaris* sp. roundworms.

Campylobacter infection

This infection (caused by *Campylobacter jejuni* or *C. coli*) is essentially a zoonosis, although contaminated water may be implicated, as the organism can survive for many weeks in fresh water. The most common sources



Spores contaminate uncooked cereals, e.g. rice
2° contamination
RICE
Parboiled (insufficient to kill spores)
Storage at warm temperature allows germination
Rapid deep-fry kills bacteria not toxins
Inadequate reheating Viable bacteria remain
Ingestion of toxin
Ingestion of spores or viable bacteria
Bacteria multiply in gut and elute toxin
Acute vomiting ± diarrhoea 2–4 hours after ingestion
Enterocolitis12–24 hours after ingestion

Fig. 14.41 ***Bacillus cereus*** **food poisoning.**

of the infection are chicken, beef and contaminated milk products. Pet puppies have also been sources. *Campylobacter* infection is now the most common cause of bacterial gastroenteritis in the UK, accounting for some 100 000 cases per annum, most of which are sporadic.

The incubation period is 2–5 days. Colicky abdominal pain may be severe and mimic acute appendicitis or other surgical pathology. Nausea, vomiting and significant diarrhoea, frequently containing blood, are common features. The majority of *Campylobacter* infections affect fit young adults and are self-limiting after 5–7 days. About 10%–20% will be prolonged, occasionally requiring treatment with a macrolide, most often azithromycin, as many organisms are resistant to ciprofloxacin.

Approximately 1 in 1000–2000 cases will develop bacteraemia and possible distant foci of infection. *Campylobacter* spp. have been linked to Guillain–Barré syndrome and post-infectious reactive arthritis (Chs 25 and 27).

Salmonella spp. infection

Salmonella enterica serovars other than Typhi and Paratyphi, of which there are more than 2000, are widespread in animals and can cause gastroenteritis. Two serovars are most important worldwide: *Salmonella* Enteritidis phage type 4 and *Salmonella* Typhimurium dt.104. The latter may be resistant to commonly used antibiotics such as ciprofloxacin. Some strains have a clear relationship to particular animals, e.g. *Salmonella arizonae* and pet reptiles. Transmission is by contaminated water or food, particularly poultry, egg products and minced beef, direct person-to-person spread or the handling of exotic pets such as salamanders, lizards or turtles. The incidence of *Salmonella* enteritis is falling in the UK due to an aggressive culling policy in broiler chicken stocks, coupled with vaccination.

The incubation period of *Salmonella* gastroenteritis is 12–72 hours and the predominant feature is diarrhoea, sometimes with passage of blood. Vomiting may be present at the outset. Approximately 5% of cases are bacteraemic and invasive non-typhoidal salmonellosis is a leading cause of bacteraemia in sub-Saharan Africa especially in people living with HIV. It is also an emerging problem in India. Reactive (post-infective) arthritis occurs in approximately 2%.

Antibiotics are not indicated for uncomplicated *Salmonella* gastroenteritis but are prescribed for bacteraemia. Salmonellae can cause persistent infection and can seed endothelial surfaces such as an atherosclerotic aorta in older patients or can lead to focal infection of bone and joints. Mortality, as with other forms of gastroenteritis, is higher in older people (see Box 14.11).

Escherichia coli infection

Many serotypes of *E. coli* constitute part of the human gut microbiome. Clinical disease requires either colonisation with a new or previously unrecognised strain, or the acquisition by current colonising bacteria of a particular pathogenicity factor for mucosal attachment or toxin production. Travel to unfamiliar areas of the world allows contact with different strains of endemic *E. coli* and the development of travellers' diarrhoea. Enteropathogenic strains may be found in the gut of healthy individuals and, if these people move to a new environment, close contacts may develop symptoms.

At least five different clinico-pathological patterns of diarrhoea are associated with specific strains of *E. coli* with characteristic virulence factors.

Enterotoxigenic *E. coli*

Enterotoxigenic *E. coli* (ETEC) is the most common cause of travellers' diarrhoea (see Box 14.19). The organisms produce either a heat-labile or a heat-stable enterotoxin, causing marked secretory diarrhoea and vomiting after 1–2 days' incubation. The illness is usually mild and self-limiting after 3–4 days. Antibiotics are of questionable value.

Entero-invasive *E. coli*

Illness caused by entero-invasive *E. coli* (EIEC) is very similar to *Shigella* dysentery and is caused by invasion and destruction of colonic mucosal cells. No enterotoxin is produced. Acute watery diarrhoea, abdominal cramps and some scanty blood-staining of the stool are common. The symptoms are rarely severe and are usually self-limiting.

Enteropathogenic *E. coli*

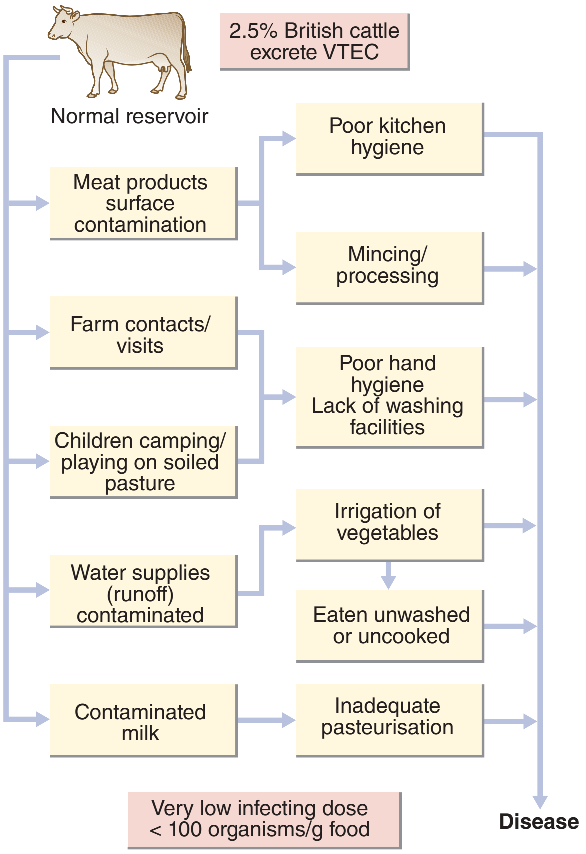
Enteropathogenic *E. coli* (EPEC) organisms are very important in infant diarrhoea. They are able to attach to the gut mucosa, inducing a specific 'attachment and effacement' lesion and causing destruction of microvilli and disruption of normal absorptive capacity. The symptoms vary from mild non-bloody diarrhoea to quite severe illness without bacteraemia.

Entero-aggregative *E. coli*

Entero-aggregative *E. coli* (EAEC) strains adhere to the mucosa and produce a locally active enterotoxin. These demonstrate a particular 'stacked brick' aggregation to tissue culture cells when viewed by microscopy. EAEC have been associated with prolonged diarrhoea in children in South America, South-east Asia and India.

Enterohaemorrhagic *E. coli*

A number of distinct 'O' serotypes of *E. coli* possess both the genes necessary for adherence (see 'Enteropathogenic *E. coli*', above) and plasmids encoding two distinct enterotoxins (verotoxins), which are identical to the toxins produced by *Shigella* ('shiga toxins 1 and 2'). *E. coli* O157:H7 is perhaps the best known of these verotoxin-producing *E. coli* (VTEC), but others, including types O126 and O11, are also implicated. In 2011, an outbreak of food-borne illness linked to fenugreek seeds occurred in Germany and was due to *E. coli* O104:H4, an EAEC strain that had acquired genes encoding shiga toxin 2a. The most recent (2024) outbreak in the UK was a STEC O145 t5:206 associated with more severe disease and an increased risk of haemolytic uraemic syndrome (HUS). Although the incidence of enterohaemorrhagic *E. coli*



2.5% British cattle excrete VTEC

Disease

Fig. 14.42 **Verocytotoxigenic *Escherichia coli* (VTEC) infections.**

(EHEC) is considerably lower than that of *Campylobacter* and *Salmonella* infection, it is increasing in lower-income countries.

The reservoir of infection is in the gut of herbivores. The organism has an extremely low infecting dose (10–100 organisms). Runoff water from pasture lands where cattle have grazed, which is used to irrigate vegetable crops, as well as contaminated milk, meat products (especially hamburgers that have been incompletely cooked), lettuce, radish shoots and apple juice have all been implicated as sources (Fig. 14.42).

The incubation period is 1–7 days. Initial watery diarrhoea becomes uniformly blood-stained in 70% of cases and is associated with severe abdominal pain. There is little systemic upset, vomiting or fever.

Enterotoxins have both a local effect on the bowel and a distant effect on particular body tissues, such as renal glomeruli, heart and brain. The potentially life-threatening haemolytic uraemic syndrome (HUS) occurs in 10%–15% of sufferers from this infection, arising 5–7 days after symptom onset. It is most frequent at the extremes of age, is heralded by a high peripheral leucocyte count, and may be induced, particularly in children, by antibiotic therapy. Thrombotic thrombocytopenic purpura (TTP) is also a recognised complication.

HUS is treated by dialysis if necessary and may be averted by plasma exchange. Antibiotics should be avoided since they can stimulate toxin release.

Clostridioides difficile infection

Clostridioides (formerly *Clostridium*) *difficile* is the most common cause of antibiotic-associated diarrhoea and is an occasional constituent of the gut microbiome. *C. difficile* can produce two toxins (A and B). *C. difficile* infection (CDI) usually follows antimicrobial therapy, which alters the composition of the gastrointestinal flora and may facilitate colonisation with toxigenic *C. difficile*, if the patient is exposed to *C. difficile* spores. The combination of toxin production and the ability to produce environmentally stable spores accounts for the clinical features and transmissibility of CDI. A hypervirulent strain of *C. difficile*, ribotype 027, emerged, which produces more toxin and more severe disease than other *C. difficile* strains.

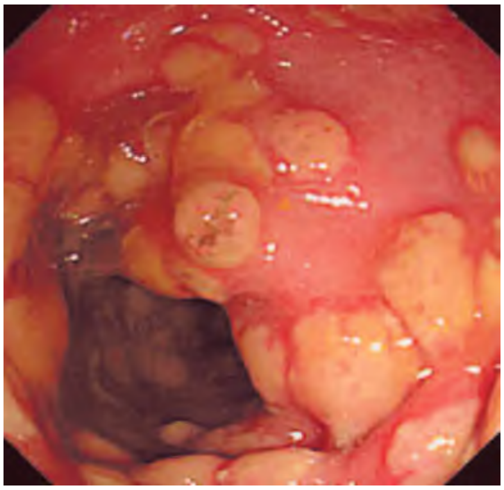

Fig. 14.43 ***Clostridioides difficile* infection.** Colonoscopic view showing numerous adherent 'pseudomembranes' on the mucosa.

Clinical features

Disease manifestations range from diarrhoea to life-threatening pseudomembranous colitis. Around 80% of cases occur in people over 65 years of age, many of whom are frail with comorbid diseases. Symptoms usually begin in the first week of antibiotic therapy but can occur up to 6 weeks after treatment has finished. The onset is often insidious, with lower abdominal pain and diarrhoea that may become profuse and watery. The presentation may resemble acute ulcerative colitis with bloody diarrhoea, fever and even toxic dilatation and perforation. Ileus is also seen in pseudomembranous colitis.

Investigations

C. difficile can be isolated from stool culture in 30% of patients with antibiotic-associated diarrhoea and over 90% of those with pseudomembranous colitis, but also from 5% of healthy adults and up to 20% of older adults in residential care. The diagnosis of CDI therefore rests on detection of toxins A or B in the stool. Current practice in the UK is to screen stool from patients with a compatible clinical syndrome by detection either of glutamate dehydrogenase (GDH), an enzyme produced by *C. difficile*, or of *C. difficile* nucleic acid (e.g. by PCR); if screening is positive, *C. difficile* toxin is sought, usually with a sensitive ELISA assay or PCR.

The rectal appearances at sigmoidoscopy may be characteristic, with erythema, white plaques or an adherent pseudomembrane (Fig. 14.43), or may resemble ulcerative colitis. In some cases, the rectum is spared and abnormalities are observed in the proximal colon. Patients who are ill require abdominal and erect chest X-rays to exclude perforation or toxic dilatation. CT may be useful when the diagnosis is in doubt.

Management

The precipitating antibiotic should be stopped and the patient should be isolated. Supportive therapy includes intravenous fluids and bowel rest. First-line antimicrobial therapy is usually vancomycin (125 mg orally 4 times daily for 7–10 days), which has replaced the use of metronidazole. Fidaxomicin is associated with a lower relapse rate than vancomycin but is more expensive and usually reserved for subsequent episodes. Intravenous immunoglobulin and/or glucocorticoids are sometimes given in the most severe or refractory cases, and faecal transplantation from a healthy donor is increasingly used to manage relapses by restoring a more advantageous gut microbiome profile. Bezlotoxumab is a monoclonal antibody against toxin B designed to prevent recurrence but its current role is uncertain and NICE have not found it to be cost effective.

Surgical intervention with colectomy needs to be considered early in severe cases.

Yersiniosis

Yersinia enterocolitica and *pseudotuberculosis*, commonly found in pork, cause mild to moderate gastroenteritis and can produce significant mesenteric adenitis after an incubation period of 3–7 days. They predominantly cause disease in children, but adults may also be affected. The illness resolves slowly and may be mistaken for appendicitis (pseudoappendicitis). Complications include reactive arthritis (10%–13% of cases), which may be persistent, and anterior uveitis.

Cholera

Cholera, caused by *Vibrio cholerae* serotype O1, is the archetypal toxin-mediated bacterial cause of acute watery diarrhoea. The enterotoxin activates adenylate cyclase in the intestinal epithelium, inducing net secretion of chloride and water. *V. cholerae* O1 has two biotypes, classical and El Tor, and each of these has two distinct serotypes, Inaba and Ogawa. Following its origin in the Ganges valley, devastating epidemics have occurred, often in association with large religious festivals, and pandemics have spread worldwide. The seventh pandemic, due to the El Tor biotype, began in 1961 and spread via the Middle East to become endemic in Africa, subsequently spreading throughout South and Central America. Numbers of cases of cholera have been increasing, with ongoing outbreaks in several African countries, particularly the Democratic Republic of Congo, but also Afghanistan and Yemen. El Tor is more resistant to commonly used antimicrobials than classical *Vibrio* and causes prolonged carriage in 5% of infections. An atypical serotype, O139, has been responsible for localised outbreaks in Bangladesh.

Infection spreads via the stools or vomit of symptomatic patients or of the much larger number of subclinical cases. Organisms survive for up to 2 weeks in fresh water and 8 weeks in saltwater. Transmission is normally through infected drinking water, shellfish and food contaminated by flies, or on the hands of carriers.

Clinical features

Severe diarrhoea without pain or colic begins suddenly and is followed by vomiting. Following the evacuation of normal gut faecal contents, typical 'rice water' material is passed, consisting of clear fluid with flecks of mucus. Classical cholera produces enormous loss of fluid and electrolytes, leading to intense dehydration with muscular cramps. Shock and oliguria develop. Death from acute circulatory failure may occur rapidly unless fluid and electrolytes are replaced. Improvement is rapid with proper treatment.

The majority of infections, however, cause mild illness with slight diarrhoea. Occasionally, a very intense illness, 'cholera sicca', occurs, with loss of fluid into dilated bowel, killing the patient before typical gastrointestinal symptoms appear. The disease is more dangerous in children.

Diagnosis and management

Clinical diagnosis is easy during an epidemic. Otherwise, the diagnosis should be confirmed bacteriologically. Stool dark-field microscopy shows the typical 'shooting star' motility of *V. cholerae*. Rectal swab or stool cultures allow identification. Cholera is notifiable under international health regulations.

Maintenance of circulation by replacement of water and electrolytes is paramount. Ringer's lactate is recommended for intravenous replacement. Vomiting usually stops once the patient is rehydrated, and fluid should then be given orally up to 500 mL hourly. Early intervention with oral rehydration solutions that include resistant starch, based on either rice or cereal, shortens the duration of diarrhoea and improves prognosis. Severe dehydration, as indicated by altered consciousness, skin tenting, very dry tongue, decreased pulses, low blood pressure or minimal urine output, mandates intravenous replacement. Total fluid requirements may exceed 50 L over a period of 2–5 days. Accurate records are greatly facilitated by the use of a 'cholera cot', which has a reinforced hole under the patient's buttocks, beneath which a graded bucket is placed.

Three days' treatment with tetracycline 250 mg 4 times daily, a single dose of doxycycline 300 mg or ciprofloxacin 1 g in adults reduces the duration of excretion of *V. cholerae* and the total volume of fluid needed for replacement.

Prevention

Strict personal hygiene is vital and drinking water should come from a clean piped supply or be boiled. Food must be protected from flies. Oral vaccines containing killed *V. cholerae* with or without the B subunit of cholera toxin are used in outbreaks and in long-term control strategies.

In epidemics, improvements in sanitation and access to clean water, public education and control of population movement are vital. Mass single-dose vaccination and tetracycline treatment are valuable control measures. Disinfection of discharges and soiled clothing, and scrupulous handwashing by medical attendants reduce spread.

Vibrio parahaemolyticus infection

This marine organism produces a disease similar to enterotoxigenic *E. coli* (see above). It is very common where ingestion of raw seafood is widespread (e.g. Japan). After an incubation period of approximately 20 hours, explosive diarrhoea, abdominal cramps and vomiting occur. Systemic symptoms of headache and fever are frequent but the illness is self-limiting after 4–7 days. Rarely, a severe septic illness arises; in this case, *V. parahaemolyticus* can be isolated using specific thiosulfate citrate bile-salts sucrose (TCBS) agar.

Bacillary dysentery (shigellosis)

Shigellae are gram-negative rods, closely related to *E. coli*, that invade the colonic mucosa. There are four main groups: *Sh. dysenteriae*, *flexneri*, *boydii* and *sonnei*. In tropical regions bacillary dysentery is usually caused by *Sh. flexneri*, while in the UK most cases are caused by *Sh. sonnei*. Shigellae are often resistant to multiple antibiotics, especially in tropical countries. The organism only infects humans and its spread is facilitated by a low infecting dose of around 10 organisms.

Spread may occur via contaminated food or flies, but person-to-person transmission by unwashed hands after defaecation is the most important factor. Outbreaks occur in psychiatric hospitals, residential schools and other closed institutions, and dysentery is a constant accompaniment of wars and natural catastrophes, due to overcrowding and poor sanitation. *Shigella* infection may spread rapidly among men who have sex with men.

Clinical features

Disease severity varies from mild *Sh. sonnei* infections that escape detection to more severe *Sh. flexneri* infections, while those due to *Sh. dysenteriae* may be fulminating and cause death within 48 hours.

In a moderately severe illness, the patient complains of diarrhoea, colicky abdominal pain and tenesmus. Stools are small, and after a few evacuations contain blood and purulent exudate with little faecal material. Fever, dehydration and weakness occur, with tenderness over the colon. Reactive arthritis or iritis occasionally complicate bacillary dysentery (p. 1062).

Management and prevention

Oral rehydration therapy or, if diarrhoea is severe, intravenous fluid replacement is necessary. Antibiotic therapy is with ciprofloxacin (500 mg twice daily for 3 days). Azithromycin and ceftriaxone are alternatives but resistance occurs to all agents, especially in Asia. The use of antidiarrhoeal medication should be avoided.

The prevention of faecal contamination of food and milk and the isolation of cases may be difficult, except in limited outbreaks. Handwashing is essential.

Respiratory bacterial infections

Most of these infections are described in Chapter 17.

Diphtheria

Infection with *Corynebacterium diphtheriae* occurs most commonly in the upper respiratory tract and is usually spread by droplet infection. Infection may also complicate skin lesions, especially in areas with poor hygiene. The organisms remain localised at the site of infection but release of a soluble exotoxin damages the heart muscle and the nervous system. Toxigenic strains usually cause pharyngeal and respiratory tract necrosis while non-toxigenic strains are more associated with cutaneous lesions.

Diphtheria has been eradicated from many parts of the world by mass vaccination using a modified exotoxin but remains important in areas where vaccination is incomplete, e.g. in Russia and South-east Asia. The disease is notifiable in all countries of Europe and North America, and international guidelines have been issued by the WHO for the management of infection.

Clinical features

The incubation period averages 2–4 days. The disease begins insidiously with a sore throat (Box 14.64). Despite modest fever, there is usually marked tachycardia. The diagnostic feature is the 'wash-leather' elevated, greyish-green membrane on the tonsils. It has a well-defined edge, is firm and adherent, and is surrounded by a zone of inflammation. There may be swelling of the neck ('bull neck') and tender enlargement of the lymph nodes. In the mildest infections, especially where there is a high degree of immunity, a membrane may not appear and inflammation is minimal.

With anterior nasal infection there is nasal discharge, frequently blood-stained. In laryngeal diphtheria, a husky voice and high-pitched cough signal potential respiratory obstruction requiring urgent tracheostomy. If infection spreads to the uvula, fauces and nasopharynx, the patient is gravely ill.

Death from acute circulatory failure may occur within the first 10 days. Late complications arise as a result of toxin action on the heart or nervous system. About 25% of survivors of the early toxaemia may later develop myocarditis with arrhythmias or cardiac failure. These are usually reversible, with no permanent damage other than heart block in survivors.

Neurological involvement occurs in 75% of cases. After tonsillar or pharyngeal diphtheria, it usually starts after 10 days with palatal palsy. Paralysis of accommodation often follows, manifest by difficulty in reading small print. Generalised polyneuritis with weakness and paraesthesia may follow in the next 10–14 days. Recovery from such neuritis is always ultimately complete.

Management

A clinical diagnosis of diphtheria must be notified to the public health authorities and the patient sent urgently to a specialist infectious diseases unit. Empirical treatment should commence after collection of appropriate swabs.

i 14.64 Clinical features of toxigenic diphtheria

Acute infection

- Membranous tonsillitis
- *or* Nasal infection
- *or* Laryngeal infection
- *or* Skin/wound/conjunctival infection (rare)

Complications

- Laryngeal obstruction or paralysis
- Myocarditis
- Peripheral neuropathy

Diphtheria antitoxin is produced from hyperimmune horse serum. It neutralises circulating toxin but not toxin already fixed to tissues, so it must be injected intramuscularly without awaiting the result of a throat swab. However, reactions to this foreign protein include a potentially lethal immediate anaphylactic reaction and a 'serum sickness' with fever, urticaria and joint pains, which occurs 7–12 days after injection. A careful history of previous horse serum injections or allergic reactions should be taken and a small test injection of serum should be given half an hour before the full dose in every patient. Epinephrine (adrenaline) solution must be available to treat any immediate type of reaction (0.5–1.0 mL of 1/1000 solution intramuscularly). An antihistamine is also given. In a severely ill patient, the risk of anaphylactic shock is outweighed by the mortal danger of diphtheritic toxaemia. A dose of up to 100 000 IU of antitoxin is injected intravenously if the test dose is tolerated. For disease of moderate severity, 16 000–40 000 IU intramuscularly will suffice, and for mild cases 4000–8000 IU.

Penicillin has been recommended for 2 weeks to eliminate *C. diphtheriae* although there are increasing reports of penicillin resistance and a macrolide such as azithromycin is now preferred as first line. Penicillins can be used if sensitivity is confirmed in vitro. Due to poor immunogenicity of primary infection, all sufferers should be immunised with diphtheria toxoid following recovery.

Non-toxigenic strains do not need antitoxin and may be managed with macrolides alone.

Patients must be managed in strict respiratory isolation and attended by staff with a clearly documented immunisation history until three swabs 24 hours apart are culture-negative.

Prevention

Active immunisation is recommended for all children. If diphtheria occurs in a closed community, contacts should be given azithromycin, which is more effective than penicillin in eradicating carriage.

All contacts should also be immunised or given a booster dose of toxoid. Booster doses are required every 10 years to maintain immunity.

Pneumococcal infection

Streptococcus pneumoniae (pneumococcus) is the leading cause of community-acquired pneumonia globally and one of the leading causes of infection-related mortality. Otitis media, meningitis and sinusitis are also frequently caused by *Strep. pneumoniae*. Occasional patients present with bacteraemia without obvious focus. Asplenic individuals are at risk of fulminant pneumococcal disease with purpuric rash.

Increasing rates of penicillin resistance have been reported around the world for *Streptococcus pneumoniae*, although they remain low in the UK. Strains with cephalosporin resistance causing meningitis require treatment with a combination of cephalosporins, glycopeptides and rifampicin. Linezolid may also be used for resistant strains. Macrolide resistance is also increasing. Newer quinolones are also used (e.g. levofloxacin and moxifloxacin) but rates of resistance are rising.

Vaccination of infants with the protein conjugate pneumococcal vaccine decreases *Strep. pneumoniae* infection in infants and in their relatives. The polysaccharide pneumococcal vaccine is used in individuals predisposed to *S. pneumoniae* infection and older people, but only modestly reduces pneumococcal bacteraemia and does not prevent pneumonia. All asplenic individuals should receive vaccination against *S. pneumoniae*.

Anthrax

Anthrax is an endemic zoonosis in many countries; it causes human disease following inoculation of the spores of *Bacillus anthracis*. *B. anthracis* was the first bacterial pathogen described by Koch and the model pathogen for 'Koch's postulates' (see Box 7.1). It is a gram-positive organism with a central spore. The spores can survive for years in soil. Infection is commonly acquired from contact with animals, particularly herbivores. The ease of production of *B. anthracis* spores makes this infection a candidate for biological warfare or bioterrorism. *B. anthracis* produces a number of toxins that mediate the clinical features of disease.

Clinical features

These depend on the route of entry of the anthrax spores.

Cutaneous anthrax

This skin lesion is associated with occupational exposure to anthrax spores during processing of hides and bone products. It accounts for the majority of clinical cases. Animal infection is a serious problem in Africa, India, Pakistan and the Middle East.

Spores are inoculated into exposed skin. A single lesion develops as an irritable papule on an oedematous haemorrhagic base. This progresses to a depressed black eschar. Despite extensive oedema, pain is infrequent.

Gastrointestinal anthrax

This is associated with the ingestion of contaminated meat. The caecum becomes infected, which produces nausea, vomiting, anorexia and fever, followed in 2–3 days by severe abdominal pain and bloody diarrhoea. Toxaemia and death can develop rapidly thereafter.

Inhalational anthrax

Inhalational anthrax is extremely rare but has been associated with bioterrorism. Without rapid and aggressive therapy at the onset of symptoms, the mortality is 50%–90%. Fever, dyspnoea, cough, headache and sepsis develop 3–14 days following exposure. Typically, the chest X-ray shows only widening of the mediastinum and pleural effusions, which are haemorrhagic. Meningitis may occur. Welders and metal workers are at risk of a similar clinical presentation associated with *Bacillus cereus* strains that contain the pXO1 plasmid that contains anthrax-related virulence factors, but mediastinal widening is not usually observed in this form of illness.

Management

B. anthracis can be cultured from skin swabs from lesions. Skin lesions are readily curable with early antibiotic therapy. Treatment is with ciprofloxacin (500 mg twice daily) until penicillin susceptibility is confirmed; the regimen can then be changed to benzylpenicillin with doses up to 2.4 g IV given 6 times daily or phenoxymethylpenicillin orally 500–1000 mg 4 times daily administered for 10 days. The addition of an aminoglycoside may improve the outlook in severe disease. In view of concerns about concomitant inhalational exposure, particularly in the era of bioterrorism, a further 2-month course of ciprofloxacin 500 mg twice daily or doxycycline 100 mg twice daily orally is added to eradicate inhaled spores. Inhalational anthrax is treated initially with two bactericidal agents from different classes until susceptibility is confirmed: ciprofloxacin plus meropenem; and one of a protein synthesis inhibitor (clindamycin or doxycycline) or alternatively a RNA synthesis inhibitor (rifampicin) for at least 14 days. Once susceptibilities are known, treatment can be altered during the induction phase (for example, simplifying therapy to penicillin and doxycycline if susceptible). After initial therapy for 14 days, or when the patient's condition has stabilised, induction therapy is followed by consolidation therapy to eradicate spores with an agent such as ciprofloxacin or doxycycline to complete 60 days' therapy. Monoclonal antibodies against *B. anthracis* protective antigen (raxibacumab) are recommended for pulmonary or systemic infection. Prophylaxis with ciprofloxacin (500 mg twice daily for 2 months) is recommended for anyone at high risk of inhalational exposure to anthrax spores and is combined with three doses of anthrax vaccine adsorbed (AVA).

Bacterial infections with neurological involvement

Infections affecting the CNS, including bacterial meningitis, botulism and tetanus, are described on page 1216.

Mycobacterial infections

Tuberculosis

Tuberculosis is predominantly, although by no means exclusively, a respiratory disease and is described in Chapter 17 and also in the section on presenting problems in HIV see page 328.

Leprosy

Leprosy (Hansen disease) is a chronic granulomatous disease affecting skin and nerves and caused by *Mycobacterium leprae*, a slow-growing mycobacterium that cannot be cultured in vitro. The clinical manifestations are determined by the degree of the patient's cell-mediated immunity (CMI) towards *M. leprae* (Fig. 14.44). High levels of CMI with elimination of leprosy bacilli produces tuberculoid leprosy, whereas absent CMI results in lepromatous leprosy. Complications arise due to nerve damage, immunological reactions and bacillary infiltration. People with leprosy are frequently stigmatised and using the word 'leper' is inappropriate.

Epidemiology and transmission

The WHO estimates there are around 200 000 new cases detected annually. About 70% of the world's leprosy patients live in India, with the highest number of annual cases in India, Brazil and Indonesia. Thirteen other African or Asian countries report > 1000 cases annually.

Untreated lepromatous patients discharge bacilli from the nose. Infection occurs through the nose, followed by haematogenous spread to skin and nerve. The incubation period is 2–5 years for tuberculoid cases and 8–12 years for lepromatous cases. Leprosy incidence peaks at 10–14 years, and is more common in males and in household contacts of leprosy cases.

Pathogenesis

M. leprae has tropism for Schwann cells and skin macrophages. In tuberculoid leprosy, effective CMI controls bacillary multiplication ('paucibacillary') and organised epithelioid granulomata form. In

Fig. 14.44 Leprosy: mechanisms of damage and tissue affected. Mechanisms under the broken line are characteristic of disease near the lepromatous end of the spectrum, and those under the solid line are characteristic of the tuberculoid end. They overlap in the centre where, in addition, instability predisposes to type 1 lepra reactions. At the peak in the centre, neither bacillary growth nor cell-mediated immunity has the upper hand. (BL = borderline lepromatous; BT = borderline tuberculoid; LL = lepromatous leprosy; TT = tuberculoid leprosy) *Adapted from Bryceson ADM, Pfaltzgraff RE. Leprosy, 3rd ed. Churchill Livingstone, Elsevier Ltd.; 1990.*

lepromatous leprosy, there is abundant bacillary multiplication ('multibacillary'), e.g. in Schwann cells and perineurium. Between these two extremes is a continuum, varying from patients with moderate CMI (borderline tuberculoid) to patients with little cellular response (borderline lepromatous).

Immunological reactions evolve as the immune response develops and the bacillary antigenic stimulus varies, particularly in borderline patients. Delayed hypersensitivity reactions produce type 1 (reversal) reactions, while immune complexes contribute to type 2 (erythema nodosum leprosum) reactions.

HIV/leprosy co-infected patients have typical lepromatous and tuberculoid leprosy skin lesions and typical leprosy histology and granuloma formation. Surprisingly, even with low circulating CD4 counts, tuberculoid leprosy may be observed and there is not an obvious shift to lepromatous leprosy.

Clinical features

Box 14.65 gives the cardinal features of leprosy. Types of leprosy are compared in Box 14.66.

- *Skin*. The most common skin lesions are macules or plaques. Tuberculoid patients have few, hypopigmented lesions (Fig. 14.45A). In lepromatous leprosy, papules, nodules or diffuse infiltration of the skin occur. The earliest lesions are ill defined; gradually, the skin becomes infiltrated and thickened. Facial skin thickening leads to the characteristic leonine facies (Fig. 14.45B).
- *Anaesthesia*. In skin lesions, the small dermal sensory and autonomic nerve fibres are damaged, causing localised sensory loss and loss of sweating. Anaesthesia can occur in the distribution of a damaged large peripheral nerve. A 'glove and stocking' sensory neuropathy is also common in lepromatous leprosy.
- *Nerve damage*. Peripheral nerve trunks are affected at 'sites of predilection'. These are the ulnar (elbow), median (wrist), radial (humerus), radial cutaneous (wrist), common peroneal (knee), posterior tibial and sural nerves (ankle), facial nerve (zygomatic arch) and great auricular nerve (posterior triangle of the neck). Damage to peripheral nerve trunks produces characteristic signs with regional sensory loss and muscle dysfunction (Fig. 14.45C). All these nerves should be examined for enlargement and tenderness and tested for motor and sensory function. The CNS is not affected.
- *Eye involvement*. Blindness is a devastating complication for a patient with anaesthetic hands and feet. Eyelid closure is impaired when the facial nerve is affected. Damage to the trigeminal nerve causes anaesthesia of the cornea and conjunctiva. The cornea is then susceptible to trauma and ulceration.
- *Other features*. Many organs can be affected. Nasal collapse occurs secondary to bacillary destruction of the nasal cartilage and bone. Diffuse infiltration of the testes causes testicular atrophy and the acute orchitis that occurs with type 2 reactions. This results in azoospermia and hypogonadism.

i 14.65 Cardinal features of leprosy

- Skin lesions, typically anaesthetic at tuberculoid end of spectrum
- Thickened peripheral nerves
- Acid-fast bacilli on skin smears or biopsy

i 14.66 Clinical characteristics of the polar forms of leprosy

Clinical and tissue-specific features	Lepromatous	Tuberculoid
Skin and nerves		
Number and distribution	Widely disseminated	One or a few sites, asymmetrical
Skin lesions		
Definition:		
Clarity of margin	Poor	Good
Elevation of margin	Never	Common
Colour:		
Dark skin	Slight hypopigmentation	Marked hypopigmentation
Light skin	Slight erythema	Coppery or red
Surface	Smooth, shiny	Dry, scaly
Central healing	None	Common
Sweat and hair growth	Impaired late	Impaired early
Loss of sensation	Late	Early and marked
Nerve enlargement and damage	Late	Early and marked
Bacilli (bacterial index)	Many (5 or 6+)	Absent (0)
Natural history	Progressive	Self-healing
Other tissues	Upper respiratory mucosa, eye, testes, bones, muscle	None
Reactions	Immune complexes (type 2)	Cell-mediated (type 1)

Leprosy reactions

Leprosy reactions (Box 14.67) are events superimposed on the cardinal features shown in Box 14.65.

- *Type 1 (reversal) reactions*. These occur in 30% of borderline patients (BT, BB or BL – see below) and are delayed hypersensitivity reactions. Skin lesions become erythematous (Fig. 14.45D). Peripheral nerves become tender and painful, with sudden loss of nerve function. These reactions may occur spontaneously, after starting treatment and also after completion of multidrug therapy (MDT).
- *Type 2 (erythema nodosum leprosum, ENL) reactions*. These are partly due to immune complex deposition and occur in BL and LL patients who produce antibodies and have a high antigen load. They manifest with malaise, fever and crops of small pink nodules on the face and limbs but also on the trunk when extensive. Iritis and episcleritis are common. Other signs are acute neuritis, lymphadenitis, orchitis, bone pain, dactylitis, arthritis and proteinuria. ENL may continue intermittently for several years.

Borderline cases

In borderline tuberculoid (BT) cases, skin lesions are more numerous than in tuberculoid (TT) cases, and there is more severe nerve damage and a risk of type 1 reactions. In borderline leprosy (BB) cases, skin lesions are numerous and vary in size, shape and distribution; annular lesions are characteristic and nerve damage is variable. In borderline lepromatous (BL) cases, there are widespread small macules in the skin and widespread nerve involvement; both type 1 and type 2 reactions occur.

Pure neural leprosy (i.e. without skin lesions) occurs principally in India and accounts for 10% of patients. There is asymmetrical involvement of peripheral nerve trunks and no visible skin lesions. On nerve biopsy, all types of leprosy have been found.

Investigations

The diagnosis is clinical, made by finding a cardinal sign of leprosy and supported by detecting acid-fast bacilli in slit-skin smears or typical histology in a skin biopsy. Slit-skin smears are obtained by scraping dermal material on to a glass slide. The smears are then stained for acid-fast bacilli, the number counted per high-power field and a score derived on a logarithmic scale (0–6): the bacterial index (BI). Smears are useful for confirming the diagnosis and monitoring response to treatment. Neither serology nor PCR is sensitive or specific enough for diagnosis.

Management

The principles of treatment are outlined in Box 14.68. All leprosy patients require MDT with an approved first-line regimen (Box 14.69).

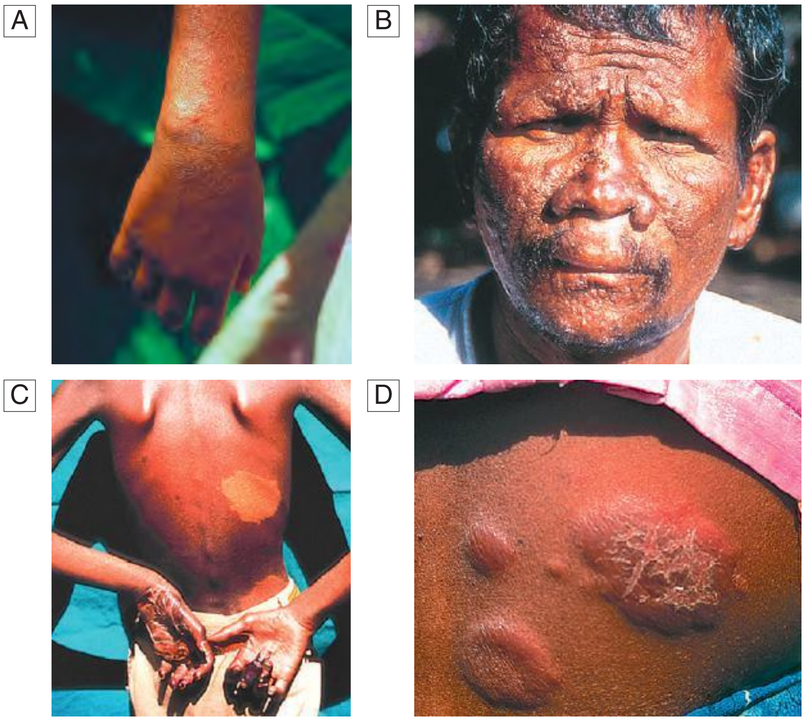

Fig. 14.45 **Clinical features of leprosy.** **A** Tuberculoid leprosy. Single lesion with a well-defined active edge and anaesthesia within the lesion. **B** Lepromatous leprosy. Widespread nodules and infiltration, with loss of the eyebrows. This man also has early collapse of the nose. **C** Borderline tuberculoid leprosy with severe nerve damage. This boy has several well-defined, hypopigmented, macular, anaesthetic lesions. He has severe nerve damage affecting both ulnar and median nerves bilaterally and has sustained severe burns to his hands. **D** Reversal (type 1) reactions. Erythematous, oedematous lesions.

14.67 Reactions in leprosy

	Lepra reaction type 1 (reversal)	Lepra reaction type 2 (erythema nodosum leprosum)
Mechanism	Cell-mediated hypersensitivity	Immune complexes
Clinical features	Painful tender nerves, loss of function Swollen skin lesions New skin lesions	Tender papules and nodules; may ulcerate Painful tender nerves, loss of function Iritis, orchitis, myositis, lymphadenitis Fever, oedema
Management	Prednisolone 40 mg, reducing over 3–6 months[1]	Moderate: prednisolone 40 mg daily Severe: thalidomide[2] or prednisolone 40–80 mg daily, reducing over 1–6 months; local if eye involved[3]

[1] Indicated for any new impairment of nerve or eye function.
[2] Contraindicated in women who may become pregnant.
[3] 1% hydrocortisone drops or ointment and 1% atropine drops.

14.68 Principles of leprosy treatment

- Stop the infection with chemotherapy
- Treat reactions
- Educate the patient about leprosy
- Prevent disability
- Support the patient socially and psychologically

14.69 World Health Organization 2018 guidelines for multidrug therapy (MDT) regimens in leprosy

Type of leprosy[1]	Monthly supervised treatment	Daily self-administered treatment	Duration of treatment
Paucibacillary	Rifampicin 600 mg	Dapsone 100 mg	6 months
	Clofazimine 300 mg	Clofazimine 50 mg	
Multibacillary	Rifampicin 600 mg	Dapsone 100 mg	12 months
	Clofazimine 300 mg	Clofazimine 50 mg	
Rifampicin resistant		Clofazimine 50 mg plus two second-line agents[2] × 6 months, then plus one second line × 18 months	24 months

[1] Classification uses the number of skin lesions: paucibacillary (1–5 skin lesions); multibacillary (> 5 skin lesions, nerve involvement or positive slit-skin smear).
[2] Second-line agents minocycline 100 mg, clarithromycin 500 mg, or a fluoroquinolone (e.g. ofloxacin 400 mg, levofloxacin 500 mg or moxifloxacin 400 mg) but only use a fluoroquinolone if TB excluded and no fluoroquinolone resistance.
From WHO. Guidelines for the Diagnosis, Treatment and Prevention of Leprosy. New Delhi: World Health Organization, Regional Office for South-East Asia; 2018.

Rifampicin is a potent bactericidal for *M. leprae* but should always be given in combination with other antileprotics, since a single-step mutation can confer resistance. Dapsone is bacteriostatic. It commonly causes mild haemolysis and rarely anaemia. Clofazimine is a red, fat-soluble crystalline dye, weakly bactericidal for *M. leprae*. Skin discoloration (red to purple–black) and ichthyosis are troublesome side-effects, particularly in pale skin. New bactericidal drugs against *M. leprae* have been identified, notably fluoroquinolones (e.g. ofloxacin). Minocycline and clarithromycin may also be used. These agents are second-line drugs. Minocycline causes grey pigmentation of skin lesions.

Single-dose combination treatment (rifampicin, ofloxacin and minocycline) is less effective than the conventional 6-month treatment for paucibacillary leprosy and has fallen out of favour.

Lepra reactions are treated as shown in Box 14.67. Chloroquine can also be used.

Patient education

Patient education emphasises that, after 3 days of chemotherapy, they are not infectious, that gross deformities are not inevitable and that they can lead a normal social life.

Patients with anaesthetic hands or feet need to avoid and treat burns or other minor injuries. Good footwear is important. Physiotherapy helps maintain range of movement of affected muscles and neighbouring joints.

Prognosis

Untreated, tuberculoid leprosy has a good prognosis; it may self-heal and peripheral nerve damage is limited. Lepromatous leprosy (LL) is a progressive condition with high morbidity if untreated.

After treatment, the majority of patients, especially those who have no nerve damage at the time of diagnosis, do well, with resolution of skin lesions. Borderline patients are at risk of developing type 1 reactions, which may result in devastating nerve damage.

Prevention and control

The previous strategy of centralised leprosy control campaigns has been superseded by integrated programmes, with primary health-care workers in many countries now responsible for case detection and provision of MDT. It is not yet clear how successful this will be, especially in the time-consuming area of disability prevention. The WHO's global strategy 2021–2030 'Towards zero leprosy' has four pillars: implementing integrated, country-owned zero leprosy roadmaps in all endemic countries; scaling up prevention alongside integrated active case detection; managing leprosy and its complications, while preventing new disability; and combatting stigma.

BCG vaccination offers protection against leprosy; adding killed *M. leprae* to BCG does not further enhance protection.

Rickettsial and related intracellular bacterial infections

Rickettsial fevers

The rickettsial fevers are the most common tick-borne infections. It is important to ask potentially infected patients about contact with ticks, lice or fleas. There are two main groups of rickettsial fevers: spotted fevers and typhus (Box 14.70).

Pathogenesis

The rickettsiae are intracellular gram-negative organisms that parasitise the intestinal canal of arthropods. Infection of humans through the skin occurs from the excreta of arthropods, but the saliva of some biting vectors is infected. The organisms multiply in capillary endothelial cells, producing lesions in the skin, CNS, heart, lungs, liver, kidneys and skeletal muscles. Endothelial proliferation, associated with a perivascular reaction, may cause thrombosis and purpura. In epidemic typhus, the brain is the target organ; in scrub typhus, the cardiovascular system and lungs in particular are attacked. An eschar, a black necrotic crusted sore, is often found in tick- and mite-borne typhus (see Fig. 14.8C). This is due to vasculitis following immunological recognition of the inoculated organism. Regional lymph nodes often enlarge.

Spotted fever group

Rocky Mountain spotted fever

Rickettsia rickettsii is transmitted by tick bites. It is widely distributed and increasing in western and south-eastern states of the USA and also in Central and South America. The incubation period is around 7 days. The rash appears on about the third or fourth day of illness, looking at first like measles, but in a few hours a typical maculopapular eruption develops. The rash spreads in 24–48 hours from wrists, forearms and ankles to the back, limbs and chest, and then to the abdomen, where it is least pronounced. Larger cutaneous and subcutaneous haemorrhages may

i 14.70 Features of rickettsial infections

[1] Eschar at bite site and local lymphadenopathy.
[2] Highest in adult males.
[3] Except in infants, older people and the debilitated.

appear in severe cases. The liver and spleen become palpable. At the extremes of life, the mortality is 2%–12%.

Other spotted fevers

R. conorii (boutonneuse fever) causes Mediterranean spotted fever, which extends to Africa and India, while *R. africae* (African tick bite fever) causes African tick typhus. The incubation period is approximately 7 days. Infected tick bites result from walking on grasslands or are acquired from pet dogs. Examination may reveal a diagnostic eschar, and the maculopapular rash on the trunk, limbs, palms and soles. There may be delirium and meningeal signs in severe infections, but recovery is usual. *R. africae* may cause multiple eschars. Some cases, particularly those with *R. africae*, present without rash ('spotless spotted fever'). Other spotted fevers are shown in Box 14.70.

Typhus group

Scrub typhus fever

Scrub typhus is caused by *Orientia tsutsugamushi*, transmitted by mites. It occurs in the Far East (Japan, China, Taiwan and South Korea), Myanmar, Pakistan, Bangladesh, India, Indonesia, the South Pacific islands and Queensland, particularly where patches of forest cleared for plantations have attracted rats and mites. Scrub typhus has re-emerged as an infectious disease in India and surrounding areas in association with changes in the predominant vectors.

In many patients, one or more eschars develop, surrounded by cellulitis (see Fig. 14.8C), with regional lymph node enlargement. The incubation period is about 9 days.

Mild or subclinical cases are common. The onset of symptoms is usually sudden, with headache (often retro-orbital), fever, malaise, weakness and cough. In severe illness, the general symptoms increase, with apathy and prostration. An erythematous maculopapular rash often appears on about the 5th–7th day and spreads to the trunk, face and limbs, including the palms and soles, with generalised painless lymphadenopathy. The rash fades by the 14th day. The temperature rises rapidly and continues as a remittent fever (i.e. the difference between maximum and minimum temperature exceeds 1°C), remaining above normal with sweating until it falls on the 12th–18th day. In severe infection, the patient is prostrate with cough, pneumonia, delirium and deafness. Cardiac failure, renal failure and haemorrhage may develop. Convalescence is often slow and tachycardia may persist for some weeks. Atypical presentations with short durations of symptoms and presentations with complications such as respiratory failure, acute kidney injury or encephalopathy are increasingly described in countries like India.

Epidemic (louse-borne) typhus

Epidemic typhus is caused by *R. prowazekii* and is transmitted by infected faeces of the human body louse, usually through scratching the skin. Patients with epidemic typhus infect lice, which leave when the patient is febrile. In conditions of overcrowding, the disease spreads rapidly. It is prevalent in parts of Africa, especially Ethiopia and Rwanda, and in the South American Andes and Afghanistan. Large epidemics have occurred in Europe, usually during wars. The incubation period is usually 12–14 days.

There may be several days of malaise but the onset is more often sudden, with rigors, fever, frontal headaches, pains in the back and limbs, constipation and bronchitis. The face is flushed and cyanotic, the eyes are congested and the patient becomes confused. The rash appears on the 4th–6th day. In its early stages, it disappears on pressure but soon becomes petechial with subcutaneous mottling. The rash appears first on the anterior folds of the axillae, sides of the abdomen or backs of the hands, then on the trunk and forearms. The neck and face are seldom affected. During the second week, symptoms increase in severity. The spleen is palpable, the pulse feeble and the patient stuporous and delirious. The temperature falls rapidly at the end of the second week and the patient recovers gradually. In fatal cases, the patient usually dies in the second week from toxaemia, cardiac or renal failure, or pneumonia.

Endemic (flea-borne) typhus

Flea-borne or 'endemic' typhus caused by *R. typhi* is endemic worldwide. Humans are infected when the faeces or contents of a crushed flea, which has fed on an infected rat, are introduced into the skin. The incubation period is 8–14 days. The symptoms resemble those of a mild louse-borne typhus. The rash may be scanty and transient.

Investigation of rickettsial infection

Routine blood investigations are not diagnostic. There is usually hepatitis and thrombocytopenia. Diagnosis is made on clinical grounds and response to treatment and may be confirmed by antibody detection or PCR in specialised laboratories. Differential diagnoses include malaria, typhoid, meningococcal sepsis and leptospirosis.

Management of rickettsial fevers

The rickettsial fevers vary in severity but all respond to tetracycline 500 mg 4 times daily, doxycycline 200 mg daily or chloramphenicol 500 mg 4 times daily for 7 days. Louse-borne typhus and scrub typhus can be treated with a single dose of 200 mg doxycycline, repeated for 2–3 days to prevent relapse. Chloramphenicol- and doxycycline-resistant strains of *O. tsutsugamushi* have been reported from Thailand and patients here may need treatment with rifampicin. Clinical trial data from India suggests that the combination of doxycycline and azithromycin is associated with better outcomes in severe scrub typhus than monotherapy with either agent alone.

Nursing care is important, especially in epidemic typhus. Sedation may be required for delirium and blood transfusion for haemorrhage. Relapsing fever and typhoid are common intercurrent infections in epidemic typhus, and pneumonia in scrub typhus. Convalescence is usually protracted, especially in older people.

To prevent rickettsial infection, lice, fleas, ticks and mites need to be controlled with insecticides.

Q fever

Q fever occurs worldwide and is caused by the rickettsia-like organism *Coxiella burnetii*, an obligate intracellular organism that survives in the extracellular environment. Cattle, sheep and goats are important reservoirs and the organism is transmitted by inhalation of aerosolised particles. Other routes of infection include direct contact with infected animal products e.g. placentas, urine or faeces, ingestion of unpasteurised milk or tick bites. *C. burnetii* exhibits phase variation, due to antigenic variation resulting from changes to its lipopolysaccharide (LPS). When isolated from animals or humans, *C. burnetii* expresses phase I antigen and is very infectious (a single bacterium is sufficient to infect a human). In culture, there is an antigenic shift to the phase II form, which is not infectious. Measurement of antigenic shift helps differentiate acute and chronic Q fever.

Clinical features

The incubation period is 3–4 weeks. The initial symptoms are non-specific with fever, headache and chills; in 20% of cases, a maculopapular rash occurs. Other presentations include pneumonia and hepatitis. Chronic Q fever may present with osteomyelitis, encephalitis and endocarditis.

Investigations and management

Diagnosis is usually serological and the stage of the infection can be distinguished by isotype tests and phase-specific antigens. Phase I and II IgM titres peak at 4–6 weeks. In acute infections, antibodies to phase II antigens predominate, but in chronic infections such as endocarditis, although both phase I and II antibody titres may be elevated, IgG titres to phase I antigens predominate or are sometimes equivalent to phase II antigens. Suspected tissue infection (e.g. endocarditis) can be diagnosed by detection of specific DNA (PCR).

Prompt treatment of acute Q fever with doxycycline reduces fever duration. Treatment of Q fever endocarditis is problematic, requiring prolonged therapy with doxycycline with hydroxychloroquine or combined with rifampicin or ciprofloxacin where there is hydroxychloroquine intolerance; even then, organisms are not always eradicated. Valve surgery is often required.

14.71 Clinical diseases caused by *Bartonella* spp.

Reservoir	Vector	Organism	Disease
Cats	Flea	*B. henselae*	Cat scratch disease, bacillary angiomatosis, endocarditis
Undefined	Lice	*B. quintana*	Trench fever, bacillary angiomatosis, endocarditis
Undefined	Sandfly	*B. bacilliformis*	Carrion disease: Oroya fever and verruga peruana
Undefined	Flea	*B. rochalimae*	Fever, rash, anaemia, splenomegaly

Bartonellosis

Bartonellae are intracellular gram-negative bacilli closely related to the rickettsiae, which are important causes of 'culture-negative' endocarditis. They are found in many domestic pets, such as cats, although for several the host is undefined (Box 14.71). The principal human pathogens are *Bartonella quintana*, *B. henselae* and *B. bacilliformis*. *Bartonella* infections are associated with the following:

- *Trench fever*. This is a relapsing fever with severe leg pain and is caused by *B. quintana*. The disease is not fatal but is very debilitating.
- *Bacteraemia and endocarditis in the homeless*. Endocarditis due to *B. quintana* or *B. henselae* is associated with severe damage to the heart valves.
- *Cat scratch disease*. *B. henselae* causes this common benign lymphadenopathy in children and young adults. A vesicle or papule develops on the head, neck or arms after a cat scratch. The lesion resolves spontaneously but there may be regional lymphadenopathy that persists for up to 4 months before also resolving spontaneously. Rare complications include retinitis and encephalopathy.
- *Bacillary angiomatosis*. This is an HIV-associated disease caused by *B. quintana* or *B. henselae* (see p. 326).
- *Oroya fever and verruga peruana* (*Carrion disease*). This is endemic in areas of Peru. It is a biphasic disease caused by *B. bacilliformis*, transmitted by sandflies of the genus *Phlebotomus*. Fever, haemolytic anaemia and microvascular thrombosis with end-organ ischaemia are features. It is frequently fatal if untreated.

Investigations and management

Bartonellae can be cultured in specialised laboratories but PCR is often used to diagnose infection. Serum antibody detection is possible but cross-reactions occur with *Chlamydia* and *Coxiella* spp. Diagnosis of bacillary angiomatosis is made by biopsy of a lesion and Warthin–Starry silver staining, which reveals aggregates of bacilli.

Bartonella spp. are typically treated with macrolides, e.g. azithromycin or tetracyclines. Antibiotic use is guided by clinical need. Cat scratch disease usually resolves spontaneously but *Bartonella* endocarditis requires valve replacement and combination antibiotic therapy with doxycycline and gentamicin.

Chlamydial infections

These are listed in Box 14.72 and are also described on pages 415 and 550.

Trachoma

Trachoma is a chronic keratoconjunctivitis caused by *Chlamydia trachomatis* and is the most common cause of avoidable blindness. The classic trachoma environment is dry and dirty, causing children to have eye and nose discharges. Transmission occurs through flies, on fingers and within families. In endemic areas, the disease is most common in children.

14.72 Chlamydial infections

Organism	Disease caused
Chlamydia trachomatis	Trachoma Lymphogranuloma venereum (see Box 15.12) Cervicitis, urethritis, proctitis (see Ch. 15)
Chlamydia psittaci	Psittacosis (see Box 17.38)
Chlamydophila (Chlamydia) pneumoniae	Atypical pneumonia (see Box 17.38) Acute/chronic sinusitis

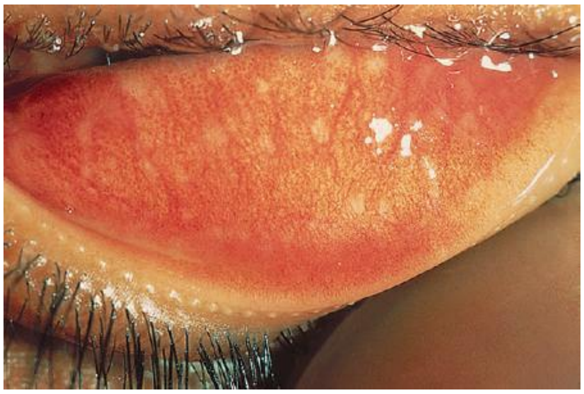

Fig. 14.46 **Trachoma.** Trachoma is characterised by hyperaemia and numerous pale follicles. *Courtesy of Institute of Ophthalmology, Moorfields Eye Hospital, London.*

Pathology and clinical features

The onset is usually insidious. Infection may be asymptomatic, last for years with prolonged latency and may recrudesce. The conjunctiva of the upper lid is first affected with vascularisation and cellular infiltration. Early symptoms include conjunctival irritation and blepharospasm. The early follicles are characteristic (Fig. 14.46), but clinical differentiation from conjunctivitis due to other causes may be difficult. Scarring causes inversion of the lids (entropion) so that the lashes rub against the cornea (trichiasis). The cornea becomes vascularised and opaque with detection only when vision begins to fail.

Investigations and management

Intracellular inclusions may be demonstrated in conjunctival scrapings by staining with iodine or immunofluorescence. Although chlamydiae may, in theory, be isolated in chick embryo or cell culture or detected by nucleic acid amplification tests, these methods are rarely available in the areas where trachoma is encountered, and in any case their sensitivity and specificity are poorly established. Diagnosis of trachoma is therefore based on clinical and epidemiological features.

A single dose of oral azithromycin (20 mg/kg) is superior to 6 weeks of tetracycline eye ointment twice daily for individuals in mass treatment programmes. Deformity and scarring of the lids, and corneal opacities, ulceration and scarring require surgical treatment after control of local infection.

Prevention

Personal and family hygiene should be improved. Proper care of the eyes of newborn and young children is essential. Family contacts should be examined. The WHO is promoting the SAFE strategy for trachoma control (surgery, antibiotics, facial cleanliness and environmental improvement).

Protozoal infections

Protozoa are important causes of infectious diseases. They can be categorised according to whether they cause systemic or local infection. Trichomoniasis is described on page 410.

Systemic protozoal infections

Malaria

Malaria in humans is caused by *Plasmodium falciparum*, *P. vivax*, *P. ovale* (subspecies *curtisi* and *wallikeri*), *P. malariae* and the zoonotic simian parasite *P. knowlesi*. It is transmitted by the bite of female *Anopheles* mosquitoes and occurs throughout the tropics and subtropics at altitudes below 1500 m (Fig. 14.47). The WHO estimates that 250 million cases of clinical malaria occurred in 2022, primarily among children and pregnant women in Africa and Asia. The incidence rate of malaria declined globally during 2010–2018 due to prevention and treatment campaigns but has since increased. *P. falciparum* has now become resistant to artemisinin in some areas, as well as chloroquine, mefloquine and sulfadoxine–pyrimethamine, initially in South-east Asia. The WHO is now planning for elimination of malaria in certain countries by utilising the 'best evidence' in bed nets, rapid diagnostic tests and artemisinin combination therapy (ACT).

Travellers are susceptible to malaria. Most cases are due to *P. falciparum*, usually from Africa, and of these 1% die because of late diagnosis. Migrants from endemic countries who spend long periods of time in non-endemic countries are particularly at risk if they visit friends and relatives (VFR) in their country of origin. They have lost their partial immunity and frequently do not take malaria prophylaxis. A few people living near airports in Europe have acquired malaria from accidentally imported mosquitoes and there is occasionally unsustained transmission.

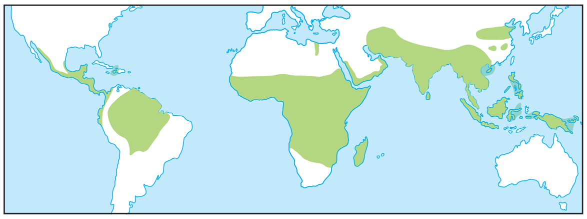

Fig. 14.47 Approximate distribution of malaria. For up-to-date information see the Malaria Atlas Project (MAP): malariaatlas.org. Map lines delineate study areas and do not necessarily depict accepted national boundaries.

Pathogenesis

Life cycle of the malarial parasite

The female anopheline mosquito becomes infected when it feeds on human blood containing gametocytes, the sexual forms of the malarial parasite (Figs. 14.48, 14.49). Development in the mosquito takes 7–20 days, and results in sporozoites accumulating in the salivary glands and being inoculated into the human blood stream. Sporozoites disappear from human blood within half an hour and enter the liver. After some days, merozoites leave the liver and invade red blood cells, where further asexual cycles of multiplication take place, producing schizonts. Rupture of the schizont releases more merozoites into the blood and causes fever, the periodicity of which depends on the species of parasite.

Fig. 14.49 Malarial parasites: life cycle. Hypnozoites (*) are present only in *Plasmodium vivax* and *P. ovale* infections. (RBC = red blood cell)

14.73 Relationships between life cycle of parasite and clinical features of malaria

Cycle/feature	*Plasmodium vivax, P. ovale*	*P. malariae*	*P. falciparum*
Pre-patent period (minimum incubation)	8–25 days	15–30 days	8–25 days
Exo-erythrocytic cycle	Persistent as hypnozoites	Pre-erythrocytic only	Pre-erythrocytic only
Asexual cycle	48 hrs synchronous	72 hrs synchronous	< 48 hrs asynchronous
Fever periodicity	Alternate days	Every third day	None
Delayed onset	Common	Rare	Rare
Relapses	Common up to 2 years	Recrudescence many years later	Recrudescence up to 1 year

P. vivax and *P. ovale* may persist in liver cells as dormant forms, hypnozoites, capable of developing into merozoites months or years later. Thus the first attack of clinical malaria may occur long after the patient has left the endemic area, and the disease may relapse after treatment with drugs that only kill the erythrocytic stage of the parasite.

P. falciparum, *P. knowlesi* and *P. malariae* have no persistent exo-erythrocytic phase but recrudescence of fever may result from multiplication of parasites in red cells that have not been eliminated by treatment and immune processes (Box 14.73).

Pathology

Red cells infected with malaria undergo haemolysis. This is most severe with *P. falciparum*, which invades red cells of all ages; *P. vivax* and *P. ovale* preferentially invade younger cells, and *P. malariae* normoblasts, so that infections remain lower. Anaemia may be profound and is worsened by dyserythropoiesis, splenomegaly and depletion of folate stores.

In *P. falciparum* malaria, red cells containing trophozoites adhere to vascular endothelium in post-capillary venules in brain, kidney, liver, lungs and gut by the formation of 'knob' proteins. They also form 'rosettes' and rouleaux with uninfected red cells. Vessel congestion results in organ damage, which is exacerbated by rupture of schizonts, liberating toxic and antigenic substances (see Fig. 14.49).

P. falciparum has influenced human evolution, with the appearance of protective human mutations such as sickle-cell (Hb), thalassaemia, glucose-6-phosphate dehydrogenase (G6PD) deficiency (see Ch. 24) and HLA-B53. *P. falciparum* does not grow well in red cells that contain haemoglobin F, C or especially S. Haemoglobin S heterozygotes (AS) are protected against the lethal complications of malaria. *P. vivax* cannot enter red cells that lack the Duffy blood group; therefore many West Africans and African Americans are protected.

Clinical features

The clinical features of malaria are non-specific and the diagnosis must be suspected in anyone returning from an endemic area who has features of fever.

P. falciparum infection

This is the most dangerous of the malarias. The onset is often insidious, with malaise, headache and vomiting. Cough and mild diarrhoea are also common. The fever has no particular pattern and the classic periodicity is rarely observed. Jaundice is common due to haemolysis and hepatic dysfunction. The liver and spleen enlarge and may become tender. Anaemia develops rapidly, as does thrombocytopenia.

A patient with *falciparum* malaria, apparently not seriously ill, may rapidly develop dangerous complications (Fig. 14.50 and Box 14.74). Cerebral malaria is manifested by delirium, seizures or coma, usually without localising signs. Children die rapidly without any specific symptoms other than fever. Immunity is impaired in pregnancy and the parasite can preferentially bind to the placental protein chondroitin sulphate A. Abortion and intrauterine growth retardation from parasitisation of the maternal side of the placenta are frequent. Previous splenectomy increases the risk of severe malaria. Recurrent infection is rarely associated with later development of endemic Burkitt lymphoma and hyper-reactive (tropical) splenomegaly.

P. vivax and *P. ovale* infection

Illness usually starts with several days of continued fever before the development of classical bouts of fever on alternate days. Fever starts with a rigor. The patient feels cold and the temperature rises to about 40°C. After half an hour to an hour, the hot or flush phase begins. It lasts several hours and gives way to profuse perspiration and a gradual fall in temperature. The cycle is repeated 48 hours later. Gradually, the spleen and liver enlarge and may become tender. Anaemia develops slowly. Relapses are frequent in the first 2 years after leaving the malarious area and infection may be acquired from blood transfusion.

P. malariae and *P. knowlesi* infection

This is usually associated with mild symptoms and bouts of fever every third day. Parasitaemia may persist for many years, with the occasional recrudescence of fever or without producing any symptoms. Chronic *P. malariae* infection causes glomerulonephritis and long-term nephrotic syndrome in children in endemic areas. *P. knowlesi* is usually mild but can deteriorate rapidly.

Investigations

WHO recommends prompt malaria diagnosis, either by microscopy or malaria rapid diagnostic test (RDT), whenever malaria is suspected. In a Giemsa-stained thick film, erythrocytes are lysed, releasing all blood stages of the parasite. This, as well as the fact that more blood is used in thick films, facilitates the diagnosis of low-level parasitaemia. A thin film is essential to confirm the diagnosis, species and, in *P. falciparum* infections, to quantify the parasite load (by counting the percentage of infected erythrocytes). *P. falciparum* parasites may be very scanty, especially in patients who have been partially treated. With *P. falciparum*, only ring forms are normally seen in the early stages (see Fig. 14.50); with the other species, all stages of the erythrocytic cycle may be found. Gametocytes appear after about 2 weeks, persist after treatment and are harmless, except that they are the source by which more mosquitoes become infected.

Immunochromatographic RDTs for malaria antigens, such as OptiMAL (which detects the *Plasmodium* LDH of *P. falciparum* and *vivax*) and Parasight-F (which detects the *P. falciparum* histidine-rich protein (HRP) 2), are extremely sensitive and specific for *falciparum* malaria but less so for other species. They are especially useful where the microscopist is less experienced in examining blood films (e.g. in non-endemic or remote areas). They are less sensitive for low-level parasitaemia and positivity may persist for a month or more in some individuals. Occasionally high parasitaemia may result in a false-negative result. Dual *pfhrp2/3* gene deletion leads to false-negative HRP2-based tests and is increasingly reported in East Africa. This may be the most frequent cause of negative results in the United Kingdom. The QBC Malaria Test is a fluorescence microscopy-based malaria diagnostic test that is also used.

Nucleic acid detection (PCR) is used mainly in research and is useful for determining whether a patient has a recrudescence of the same malaria parasite or a reinfection with a new parasite.

Management

Mild *P. falciparum* malaria

Since *P. falciparum* is widely resistant to chloroquine and sulfadoxine–pyrimethamine (Fansidar) almost worldwide, an artemisinin-based treatment is recommended (Box 14.75). WHO policy recommends always using ACT, e.g. co-artemether or artesunate–amodiaquine. Partial artemisinin resistance results in delay in clearance of malaria parasites. As long as the partner drug is fully efficacious in the region, strains with partial resistance are still cleared with treatment. A range of PfKelch13 mutations

serve as markers of partial artemisinin resistance. Partial artemisinin resistance has now been reported in the Greater Mekong sub-region of South-east Asia, mandating strict adherence to local guidance on the selection of ACT, e.g. dihydroartemisinin–piperaquine or pyronaridine–artesunate in Thailand. Partial artemisinin resistance has spread to Africa with reports from Eritrea, Rwanda, Uganda and Tanzania and has been observed in South America.

Complicated *P. falciparum* malaria

Severe malaria should be considered in any non-immune patient with a parasite count greater than 2% or with complications, and is a medical emergency (see Box 14.74). Management includes early and appropriate antimalarial chemotherapy, active treatment of complications, correction of fluid, electrolyte and acid–base balance, and avoidance of harmful ancillary treatments.

The treatment of choice is intravenous artesunate. Late haemolysis (after 1 month) is a treatment side-effect in some patients. Rectal administration of artesunate is also available to allow administration in remote rural areas. Quinine salt is the alternative.

Exchange transfusion has not been tested in randomised controlled trials but may be beneficial for non-immune patients with persisting high parasitaemias (> 10% circulating erythrocytes).

Non-*falciparum* malaria

P. vivax, *P. ovale*, *P. knowlesi* and *P. malariae* infections can be treated with oral chloroquine but chloroquine resistance has been reported from Indonesia and all are sensitive to ACT so it is often preferred. 'Radical cure' is essential in patients with *P. vivax* or *P. ovale* malaria using a course of primaquine or tafenoquine, which destroys the hypnozoite phase in the liver. Severe haemolysis may develop in those who are G6PD-deficient. Cyanosis due to the formation of methaemoglobin in the red cells is more common but not dangerous (see Fig. 11.1).

Prevention

Clinical attacks of malaria may be preventable with chemoprophylaxis using chloroquine plus proguanil, atovaquone plus proguanil (Malarone), doxycycline or mefloquine. Chloroquine alone is rarely recommended nowadays due to resistance and the lack of availability of proguanil. Box 14.76 gives the recommended doses for protection of the non-immune. The risk of malaria in the area to be visited and the degree of chloroquine resistance guide the recommendations for prophylaxis. Updated recommendations are summarised at nhsinform.scot/healthy-living/travel-health/travel-health-and-vaccinations and NaTHNaC. Mefloquine is useful in areas of multiple drug resistance, such as East and Central Africa and Papua New Guinea. Experience shows it to be safe for at least 2 years, but there are several contraindications to its use (see Box 14.76).

Expert advice is required for individuals unable to tolerate the first-line agents listed or in whom they are contraindicated. Mefloquine should be started 2–3 weeks before travel to give time for assessment of side-effects. Chloroquine should not be taken continuously as a prophylactic for more than 5 years without regular ophthalmic examination, as it may cause irreversible retinopathy. Pregnant and lactating women may take proguanil or chloroquine safely. Artemisinins cannot be used as prophylaxis.

14.74 Severe manifestations/complications of *falciparum* malaria and their immediate management

Coma (cerebral malaria)

- Maintain airway
- Nurse on side
- Exclude other treatable causes of coma (e.g. hypoglycaemia, bacterial meningitis)
- Avoid harmful ancillary treatments such as glucocorticoids, phenobarbitone, heparin and adrenaline (epinephrine)
- Intubate if necessary

Hyperpyrexia

- Tepid sponging, fanning, cooling blanket
- Antipyretic drug (paracetamol)

Convulsions

- Maintain airway
- Treat promptly with diazepam or paraldehyde injection

Hypoglycaemia

- Measure blood glucose
- Give 50% dextrose injection followed by 10% dextrose infusion (glucagon may be ineffective)

Severe anaemia (packed cell volume <15%)

- Transfuse fresh whole blood or packed cells if pathogen screening of donor blood is available

Acute pulmonary oedema

- Nurse at 45°, give oxygen, venesect 250 mL of blood, give diuretic, stop intravenous fluids
- Intubate and add PEEP/CPAP in life-threatening hypoxaemia
- Haemofilter

Acute kidney injury

- Exclude pre-renal causes
- Fluid resuscitation if appropriate
- Peritoneal dialysis (haemofiltration or haemodialysis if available)

Spontaneous bleeding and coagulopathy

- Transfuse screened fresh whole blood (cryoprecipitate/fresh frozen plasma and platelets if available)
- Vitamin K injection

Metabolic acidosis

- Exclude or treat hypoglycaemia, hypovolaemia and gram-negative sepsis
- Fluid resuscitation
- Give oxygen

Shock ('algid malaria')

- Suspect gram-negative sepsis
- Take blood cultures
- Give parenteral antimicrobials
- Correct haemodynamic disturbances

Aspiration pneumonia

- Give parenteral antimicrobial drugs
- Change position
- Physiotherapy
- Give oxygen

Hyperparasitaemia

- Consider exchange transfusion (e.g. > 10% of circulating erythrocytes parasitised in non-immune patient with severe disease)

Specific therapy

- Intravenous artesunate
- Mefloquine should be avoided due to increased risk of post-malaria neurological syndrome

From WHO. Severe *falciparum* malaria. In: Severe and complicated malaria, 3rd ed. *Trans R Soc Trop Med Hyg* 2000;94 (suppl. 1):S1–41.
(CPAP = continuous positive airway pressure; PEEP = positive end-expiratory pressure)

14.75 Malaria treatment

Mild *falciparum* malaria

Preferred therapy

- Co-artemether (CoArtem or Riamet); contains artemether and lumefantrine (4 tablets orally at 0, 8, 24, 36, 48 and 60 hrs)

Alternative therapy

- Quinine (600 mg of quinine salt 3 times daily orally for 5–7 days), together with or followed by doxycycline (200 mg once daily orally for 7 days)
- Use clindamycin not doxycycline if the patient is a pregnant woman or young child

or

- Atovaquone–proguanil (Malarone, 4 tablets orally once daily for 3 days)

Pregnancy

- Co-artemether but avoid in early pregnancy
- If not using co-artemether, use quinine plus clindamycin (450 mg 3 times daily orally for 7 days)

Other regimens

- Artesunate (200 mg orally daily for 3 days) and mefloquine (1 g orally on day 2 and 500 mg orally on day 3)

Severe *falciparum* malaria

Preferred therapy

- Artesunate 2.4 mg/kg IV at 0, 12 and 24 hrs and then once daily for 7 days. Once the patient is able to recommence oral intake, switch to 2 mg/kg orally once daily, to complete a total cumulative dose of 17–18 mg/kg

Alternative therapy

- Quinine, loading dose 20 mg/kg IV over 4 hrs, up to a maximum of 1.4 g, then maintenance doses of 10 mg/kg quinine salt given as 4-hr infusions 3 times daily for the first 48 hrs then twice a day, up to a maximum of 700 mg per dose or until the patient can take drugs orally. Combine with doxycycline (or clindamycin if there are contraindications to doxycycline)
- Note the loading dose should not be given if quinine, quinidine or mefloquine has been administered in the previous 24 hrs
- Patients should be monitored by ECG while receiving quinine, with special attention to QRS duration and QT interval

Non-*falciparum* malaria

Preferred therapy (if sensitive)

- Chloroquine: 600 mg chloroquine base orally, followed by 300 mg base in 6 hrs, then 150 mg base twice daily for 2 more days plus primaquine (30 mg orally daily (for *P. vivax*) or 15 mg orally daily (for *P. ovale*) for 14 days) after confirming G6PD-negative

Alternative therapy

- Co-artemether (CoArtem or Riamet); contains artemether and lumefantrine (4 tablets orally at 0, 8, 24, 36, 48 and 60 hrs) plus primaquine (30 mg orally daily (for *P. vivax*) or 15 mg orally daily (for *P. ovale*) for 14 days) after confirming G6PD-negative

Patients with mild to moderate G6PD deficiency and *P. vivax* or *P. ovale*

- Chloroquine plus primaquine 0.75 mg/kg weekly orally for 8 weeks

Chloroquine-resistant *P. vivax*

- Co-artemether as for *P. falciparum*

(ECG = electrocardiogram; G6PD = glucose-6-phosphate dehydrogenase; IV = intravenous)

i 14.76 Chemoprophylaxis of malaria[1]

Antimalarial tablets	Adult prophylactic dose	Regimen
Chloroquine resistance high		
Mefloquine[2]	250 mg weekly	Started 2–3 weeks before travel and continued until 4 weeks after
or Doxycycline[3,4]	100 mg daily	Started 1 week before and continued until 4 weeks after travel
or Atovaquone plus proguanil (Malarone)[4]	1 tablet daily	From 1–2 days before travel until 1 week after return
Chloroquine resistance absent		
Chloroquine[5] *and* proguanil	300 mg base weekly 100–200 mg daily	Started 1 week before and continued until 4 weeks after travel (no longer available in UK)

[1] Choice of regimen is determined by area to be visited, length of stay, level of malaria transmission, level of drug resistance, presence of underlying disease in the traveller and concomitant medication taken.
[2] Contraindicated in the first trimester of pregnancy, lactation, cardiac conduction disorders, epilepsy, psychiatric disorders; may cause neuropsychiatric disorders.
[3] Causes photosensitisation and sunburn if high-protection sunblock is not used.
[4] Avoid in pregnancy.
[5] British preparations of chloroquine usually contain 150 mg base, French preparations 100 mg base and American preparations 300 mg base.

Prevention also involves advice about the use of high-percentage diethyltoluamide (DEET), covering up extremities when out after dark, and sleeping under permethrin-impregnated mosquito nets.

Malaria control in endemic areas

There are major initiatives to reduce and eliminate malaria in endemic areas, particularly 11 countries with the greatest burden (e.g. the ‘High Burden High Impact’ approach). Successful programmes combine vector control, including indoor residual spraying, use of long-lasting insecticide-treated bed nets (ITNs) and intermittent preventative therapy (IPT; repeated dose of prophylactic drugs in high-risk groups, such as children and pregnant women, which reduces malaria and anaemia).

The WHO recommends programmatic use of one of two malaria vaccines: RTS,S and R21. Both are protein sub-unit adjuvanted vaccines expressing peptides derived from the *P. falciparum* circumsporozoite protein (CSP). Both have shown efficacy in African children. These vaccines are recommended by the WHO for use primarily in moderate- to high-transmission settings with four doses recommended by the WHO in the first year of life and a fifth a year after the fourth where a significant malaria risk remains.

Babesiosis

Babesiosis is a tick-borne intra-erythrocytic protozoon parasite. There are more than 100 species of *Babesia*, all of which have an animal reservoir, typically either rodents or cattle. These are transmitted to humans via the tick vector *Ixodes scapularis*. Most American cases of babesiosis are due to *B. microti* and most European cases to *B. divergens*. Patients present with fever and malaise 1–4 weeks after a tick bite. Illness may be complicated by haemolytic anaemia. Severe illness is seen in splenectomised patients. The diagnosis is made by blood-film examination. Treatment is with azithromycin and atovaquone or quinine and clindamycin.

African trypanosomiasis (sleeping sickness)

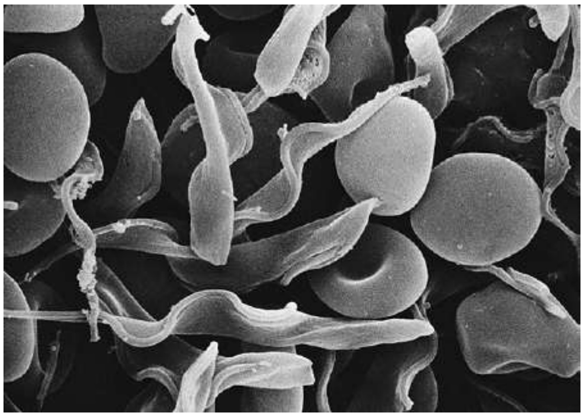

Fig. 14.51 Trypanosomiasis. Scanning electron micrograph showing trypanosomes swimming among erythrocytes.

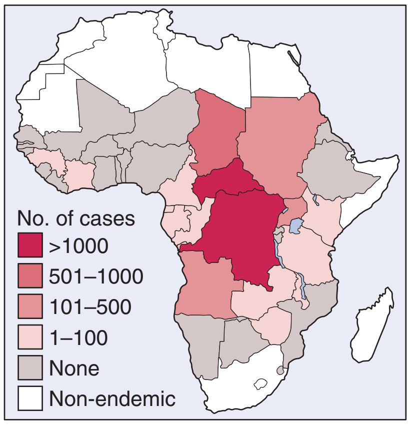

Fig. 14.52 Distribution of human African trypanosomiasis. Data are from 2009. Map lines delineate study areas and do not necessarily depict accepted national boundaries. *From Simarro PP, Diarra A, Ruiz Postigo JA, et al. The human African trypanosomiasis control and surveillance programme of the World Health Organization 2000–2009: the way forward. PLoS Negl Trop Dis 2011;5(2):e1007.*

African sleeping sickness is caused by trypanosomes (Fig. 14.51) carried by tsetse flies and is unique to sub-Saharan Africa (Fig. 14.52). The incidence of sleeping sickness across Africa has declined 95% since 1999 to < 1000 cases per year. It is now on the verge of eradication. *Trypanosoma brucei gambiense* trypanosomiasis is found in West and Central Africa, and accounted for more than 97% of reported cases of sleeping sickness in 2023. *T. b. rhodesiense* is endemic in 13 countries of eastern and southern Africa, representing about 3% of reported cases in 2023. There has been a steep decline in the incidence of the chronic form of human African trypanosomiasis (*T. b. gambiense*) by 98% between 1999 and 2023. During the same period, the number of newly reported cases of the acute form of human African trypanosomiasis (*T. b. rhodesiense*) fell by 96% to 24. In West Africa, transmission is mainly at the riverside, where the fly rests in the shade of trees; no animal reservoir has been identified for *T. gambiense*. *T. rhodesiense* has a large reservoir in numerous wild animals and transmission takes place in the shade of woods bordering grasslands. Rural populations employed in agriculture, fishing and animal husbandry are susceptible. Local people and tourists visiting forests infested with tsetse flies and animal reservoirs may become infected.

Clinical features

A bite by a tsetse fly is painful and commonly becomes inflamed; if trypanosomes are introduced, the site may again become painful and swollen about 10 days later (‘trypanosomal chancre’), associated with regional lymphadenopathy. Within 2–3 weeks of infection, the trypanosomes invade the blood stream. The disease is characterised by an early haematolymphatic (stage 1) and a late chronic encephalopathy phase (stage 2).

Rhodesiense infections

This disease is more acute and severe than in *gambiense* infections. Within days or a few weeks, the patient is usually severely ill and may have developed pleural effusions and signs of myocarditis or hepatitis. There may be a petechial rash. The patient may die before there are signs of involvement of the CNS. If the illness is less acute, drowsiness, tremors and coma develop.

Gambiense infections

The distinction between early and late stages may not be apparent in *gambiense* infections. The disease usually runs a slow course over months or years, with irregular bouts of fever and enlargement of lymph nodes. These are characteristically firm, discrete, rubbery and painless, and are particularly prominent in the posterior triangle of the neck. Hepatosplenomegaly may develop. After some months without treatment, the CNS is invaded. Patients develop headache, altered behaviour, blunting of higher mental functions, insomnia by night and sleepiness by day, delirium and eventually tremors, pareses, wasting, coma and death.

Investigations

Trypanosomiasis should be considered in any febrile patient from an endemic area. In *rhodesiense* infections, thick and thin malaria blood films will reveal trypanosomes. The trypanosomes may be seen in the blood or from puncture of the primary lesion in the earliest stages of *gambiense* infections, but it is usually easier to demonstrate them by aspiration of a lymph node. Concentration methods include buffy coat microscopy and miniature anion exchange chromatography.

Due to the cyclical nature of parasitaemia, the diagnosis is often made by demonstration of antibodies using a simple, rapid screening card agglutination trypanosomiasis test (CATT) for *gambiense* human African trypanosomiasis (HAT), followed by parasitological confirmation.

No reliable serological test is available for *rhodesiense* HAT. PCR diagnosis is available, although technical requirements limit its availability. If the CNS is affected, the cell count and protein content of the CSF are increased and the glucose is diminished. A very high level of serum IgM or the presence of IgM in the CSF is suggestive of trypanosomiasis. Recognition of CNS involvement is critical, as failure to treat it might be fatal.

Management

The prognosis is good if treatment is begun early, before the brain has been invaded. For the treatment of HAT (*T. b. gambiense*), fexinidazole, an oral nitroimidazole derivative, acts on the parasite nitroreductase. It is the preferred treatment for *gambiense* infections that are stage 1 or stage 2 with a CSF white cell count $<0.1 \times 10^9$/L. The adult dose is 1800 mg days 1–4, and 1200 mg days 5–10, taken with food. For adults weighing <35 kg, the loading dose is 1200 mg (days 1–4) followed by 600 mg (days 5–10). It is not used for children <6 years of age or individuals weighing <20 kg. Fexinidazole can be used in pregnant women after the first trimester. For *gambiense* infections, deep intramuscular or intravenous pentamidine 4 mg/kg for 7 days is now used mainly in children <6 years of age with stage 1 disease and in those weighing <20 kg. For rhodesiense infections, fexinidazole is also used, but in those <6 years of age or <20 kg in body weight, an LP is used to guide treatment. Suramin is then used if LP findings do not demonstrate CSF white cells, but in the presence of CSF white cells, stage 2 treatment is indicated as below.

For the treatment of stage 2 (nervous system) infection caused by *gambiense* HAT with CSF white cell count $\geq 0.1 \times 10^9$/L or in whom a CSF exam is indicated but not performed, nifurtimox (15 mg/kg daily orally in three divided doses for 10 days) and eflornithine (DFMO, an irreversible inhibitor of ornithine decarboxylase; 400 mg/kg in two 2-hour IV infusions for 7 days) combination therapy (NECT) is recommended. Children <6 years of age or individuals weighing <20 kg with stage 2 disease and white cell count $<0.1 \times 10^9$/L should also be treated with NECT. DFMO at 100 mg/kg IV 4 times daily for 14 days was formerly given without nifurtimox. This regimen had more side-effects and more injections. Stage 2 *rhodesiense* infection was formerly treated with melarsoprol, an arsenical (2.2 mg/kg IV for 10 days). Treatment-related mortality with melarsoprol is 4%–12% due to reactive encephalopathy. However, updated WHO guidelines in 2025 now recommend fexinidazole as first-line therapy for stage 2 *rhodesiense* infection on the basis of better tolerability with melarsopol retained as second choice or in cases where fexinidazole is not recommended (e.g. <6 years of age or <20 kg body weight).

Prevention

In endemic areas, various measures are taken against tsetse flies, and field teams help detect and treat early HAT.

American trypanosomiasis (Chagas disease)

Chagas disease occurs widely in South and Central America. The cause is *Trypanosoma cruzi*, transmitted to humans from the faeces of a reduviid (triatomine) bug, in which the trypanosomes develop. These bugs live in wild forests in crevices, burrows and palm trees. The *Triatoma infestans* bug has become domesticated in the Southern Cone countries (Argentina, Brazil, Chile, Paraguay and Uruguay). It lives in the mud and wattle walls and thatched roofs of simple rural houses and emerges at night to feed and defaecate on the sleeping occupants. Infected faeces are rubbed in through the conjunctiva, mucosa of mouth or nose, or abrasions of the skin. Over 100 species of mammal – domestic, peridomestic and wild – may serve as reservoirs of infection. In some areas, blood transfusion accounts for about 5% of cases. Congenital transmission occasionally occurs.

Pathology

The trypanosomes migrate via the blood stream, develop into amastigote forms in the tissues and multiply intracellularly by binary fission. In the acute phase, inflammation (primarily cell-mediated) associated with parasitised and non-parasitised cardiac muscles and capillaries occurs, resulting in acute myocarditis. In the chronic phase, focal myocardial atrophy, signs of chronic passive congestion and thromboembolic phenomena, cardiomegaly and apical cardiac aneurysm are salient findings. In the digestive form of disease, focal myositis and discontinuous lesions of the intramural myenteric plexus are seen, predominantly in the oesophagus and colon.

Clinical features

Acute phase

Clinical manifestations of the acute phase are seen in only 1%–2% of individuals infected before the age of 15 years. Young children (1–5 years) are most commonly affected. The entrance of *T. cruzi* through an abrasion produces a dusky-red, firm swelling and enlargement of regional lymph nodes. A conjunctival lesion, although less common, is characteristic; the unilateral firm, reddish swelling of the lids may close the eye and constitutes 'Romaña sign'. In a few patients, an acute generalised infection soon appears, with a transient morbilliform or urticarial rash, fever, lymphadenopathy and enlargement of the spleen and liver. In a small minority of patients, acute myocarditis and heart failure or neurological features, including personality changes and signs of meningoencephalitis, may be seen. The acute infection may be fatal to infants.

Chronic phase

About 50%–70% of infected patients become seropositive and develop an indeterminate form when parasitaemia occurs only at low levels and is not usually detectable. They have a normal lifespan with no symptoms but are a natural reservoir for the disease and maintain the life cycle of parasites in tissues. After a latent period of several years, 10%–30% of chronic cases develop low-grade myocarditis and damage to conducting fibres, which causes cardiomyopathy characterised by cardiac dilatation, arrhythmias, partial or complete heart block and sudden death. In nearly 10% of patients, damage to the Auerbach plexus results in dilatation of various parts of the alimentary canal, especially the colon and oesophagus, so-called 'mega' disease. Dilatation of the bile ducts and bronchi are also recognised sequelae. Autoimmune processes may be responsible for much of the damage. There are geographical variations of the basic pattern of disease. Reactivation of Chagas disease can occur in patients with HIV if the CD4 count falls lower than 200 cells/mm^3; this can cause space-occupying lesions with a presentation similar to *Toxoplasma gondii* encephalitis in HIV, a more diffuse encephalitis, meningoencephalitis or myocarditis (p. 330).

Investigations

T. cruzi is easily detectable by direct microscopic examination in a blood film in the acute illness. In chronic disease, antibody detection is highly sensitive, and a positive result with two different serological tests confirms the infection. Loop mediated isothermal amplification (LAMP) assay based on satDNA sequence and rapid diagnostic point-of-care tests (RDTs) with rapid turnaround and without the requirement of expensive equipment are feasible and promising in low-resource settings.

Management and prevention

Parasiticidal agents are used to treat the acute phase, congenital disease and early chronic phase (within 10 years of infection). Benznidazole is given at a dose of 5–8 mg/kg daily orally, in two divided doses for 60 days. Nifurtimox is an alternative treatment dosed at 8–20 mg/kg orally in three divided doses for 60 days. All doses of either treatment are weight adjusted. Treatment with either agent has to be carefully supervised to minimise toxicity while preserving parasiticidal activity. Cure rates of 80% in acute disease are obtained. Both benznidazole and nifurtimox are toxic, with adverse reaction rates of 30%–55%. Parasiticidal treatment of the chronic phase is usually performed but, in the cardiac or digestive ‘mega’ diseases, does not reverse tissue damage. Surgery may be needed.

Preventative measures include improvement of housing and destruction of reduviid bugs by spraying of houses with insecticides. Blood and organ donors should be screened.

Toxoplasmosis

Toxoplasma gondii is an intracellular parasite. The sexual phase of the parasite’s life cycle (Fig. 14.53) occurs in the small intestinal epithelium of the domestic cat. Oöcysts in cat faeces are spread to intermediate hosts (pigs, sheep and also humans) via soil contamination. Oöcysts may survive in moist conditions for weeks or months. After ingestion, the parasite transforms into rapidly dividing tachyzoites through cycles of asexual multiplication. Microscopic tissue cysts develop containing bradyzoites, which persist for the lifetime of the host. Cats become infected or reinfected by ingesting tissue cysts in prey such as rodents and birds.

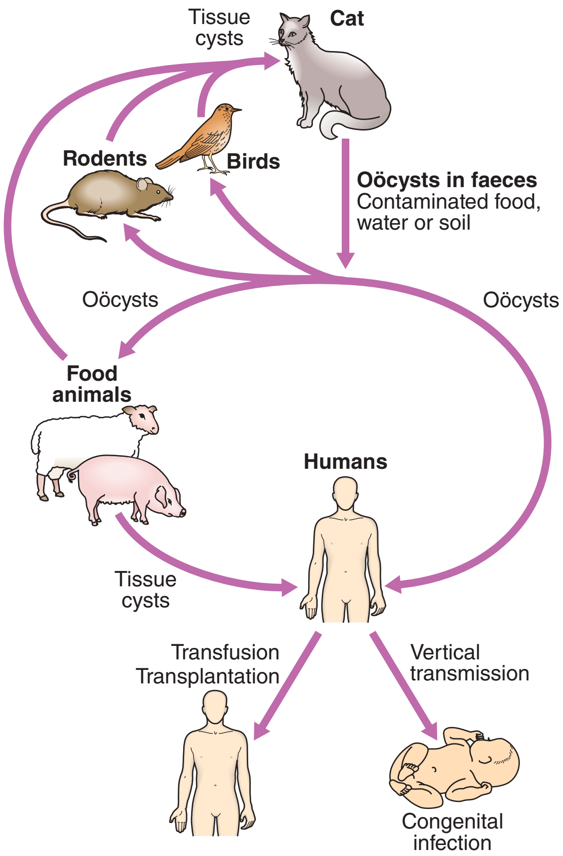

Fig. 14.53 Life cycle of *Toxoplasma gondii*.

Human infection occurs via oöcyst-contaminated soil, salads and vegetables, or by ingestion of raw or under-cooked meats containing tissue cysts. Infection by blood transfusion or organ transplantation may also occur. Sheep, pigs and rabbits are the most common meat sources. Outbreaks of toxoplasmosis have followed consumption of unfiltered water. In high-income countries, toxoplasmosis is the most common protozoal infection; around 22% of adults in the UK are seropositive. Most primary infections are subclinical; however, toxoplasmosis is thought to account for about 15% of heterophile antibody-negative infectious mononucleosis. In India or Brazil, approximately 40%–60% of pregnant females are seropositive for *T. gondii*. Toxoplasmosis is an important opportunistic infection in people with HIV, with considerable morbidity and mortality (p. 330). Generalised toxoplasmosis has followed occupational exposure of laboratory workers.

Clinical features

In most immunocompetent individuals, including children and pregnant women, the infection goes unnoticed. In approximately 10% of patients, it causes a self-limiting illness, most often in adults aged 25–35 years. The presenting feature is usually localised or generalised painless lymphadenopathy. The cervical nodes are primarily involved but mediastinal, mesenteric or retroperitoneal groups may be affected. The spleen is seldom palpable. Most patients have no systemic symptoms but some complain of malaise, fever, fatigue, muscle pain, sore throat and headache. Complete resolution usually occurs within a few months, although symptoms and lymphadenopathy tend to fluctuate unpredictably and some patients do not recover completely for a year or more. Encephalitis, myocarditis, polymyositis, pneumonitis or hepatitis occasionally occur in immunocompetent patients but are more frequent in immunocompromised hosts. *Toxoplasma* encephalitis is a cause of space occupying lesions in PWH. Retinochoroiditis (Fig. 14.54) is usually the result of congenital infection but has also been reported in acquired disease.

Congenital toxoplasmosis

Acute toxoplasmosis, mostly subclinical, affects 0.3%–1% of pregnant women, with approximately 60% transmission rate to the fetus, which rises with increasing gestation. Seropositive females infected 6 months before conception have no risk of fetal transmission. Congenital disease affects approximately 40% of infected fetuses, and is more likely and more severe with infection early in gestation (see Box 14.24). Many fetal

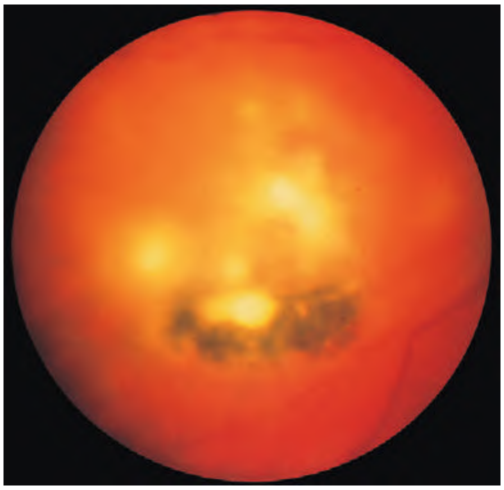

Fig. 14.54 Retinochoroiditis due to toxoplasmosis.

infections are subclinical at birth, but long-term sequelae include retinochoroiditis, microcephaly and hydrocephalus.

Investigations

In contrast to immunocompromised patients, in whom the diagnosis often requires direct detection of parasites, serology is often used in immunocompetent individuals. The Sabin–Feldman dye test (indirect fluorescent antibody test), which detects IgG antibody, is most commonly used. Recent infection induces a fourfold or greater increase in titre when paired sera are tested. Peak titres $\geq 1/1000$ are reached 1–2 months after infection, and serology then becomes an unreliable indicator of recent infection. The detection of significant levels of *Toxoplasma*-specific IgM antibody may be useful in confirming acute infection. A false-positive result or persistence of IgM antibodies for years after infection makes interpretation difficult; however, negative IgM antibodies virtually rule out acute infection.

During pregnancy, it is critical to differentiate recent from past infection; the presence of high-avidity IgG antibodies excludes infection acquired in the preceding 3–4 months.

If necessary, the presence of *Toxoplasma* organisms in a lymph node biopsy or other tissue can be detected histochemically with *T. gondii* antiserum, or by the use of PCR to detect *Toxoplasma*-specific DNA. In PWH and suspected *Toxoplasma* encephalitis, *Toxoplasma* serology shows evidence of previous exposure (positive IgG antibodies); a negative serological test effectively rules out toxoplasmosis but a positive test is not specific. Cerebrospinal fluid *Toxoplasma* PCR is highly specific but has a sensitivity of as low as 50%, though modifications in methodology have been reported to increase sensitivity. Definitive diagnosis is by brain biopsy, but this is seldom necessary.

Management

In immunocompetent subjects, uncomplicated toxoplasmosis is self-limiting and responds poorly to antimicrobial therapy. In pregnant women with established recent infection, spiramycin (3 g daily in divided doses) is given until term. Once fetal infection is established, treatment with sulfadiazine and pyrimethamine plus calcium folinate is recommended (spiramycin does not cross the placental barrier). The cost/benefit of routine *Toxoplasma* screening and treatment in pregnancy is being debated in many countries. There is insufficient evidence to determine the effects on mother or baby of current antiparasitic treatment for women who seroconvert in pregnancy.

Treatment with sulfadiazine, pyrimethamine and folinic acid is usually reserved for severe or progressive disease, and for infection in immunocompromised patients. Often empirical treatment is initiated in people living with HIV if space-occupying lesions are found in the CNS (p. 330). The standard therapy for *Toxoplasma* encephalitis is sulfadiazine with pyrimethamine, together with folinic acid, to reduce the risk of bone marrow suppression with pyrimethamine. Clindamycin can be used instead of sulfadiazine. However, co-trimoxazole has been shown to be effective and less toxic than sulfadiazine containing regimens and is also much more widely available. Following initiation of treatment, clinical improvement is observed in 1–2 weeks and shrinkage of lesions on imaging in 2–4 weeks.

Leishmaniasis

Leishmaniasis is caused by unicellular, flagellate, intracellular protozoa belonging to the genus *Leishmania* (order Kinetoplastidae). The 21 leishmanial species that cause human disease are responsible for three clinical syndromes:

- visceral leishmaniasis (VL, kala-azar)
- cutaneous leishmaniasis (CL)
- mucosal leishmaniasis (ML).

Epidemiology and transmission

Although most clinical syndromes are caused by zoonotic transmission of parasites from animals (chiefly canine and rodent reservoirs) to humans through phlebotomine sandfly vectors (Fig. 14.55A), humans are the only known reservoir (anthroponotic person-to-person transmission) in major VL foci in South Asia and in injection drug-users (Fig. 14.55B,C). More than 1 billion people live in areas endemic for leishmaniasis and are at risk of infection. An estimated 30 000 new cases of VL and more than 1 million new cases of CL occur annually. CL is common in South America, Africa, and Asia, while VL commonly occurs in East Africa, Brazil and the Indian subcontinent. ML is limited to South America.

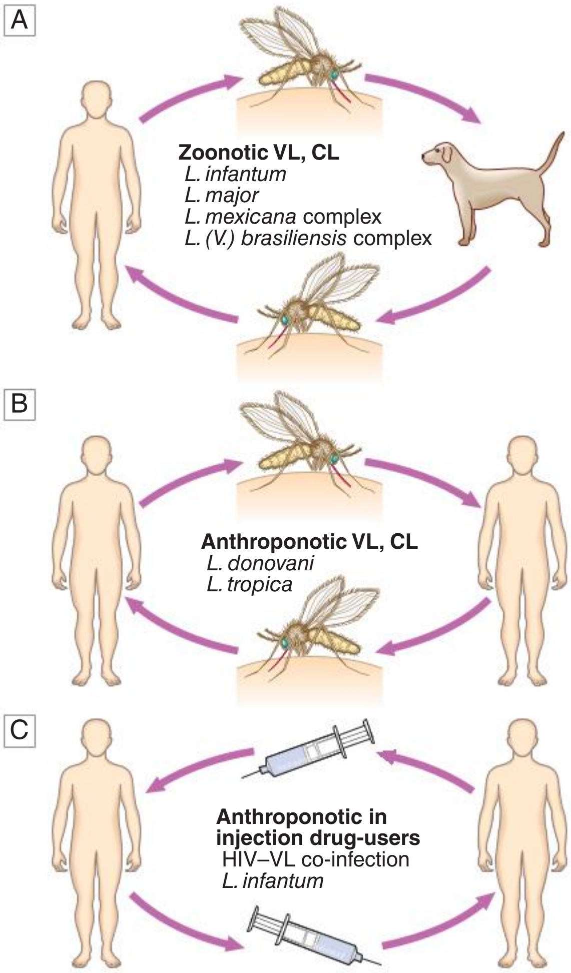

Fig. 14.55 Transmission of leishmaniasis. **A** Zoonotic transmission. **B** Anthroponotic transmission. **C** Anthroponotic transmission in the injection drug-user. (CL = cutaneous leishmaniasis; HIV = human immunodeficiency virus; VL = visceral leishmaniasis)

The life cycle of *Leishmania* is shown in Figure 14.56. Flagellar promastigotes (10–20 μm) are introduced by the feeding female sandfly. The promastigotes are taken up by neutrophils, which undergo apoptosis and are then engulfed by macrophages, in which the parasites transform into amastigotes (2–4 μm; Leishman–Donovan body). These multiply, causing macrophage lysis and infection of other cells. Sandflies pick up amastigotes when feeding on infected patients or animal reservoirs. In the sandfly, the parasite transforms into a flagellar promastigote, which multiplies by binary fission in the gut of the vector and migrates to the proboscis to infect a new host.

Sandflies live in hot and humid climates in the cracks and crevices of mud or straw houses and lay eggs in organic matter. People living in such conditions are more prone to leishmaniasis. Female sandflies bite during the night and preferentially feed on animals; humans are incidental hosts.

Visceral leishmaniasis (kala-azar)

VL is caused by the protozoon *Leishmania donovani* complex (comprising *L. donovani* and *L. infantum*). In the Indian subcontinent (India,

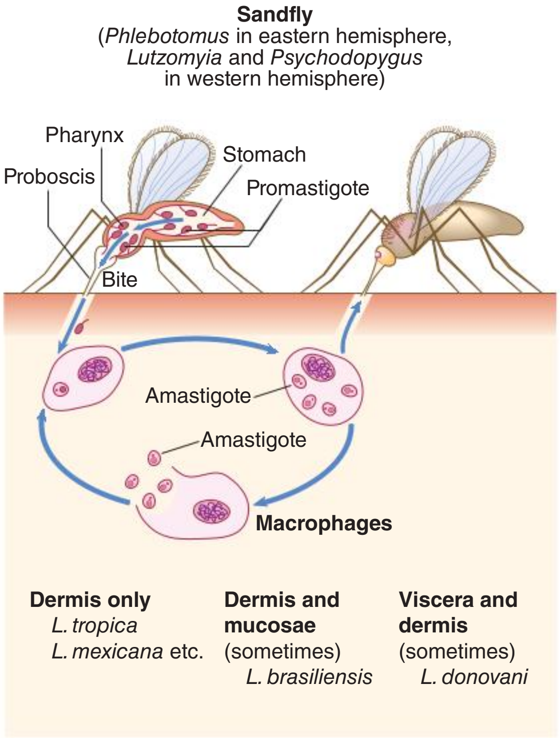

Fig. 14.56 **Life cycle of *Leishmania*.** *From Knight R. Parasitic disease in man. Edinburgh: Churchill Livingstone, Elsevier Ltd.; 1982.*

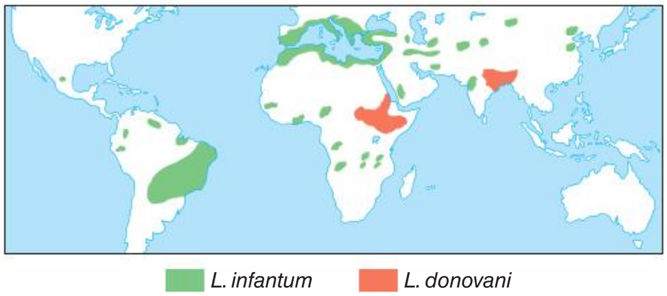

Fig. 14.57 **World distribution of visceral leishmaniasis.** Map lines delineate study areas and do not necessarily depict accepted national boundaries.

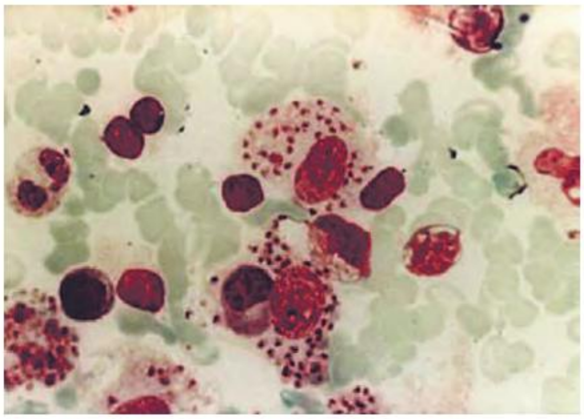

Fig. 14.58 **Splenic smear showing numerous intracellular, and a few extracellular, amastigotes.** *Courtesy of Dr S. Sundar and Dr H.W. Murray.*

Nepal and Bangladesh), where a VL elimination programme has been implemented, VL incidence has markedly declined. Now, East Africa (Ethiopia, Sudan and South Sudan) has the highest incidence of VL followed by Brazil and the Indian subcontinent, showing a downward trend from the previous estimates. Other affected regions include the Mediterranean, East Africa, China, Arabia, Israel and other South American countries (Fig. 14.57). In addition to sandfly transmission, VL can result from blood transfusion, and disease can present unexpectedly in immunosuppressed patients – for example, after renal transplantation and in HIV infection.

The majority of infections remain asymptomatic. In visceral disease, the spleen, liver, bone marrow and lymph nodes are primarily involved.

Clinical features

In South Asia, adults and children are equally affected; elsewhere, VL is mainly a disease of small children and infants, except in adults with HIV co-infection. The incubation period is 2–3 months but may be up to 1 year or more.

The first sign of infection is high fever, usually accompanied by rigor and chills. Fever intensity decreases over time and patients may become afebrile for weeks to months. This is followed by a relapse of fever, often of lesser intensity. Splenomegaly develops quickly in the first few weeks and becomes massive as the disease progresses. Moderate hepatomegaly occurs later. Lymphadenopathy is common in Africa, the Mediterranean and South America but is rare in South Asia. Blackish discoloration of the skin, from which the disease derived its name, kala-azar (the Hindi word for ‘black fever’), is a feature of advanced illness but is now rarely seen. Pancytopenia is common. Moderate to severe anaemia develops rapidly and can cause cardiac failure. Thrombocytopenia, often compounded by hepatic dysfunction, may result in bleeding from the retina, gastrointestinal tract and nose. In advanced illness, hypoalbuminaemia may manifest as pedal oedema, ascites and anasarca (gross generalised oedema and swelling).

As disease progresses, there is profound immunosuppression and secondary infections are very common. These include tuberculosis, pneumonia, gastroenteritis, severe amoebic or bacillary dysentery, boils, chickenpox, shingles and scabies. Without adequate treatment, most patients with clinical VL die.

Investigations

Pancytopenia is the dominant feature, with granulocytopenia. Polyclonal hypergammaglobulinaemia, chiefly IgG followed by IgM, and hypoalbuminaemia are seen later.

Demonstration of amastigotes (Leishman–Donovan bodies) in splenic smears is the most efficient means of diagnosis, with 98% sensitivity (Fig. 14.58); however, it carries a risk of serious haemorrhage in inexperienced hands. Safer methods, such as bone marrow or lymph node smears, are less sensitive but are frequently employed. Parasites may be demonstrated in buffy coat smears, especially in immunosuppressed patients. Sensitivity is improved in specialised laboratories by culturing the aspirate material or by using PCR for DNA detection and species identification. Using blood samples, LAMP of nucleic acids performs better compared with microscopy.

Serodiagnosis, by ELISA or immunofluorescence antibody test, is employed where resources allow. In endemic regions, rapid immunochromatographic k39 strip tests have become popular. These tests remain positive for several months to years after cure has been achieved, so do not predict response to treatment or relapse. The vast majority of people exposed to the parasite do not develop clinical illness but may have positive serological tests thereafter.

Differential diagnosis

This includes malaria, typhoid, tuberculosis, schistosomiasis and many other infectious and neoplastic conditions, some of which may coexist with VL. Fever, splenomegaly, pancytopenia and non-response to antimalarial therapy may provide clues before specific laboratory diagnosis is made.

Management

Pentavalent antimonials Pentavalent antimony (Sb^V) compounds were the first drugs to be used for the treatment of leishmaniasis and remain the mainstay of treatment in most parts of the world. The exception is South Asia, especially the Indian state of Bihar, where almost two-thirds of cases are refractory to Sb^V treatment. Traditionally, pentavalent antimony is available as sodium stibogluconate (100 mg/mL) in English-speaking countries and meglumine antimoniate (85 mg/mL) in French-speaking ones. The daily dose is 20 mg/kg body weight, intravenously or intramuscularly, for 28–30 days. Side-effects are common and include arthralgia, myalgia, raised hepatic transaminases, pancreatitis (especially in patients co-infected with HIV) and ECG changes (T-wave inversion and reduced amplitude). Severe cardiotoxicity, manifest by concave ST segment elevation, prolongation of QT_c greater than 500 msec and ventricular dysrhythmias, is not uncommon. The incidence of cardiotoxicity and death is particularly high with improperly manufactured Sb.

Amphotericin B Amphotericin B deoxycholate, given once daily or on alternate days at a dose of 0.75–1.00 mg/kg for 15–20 doses, is used as the first-line drug in many regions like the Bihar state of India, where there is a significant level of Sb^V unresponsiveness. It has a cure rate of nearly 100%. Infusion-related side-effects, such as high fever with rigor, thrombophlebitis, diarrhoea and vomiting, are extremely common. Serious side-effects, including renal or hepatic toxicity, hypokalaemia and thrombocytopenia, are observed frequently.

Lipid formulations of amphotericin B are less toxic. Liposomal amphotericin B (LAmB) is first-line therapy in Europe for VL. Dosing recommendations vary according to geographical region. In South Asia, a total dose of 10 (in a single dose) or 15 mg/kg administered in multiple doses over several days are considered adequate, whereas in Africa 14–18 mg/kg, and in South America and Europe 21–24 mg/kg, in 5–7 divided doses, is recommended for immunocompetent patients. High daily doses of the lipid formulations are well tolerated, and in one study a single dose of 10 mg/kg of LAmB cured 96% of Indian patients. This regimen is used as first-line therapy in the Kala-azar Elimination Programme in India, Nepal and Bangladesh.

Other drugs The oral drug miltefosine, an alkyl phospholipid, has been approved in several countries for the treatment of VL. A daily dose of 50 mg (patient's body weight <25 kg) to 100 mg (≥ 25 kg), or 2.5 mg/kg for children, for 28 days, cures over 90% of patients. Side-effects include mild to moderate vomiting and diarrhoea, and rarely skin allergy or renal or liver toxicity. Since it is a teratogenic drug, it cannot be used in pregnancy; female patients are advised not to become pregnant for the duration of treatment and 5 months thereafter because of its half-life of nearly 1 week.

Paromomycin is an aminoglycoside that has undergone trials in India and Africa, and is highly effective if given intramuscularly at 11 mg/kg of paromomycin base, daily for 3 weeks. No significant auditory or renal toxicity is seen. The drug is approved in India for VL treatment.

Pentamidine isethionate was used to treat Sb^V-refractory patients with VL. However, declining efficacy and serious side-effects, such as type 1 diabetes, hypoglycaemia and hypotension, have led to it being abandoned.

Multidrug therapy of VL is likely to be used increasingly to prevent emergence of drug resistance, and in India short-course combinations (a single dose of LAmB 5 mg/kg with either 7 days of miltefosine or 10 days of paromomycin, or 10 days each of miltefosine and paromomycin) were as effective as standard therapy. In India, in treatment centres where the cold chain (a temperature-controlled supply chain) is not maintained, 10 days of paromomycin combined with miltefosine is an alternative treatment regimen. In Africa a combination of Sb^V and paromomycin for 17 days is as effective and safe as Sb^V given for 30 days, and is the treatment of choice.

Response to treatment A good response results in fever resolution, improved well-being, reduction in splenomegaly, weight gain and recovery of blood counts. Patients require 6–12 months of regular follow-up, as some may experience relapse irrespective of the treatment regimen.

HIV/visceral leishmaniasis co-infection

HIV-induced immunosuppression increases the risk of contracting VL more than 100 times. Most cases of HIV/VL co-infection have been reported from Spain, France, Italy and Portugal, but antiretroviral therapy (ART) has led to a remarkable decline. HIV-associated VL is also reported in Africa (mainly Ethiopia), Brazil and South Asia.

Although the clinical triad of fever, splenomegaly and hepatomegaly is found in the majority of co-infected patients, those with low CD4 count may have atypical clinical presentations. VL may present with gastrointestinal involvement (stomach, duodenum or colon), ascites, pleural or pericardial effusion, or involvement of lungs, tonsil, oral mucosa or skin. Diagnostic principles remain the same as those in non-HIV patients. Parasites are numerous and easily demonstrable, even in buffy coat preparations. Sometimes amastigotes are found in unusual sites, such as bronchoalveolar lavage fluid, pleural fluid or biopsies of the gastrointestinal tract. Serological tests have low sensitivity. DNA detection by PCR of the blood or its buffy coat is at least 95% sensitive and accurately tracks recovery and relapse.

LAmB is the drug of choice for HIV/VL co-infection – both for primary treatment and for treatment of relapses. A total dose of 40 mg/kg, administered as 4 mg/kg on days 1–5, 10, 17, 24, 31 and 38, is considered optimal for the Americas and Mediterranean countries, and is approved by the FDA, but most patients experience a relapse within 1 year. Recently there has been significant change in the WHO recommendations for treatment of HIV/VL co-infection for the Indian subcontinent and East Africa. LAmB infusions (total dose 30 mg/kg; 5 mg/kg on days 1, 3, 5, 7, 9 and 11) co-administered with oral miltefosine (100 mg/day for 14 days for the Indian subcontinent; and 28 days for East Africa) should be used to treat HIV/VL co-infection. However, co-infected patients have a tendency to relapse and secondary prophylaxis every 3 to 4 weeks with pentamidine or LAmB has been shown to delay relapses, but no regimen has been established as optimal.

Post-kala-azar dermal leishmaniasis

After treatment and apparent recovery from VL in India and Sudan, some patients develop dermatological manifestations due to local parasitic infection.

Clinical features In India, dermatological changes occur in a small minority of patients 6 months to at least 3 years after the initial infection. They are seen as macules, papules, nodules (most frequently) and plaques, which have a predilection for the face, especially the area around the chin. The face often appears erythematous (Fig. 14.59A). Hypopigmented macules can occur over all parts of the body and are highly variable in extent. There are no systemic symptoms and little spontaneous healing occurs.

In Sudan and South Sudan, approximately 50% of patients with VL develop post-kala-azar dermal leishmaniasis (PKDL), experiencing skin manifestations concurrently with VL or within 6 months. In addition to the dermatological features, a measles-like maculopapular rash (Fig. 14.59B) may be seen all over the body. In Sudan, children are more frequently affected than in India. Spontaneous healing occurs in about three-quarters of cases within 1 year.

Investigations and management The diagnosis is clinical, supported by demonstration of scanty parasites in lesions by slit-skin smear and culture. Immunofluorescence and immunohistochemistry may demonstrate the parasite in skin tissues. In the majority of patients, serological tests

Fig. 14.59 Post-kala-azar dermal leishmaniasis. **A** In India, with macules, papules, nodules and plaques. **B** In Sudan, with micronodular rash. *(A) From Sundar S, Kumar K, Chakravarty J, et al. Cure of antimony-unresponsive Indian post-kala-azar dermal leishmaniasis with oral miltefosine. Trans R Soc Trop Med Hyg 2006;100(7):698–700. (B) Courtesy of Dr E.E. Zijlstra.*

(direct agglutination test or k39 strip tests) are positive. PCR is very useful in the molecular diagnosis of PKDL and is being used more frequently now.

Treatment of PKDL is difficult. In India, Sb^{V} for 120 days, several courses of amphotericin B infusions, or miltefosine for 12 weeks is required; however, each of these regimens is associated with unacceptable adverse events. In a multicountry study from India and Bangladesh for the treatment of PKDL, the efficacy of LAmB alone (total dose 20 mg/kg) or in combination with miltefosine (for 3 weeks) was 83% and 88%, respectively. In Sudan, Sb^{V} for 2 months is considered adequate. In the absence of a physical handicap, most patients are reluctant to complete therapy. PKDL patients are a human reservoir, and focal outbreaks have been linked to patients with PKDL in areas previously free of VL. PKDL and cases with active VL infected sandflies efficiently in xenodiagnosis experiments done in India and Bangladesh.

Prevention and control

Sandfly control through insecticide spray is very important. Mosquito nets or curtains treated with insecticides will keep out the tiny sandflies. In endemic areas with zoonotic transmission, infected or stray dogs should be destroyed.

In areas with anthroponotic transmission, early diagnosis and treatment of human infections, to reduce the reservoir and control epidemics of VL, is extremely important. Serology is useful in diagnosis of suspected cases in the field. No vaccine is currently available.

Cutaneous and mucosal leishmaniasis

Cutaneous leishmaniasis

CL (oriental sore) occurs in both the Old World (Asia, Africa and Europe) and the New World (the Americas). Transmission is described in Figure 14.55.

In the Old World, CL is mild. It is found around the Mediterranean basin, throughout the Middle East and Central Asia as far as Pakistan, and in sub-Saharan West Africa and Sudan (Fig. 14.60). The causative organisms for Old World zoonotic CL are *L. major*, *L. tropica* and *L. aethiopica* (Box 14.77). Anthroponotic CL is caused by *L. tropica*, and is confined to urban or suburban areas of the Old World. Afghanistan is currently the biggest focus but infection is endemic in Pakistan, the western deserts of India, Iran, Iraq, Syria and other areas of the Middle East. In recent years there has been an increase in the incidence of zoonotic CL in both the Old and the New Worlds due to urbanisation and deforestation, which led to peridomestic transmission (in and around human dwellings).

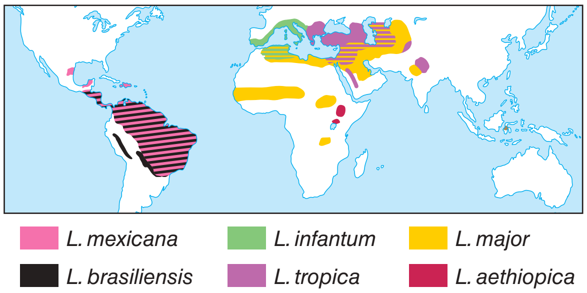

Fig. 14.60 World distribution of cutaneous leishmaniasis. Map lines delineate study areas and do not necessarily depict accepted national boundaries.

i 14.77 Types of Old World cutaneous leishmaniasis

Leishmania spp.	Host	Clinical features
L. tropica	Dogs	Slow evolution, less severe
L. major	Gerbils, desert rodents	Rapid necrosis, wet sores
L. aethiopica	Hyraxes	Solitary facial lesions with satellites

New World CL is a more significant disease, which may disfigure the nose, ears and mouth, and is caused by the *L. mexicana* complex (comprising *L. mexicana*, *L. amazonensis* and *L. venezuelensis*) and by the *Viannia* subgenus *L. (V.) brasiliensis* complex (comprising *L. (V.) guyanensis*, *L. (V.) panamensis*, *L. (V.) brasiliensis* and *L. (V.) peruviana*).

CL is commonly imported and should be considered in the differential diagnosis of an ulcerating skin lesion, especially in travellers who have visited endemic areas of the Old World or forests in Central and South America.

Pathogenesis

Inoculated parasites are taken up by dermal macrophages, in which they multiply and form a focus for lymphocytes, epithelioid cells and plasma cells. Self-healing may occur with necrosis of infected macrophages, or the lesion may become chronic with ulceration of the overlying epidermis, depending on the aetiological pathogen.

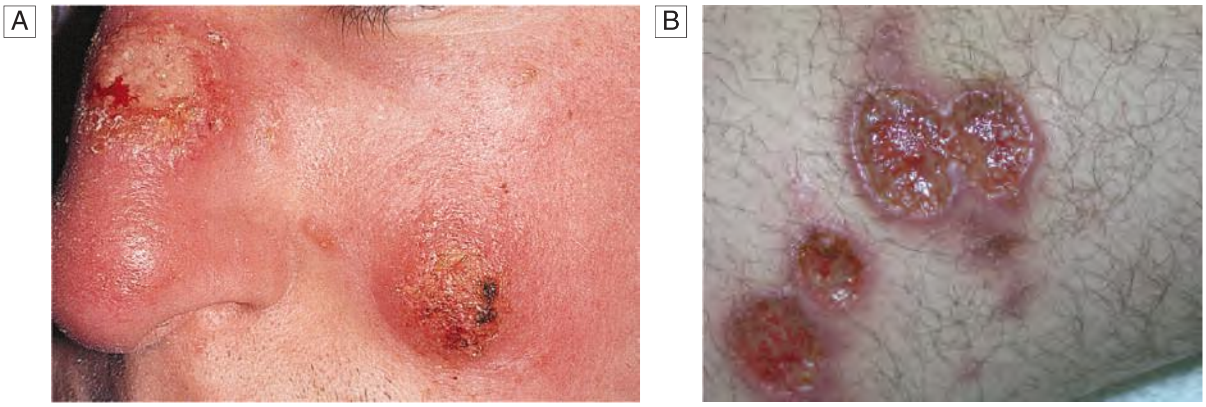

Fig. 14.61 **Cutaneous leishmaniasis.** **A** Papule. **B** Ulcer. *(B) Courtesy of Dr Ravi Gowda, Royal Hallamshire Hospital, Sheffield.*

Clinical features

The incubation period is typically 2–3 months (range 2 weeks to 5 years). In all types of CL a papule develops at the site of the vector bite. The small, red papules may be single or multiple and increase gradually in size, reaching 2–10 cm in diameter. A crust forms, overlying an ulcer with a granular base and with raised borders (Fig. 14.61). These ulcers develop a few weeks or months after the bite. There can be satellite lesions, especially in *L. major* and occasionally in *L. tropica* infections. Regional lymphadenopathy, pain, pruritus and secondary bacterial infections may occur.

Lesions of *L. mexicana* and *L. peruviana* closely resemble those seen in the Old World, but lesions on the pinna of the ear are common and are chronic and destructive. *L. mexicana* is responsible for chiclero ulcers, the self-healing sores of Mexico.

If immunity is effective, there is usually spontaneous healing in *L. tropica*, *L. major* and *L. mexicana* lesions. In some patients with anergy to *Leishmania*, the skin lesions of *L. aethiopica*, *L. mexicana* and *L. amazonensis* infections progress to the development of diffuse CL; this is characterised by spread of the infection from the initial ulcer, usually on the face, to involve the whole body in the form of non-ulcerative nodules. Occasionally, in *L. tropica* infections, sores that have apparently healed relapse persistently (recidivans or lupoid leishmaniasis).

Mucosal leishmaniasis

The *Viannia* subgenus extends widely from the Amazon basin as far as Paraguay and Costa Rica, and is responsible for deep sores and ML. In *L. (V.) brasiliensis* complex infections, cutaneous lesions may be followed by mucosal spread of the disease simultaneously or even years later. Young men with chronic lesions are particularly at risk, and 2%–40% of infected persons develop ‘espundia’, metastatic lesions in the mucosa of the nose or mouth. This is characterised by thickening and erythema of the nasal mucosa, typically starting at the junction of the nose and upper lip. Later, ulceration develops. The lips, soft palate, fauces and larynx may also be invaded and destroyed, leading to considerable suffering and deformity. There is no spontaneous healing, and death may result from severe respiratory tract infections due to massive destruction of the pharynx.

Investigations in CL and ML

CL is often diagnosed by the clinical features. Parasitological confirmation is important, however, because clinical manifestations may be mimicked by other infections. Amastigotes can be demonstrated on a slit-skin smear with Giemsa staining, with yields highest at the ulcer margin; alternatively, they can be cultured from the sores early during the infection. Parasites are difficult to isolate from sores caused by *L. brasiliensis*, responsible for the vast majority of cases in Brazil. Touch preparations from biopsies and histopathology usually have a low sensitivity. Culture of fine needle aspiration material has been reported to be the most sensitive method.

ML is more difficult to diagnose parasitologically. The leishmanin skin test measures delayed-type hypersensitivity to killed *Leishmania* organisms. A positive test is defined as induration of more than 5 mm, 48 hours after intradermal injection. The test is positive, except in diffuse CL and during active VL. PCR is used increasingly for diagnosis and speciation, which is useful in selecting therapy.

Management of CL and ML

Small lesions may self-heal or are treated by freezing with liquid nitrogen or curettage. There is no ideal antimicrobial therapy. Treatment should be individualised on the basis of the causative organism, severity of the lesions, availability of drugs, anticipated toxicity, and local resistance patterns.

In CL, topical application of paromomycin 15% plus methylbenzethonium chloride 12% is beneficial. Intralesional antimony (Sb 0.2–0.8 mL/lesion) up to 2 g seems to be rapidly effective in suitable cases; it is well tolerated and economic, and is safe in patients with cardiac, liver or renal diseases.

In ML, and in CL when the lesions are multiple or in a disfiguring site, it is better to treat with parenteral Sb^V (20 mg/kg daily, usually given for 20 days for CL and 28 days for ML), or with conventional or liposomal amphotericin B (see treatment of VL above). Sb^V is also indicated to prevent the development of mucosal disease, if there is any chance that a lesion acquired in South America is due to an *L. brasiliensis* strain. Refractory CL or ML should be treated with an amphotericin B preparation.

Orally administered miltefosine makes it very attractive and is a major advancement in the treatment of CL. Miltefosine has been used in CL in doses of 2.5 mg/kg for 28 days. This agent is effective against L. major infections. There is a strong recommendation for oral miltefosine treatment for New World CL where *L. panamensis, L. mexicana, L. guyanensis*, and *L. braziliensis* are the species involved. Overall there has been a shift towards the use of miltefosine in CL and ML instead of antimonials, both in the New and Old Worlds.

Other regimens may be effective. Two to four doses of pentamidine (2–4 mg/kg), administered on alternate days, are effective in New World CL caused by *L. guyanensis*. In ML, 8 injections of pentamidine (4 mg/kg on alternate days) cure the majority of patients. Various azole compounds, fluconazole, ketoconazole and itraconazole, have similar and modest efficacy rates in the treatment of cutaneous leishmaniasis.

Prevention of CL and ML

Personal protection against sandfly bites is important. No effective human vaccine is available.

Gastrointestinal protozoal infections

Amoebiasis

Amoebiasis is caused by *Entamoeba histolytica*, which is spread between humans by its cysts. It is one of the leading parasitic causes of morbidity

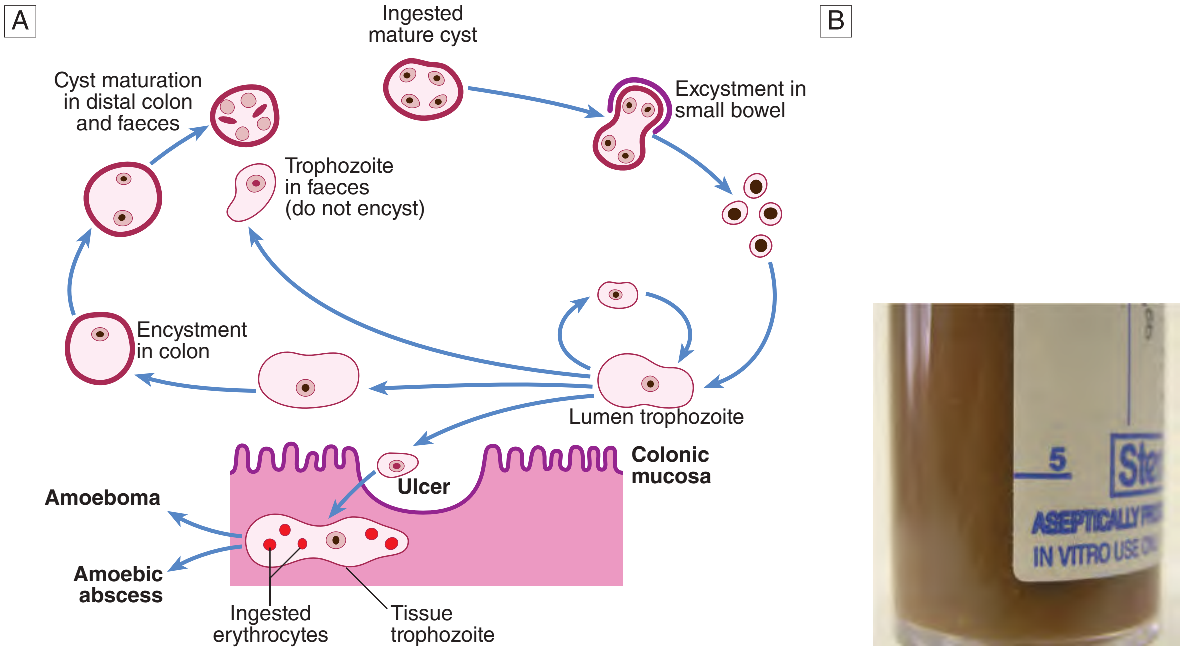

Fig. 14.62 **Amoebiasis.** **A** The life cycle of *Entamoeba histolytica*. **B** The chocolate-brown appearance of aspirated material from an amoebic liver abscess. *(A) From Knight R. Parasitic disease in man. Edinburgh: Churchill Livingstone, Elsevier Ltd.; 1982. (B) Courtesy of Dr Ravi Gowda, Royal Hallamshire Hospital, Sheffield.*

and mortality in the tropics and is occasionally acquired in non-tropical countries. Two non-pathogenic *Entamoeba* species (*E. dispar* and *E. moshkovskii*) are morphologically identical to *E. histolytica*, and are distinguishable only by molecular techniques, isoenzyme studies or monoclonal antibody typing. However, only *E. histolytica* causes amoebic dysentery or liver abscess. The life cycle of the amoeba is shown in Figure 14.62A.

Pathology

Cysts of *E. histolytica* are ingested in water or uncooked foods contaminated by human faeces. Infection may also be acquired through anal/oral sexual practices. Trophozoites emerge from the cysts in the small bowel and enter the large bowel. The parasite invades the mucous membrane of the large bowel, producing lesions that are maximal in the caecum but extend to the anal canal. These are flask-shaped ulcers, varying greatly in size and surrounded by healthy mucosa. A rare complication is amoeboma, a localised granuloma that may present as a palpable abdominal mass (usually in the right iliac fossa), a rectal mass (rarely) or a filling defect on colonic radiography. This has to be distinguished from other causes of colonic mass (e.g. cancer). Amoebic ulcers may cause severe haemorrhage but rarely perforate the bowel wall.

Amoebic trophozoites can emerge from the vegetative cyst from the bowel and be carried to the liver in a portal venule. They can multiply rapidly and destroy the liver parenchyma, causing an abscess (see also p. 910). The liquid contents at first have a characteristic pinkish colour, which may later change to chocolate-brown (said to resemble anchovy sauce).

Cutaneous amoebiasis, though rare, causes progressive genital, perianal or peri-abdominal surgical wound ulceration.

Clinical features

Intestinal amoebiasis – amoebic dysentery

Most amoebic infections are asymptomatic. The incubation period of amoebiasis ranges from 2 weeks to many years, followed by a chronic course with abdominal pains and two or more unformed stools a day. Offensive diarrhoea, alternating with constipation, and blood or mucus in the stool are common. There may be abdominal pain, especially in the right lower quadrant (which may mimic acute appendicitis). A dysenteric presentation with passage of blood, simulating bacillary dysentery or ulcerative colitis, occurs particularly in older people, in the puerperium and with super-added pyogenic infection of the ulcers.

Amoebic liver abscess

The abscess is usually found in the right hepatic lobe. There may not be associated diarrhoea. Early symptoms may be only local discomfort and malaise; later, a swinging temperature and sweating may develop, usually without marked systemic symptoms or signs. An enlarged, tender liver, cough and pain in the right shoulder are characteristic but symptoms may remain vague and signs minimal. A large abscess may penetrate the diaphragm, rupturing into the lung, and may be coughed up through a hepatobronchial fistula. Rupture into the pleural or peritoneal cavity, or rupture of a left lobe abscess in the pericardial sac, is less common but more serious.

Investigations

Microscopic examination of the stool and exudate can reveal motile trophozoites containing red blood cells. Trophozoite motility decreases rapidly as the stool preparation cools. Several stools may need to be examined in chronic amoebiasis before cysts are found. Sigmoidoscopy may reveal typical flask-shaped ulcers, which should be scraped and examined immediately for *E. histolytica*. In endemic areas, one-third of the population are symptomless passers of amoebic cysts.

An amoebic abscess of the liver is suspected on clinical grounds; there is often a neutrophil leucocytosis and a raised right hemidiaphragm on chest X-ray. Confirmation is by ultrasonic scanning. Aspirated pus from an amoebic abscess has the characteristic chocolate-brown appearance but rarely contains free amoebae (Fig. 14.62B).

Serum antibodies are detectable by immunofluorescence in over 95% of patients with hepatic amoebiasis and intestinal amoeboma, but in only about 60% of dysenteric amoebiasis. DNA detection by PCR or by loop-mediated isothermal amplification (LAMP) assay have been shown to be useful in diagnosis of *E. histolytica* infections but are not generally available.

Management

Intestinal and early hepatic amoebiasis responds quickly to oral metronidazole (800 mg 3 times daily for 5–10 days) or other long-acting nitroimidazoles like tinidazole or ornidazole (both in doses of 2 g daily for 3 days). Nitazoxanide (500 mg twice daily for 3 days) is an alternative drug. Either diloxanide furoate or paromomycin, in doses of 500 mg orally 3 times daily for 10 days after treatment, should be given to eliminate luminal cysts.

If a liver abscess is large or threatens to burst, or if the response to chemotherapy is not prompt, aspiration is required and is repeated if necessary. Rupture of an abscess into the pleural cavity, pericardial sac or peritoneal cavity necessitates immediate aspiration or surgical drainage. Small serous effusions resolve without drainage.

Prevention

Personal precautions against contracting amoebiasis include not eating fresh, uncooked vegetables or drinking unclean water.

Giardiasis

Infection with *Giardia lamblia* (also known as *G. intestinalis*) is found worldwide and is common in the tropics. It particularly affects children, tourists and immunosuppressed individuals, and is the parasite most commonly imported into the UK. Cysts remain viable in water for up to 3 months and infection usually occurs by ingesting contaminated water. Its flagellar trophozoite form attaches to the duodenal and jejunal mucosa, causing inflammation.

Clinical features and investigations

After an incubation period averaging 1–3 weeks, but which can be as short as 1–3 days. there is diarrhoea, abdominal pain, weakness, anorexia, nausea and vomiting. On examination, there may be abdominal distension and tenderness. Chronic diarrhoea and malabsorption may occur, with bulky stools that float.

Stools obtained at 2- to 3-day intervals should be examined for cysts. Duodenal or jejunal aspiration by endoscopy gives a higher diagnostic yield. A number of stool antigen detection tests are available. Jejunal biopsy specimens may show *Giardia* on the epithelial surface. PCR/multiplex PCR are increasingly being used in the diagnosis of giardiasis, but may not be freely accessible in low-income countries.

Management

Treatment is with a single dose of tinidazole 2 g, metronidazole 400 mg 3 times daily for 10 days, or nitazoxanide 500 mg orally twice daily for 3 days.

Cryptosporidiosis

Cryptosporidium spp. are coccidian protozoal parasites of humans and domestic animals. Infection is acquired by the faecal–oral route through contaminated water supplies. The incubation period is approximately 7–10 days and is followed by watery diarrhoea and abdominal cramps. The illness is usually self-limiting but in immunocompromised patients, especially those with HIV, the illness can be devastating, with persistent severe diarrhoea and substantial weight loss. Diagnosis is by detection of oöcysts on faecal microscopy or PCR of stool. Treatment is not usually required; nitazoxanide can be used in immunocompromised hosts but efficacy is uncertain.

Cyclosporiasis

Cyclospora cayetanensis is a globally distributed coccidian protozoal parasite of humans. Infection is acquired by ingestion of contaminated water and recent food-borne outbreaks have been associated with raspberries and coriander (cilantro). The incubation period of approximately 2–11 days is followed by diarrhoea with abdominal cramps, which may remit and relapse. Although usually self-limiting, the illness may last as long as 6 weeks, with significant weight loss and malabsorption, and is more severe in immunocompromised individuals. Diagnosis is as for cryptosporidiosis. Treatment may be necessary in a few cases, using co-trimoxazole 960 mg twice daily for 7 days.

Cystoisospora belli

Cystoisospora belli is a rarer coccidian parasite causing enteric infection. It is found worldwide and causes an illness similar to cryptosporidiosis in immunocompromised groups such as PWH. Diagnosis is by identification of oocysts in stool or duodenal aspirates using wet mounts, modified acid fast stains or epifluorescence. Treatment involves co-trimoxazole, as for cyclosporiasis.

Infections caused by helminths

Helminths (from the Greek *helmins*, meaning worm) include three groups of parasitic worm (Box 14.78), large multicellular organisms with complex tissues and organs.

Intestinal human nematodes

Adult nematodes living in the human gut can cause disease. There are two types:

- the hookworms, which have a soil stage in which they develop into larvae that then penetrate the host
- a group of nematodes that survive in the soil merely as eggs, which have to be ingested for their life cycle to continue.

The geographical distribution of hookworms is limited by the larval requirement for warmth and humidity. Soil-transmitted nematode infections can be prevented by avoidance of faecal soil contamination (adequate sewerage disposal) or skin contact (wearing shoes), and by strict personal hygiene.

Ancylostomiasis (hookworm)

Ancylostomiasis is caused by *Ancylostoma duodenale* or *Necator americanus*. The complex life cycle is shown in Figure 14.63. The adult hookworm is 1 cm long and lives in the duodenum and upper jejunum. Eggs are passed in the faeces. In warm, moist, shady soil, the larvae develop into rhabditiform and then the infective filariform stages; they then penetrate human skin and are carried to the lungs. After entering the alveoli, they ascend the bronchi, are swallowed and mature in the small intestine, reaching maturity 4–7 weeks after infection. The worms attach to the mucosa of the small intestine by their buccal capsule (Fig. 14.64) and withdraw blood. The mean daily blood loss from one *A. duodenale* is 0.15 mL and that from *N. americanus* 0.03 mL.

Hookworm infection is a leading cause of anaemia in the tropics and subtropics. *A. duodenale* is endemic in the Far East and Mediterranean coastal regions, and is also present in Africa, while *N. americanus* is endemic in West, East and Central Africa, and Central and South America, as well as in the Far East.

14.78 Classes of helminth that parasitise humans

Nematodes or roundworms

- Intestinal human nematodes: *Ancylostoma duodenale*, *Necator americanus*, *Strongyloides stercoralis*, *Ascaris lumbricoides*, *Enterobius vermicularis*, *Trichuris trichiura*
- Tissue-dwelling human nematodes: *Wuchereria bancrofti*, *Brugia malayi*, *Loa loa*, *Onchocerca volvulus*, *Dracunculus medinensis*, *Mansonella perstans*, *Dirofilaria immitis*
- Zoonotic nematodes: *Trichinella spiralis*

Trematodes or flukes

- Blood flukes: *Schistosoma haematobium*, *S. mansoni*, *S. japonicum*, *S. mekongi*, *S. intercalatum*
- Lung flukes: *Paragonimus* spp.
- Hepatobiliary flukes: *Clonorchis sinensis*, *Fasciola hepatica*, *Opisthorchis felineus*
- Intestinal flukes: *Fasciolopsis buski*

Cestodes or tapeworms

- Intestinal tapeworms: *Taenia saginata*, *T. solium*, *Diphyllobothrium latum*, *Hymenolepis nana*
- Tissue-dwelling cysts or worms: *Taenia solium*, *Echinococcus granulosus*

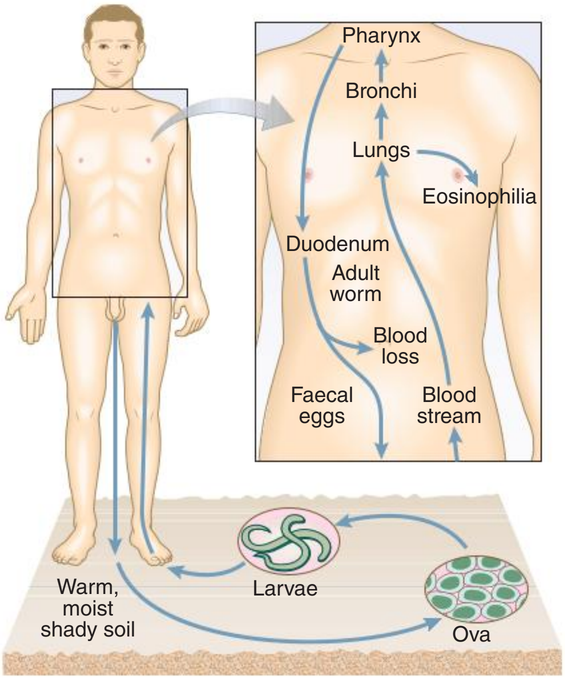

Fig. 14.63 **Ancylostomiasis.** Life cycle of *Ancylostoma*.

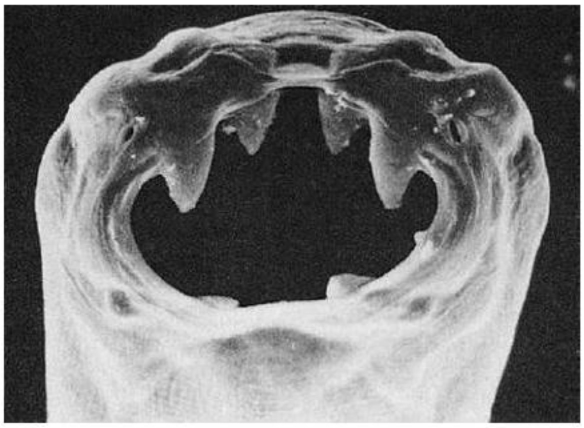

Fig. 14.64 ***Ancylostoma duodenale.*** Electron micrograph showing the ventral teeth. *From Gibbons LM. SEM guide to the morphology of nematode parasites of vertebrates. Farnham Royal, Slough: Commonwealth Agricultural Bureau International; 1986.*

Clinical features

An allergic dermatitis, usually on the feet (ground itch), may be experienced at the time of infection. The passage of the larvae through the lungs in a heavy infection causes a paroxysmal cough with blood-stained sputum, associated with patchy pulmonary consolidation and eosinophilia. When the worms reach the small intestine, vomiting and epigastric pain resembling peptic ulcer disease may occur. Sometimes, frequent loose stools are passed. The degree of iron and protein deficiency depends on the worm burden, patient nutrition and iron stores. Anaemia with high-output cardiac failure may result. The mental and physical development of children may be delayed in severe infection.

Investigations

There is eosinophilia. The characteristic ovum can be recognised in the stool. If hookworms are present in numbers sufficient to cause anaemia, faecal occult blood testing will be positive.

14.79 Clinical features of strongyloidiasis

Penetration of skin by infective larvae

- Itchy rash

Presence of worms in gut

- Abdominal pain, diarrhoea, steatorrhoea, weight loss

Allergic phenomena

- Urticarial plaques and papules, wheezing, arthralgia

Autoinfection

- Transient itchy, linear, urticarial weals across abdomen and buttocks (larva currens)

Systemic (super-)infection

- Diarrhoea, pneumonia, meningoencephalitis, death

Management

A single dose of albendazole (400 mg) is the treatment of choice. Alternatively, mebendazole 100 mg twice daily for 3 days may be used. Anaemia and heart failure associated with hookworm infection respond well to oral iron, even when severe; blood transfusion is rarely required.

Strongyloidiasis

Strongyloides stercoralis is a small nematode (2 mm × 0.4 mm) that parasitises the mucosa of the upper part of the small intestine, often in large numbers, causing persistent eosinophilia. The eggs hatch in the bowel but only larvae are passed in the faeces. In moist soil, they moult and become the infective filariform larvae. After penetrating human skin, they undergo a development cycle similar to that of hookworms, except that the female worms burrow into the intestinal mucosa and submucosa. Some larvae in the intestine may develop into filariform larvae, which may then penetrate the mucosa or the perianal skin and lead to autoinfection and persistent infection. Patients with *Strongyloides* infection persisting for more than 35 years have been described. Strongyloidiasis occurs in the tropics and subtropics, and is especially prevalent in the Far East.

Clinical features

These are shown in Box 14.79. The classic triad of symptoms consists of abdominal pain, diarrhoea and urticaria. Cutaneous manifestations, either urticaria or larva currens (a highly characteristic pruritic, elevated, erythematous lesion, rapidly advancing along the course of larval migration), are characteristic and occur in 66% of patients.

Systemic strongyloidiasis (the *Strongyloides* hyperinfection syndrome), with dissemination of larvae throughout the body, occurs with immune suppression (HIV or HTLV-1 infection, steroid or immunosuppressant treatment). Patients present with severe, generalised abdominal pain, abdominal distension and shock. Massive larval invasion of the lungs causes cough, wheeze and dyspnoea; cerebral involvement has manifestations ranging from subtle neurological signs to coma. Gram-negative sepsis frequently results.

Investigations

There is eosinophilia. Serology (ELISA) is helpful but definitive diagnosis requires microscopic examination of faeces for motile rhabditiform larvae; excretion is intermittent and so repeated examinations are necessary. Larvae may be found in jejunal aspirates or can also be cultured from faeces. PCR can be used for greater specificity and sensitivity.

Management

A course of two doses of ivermectin (200 µg/kg), administered on successive days, is effective. Alternatively, albendazole is given orally (15 mg/kg twice daily for 3 days). A second course may be required. For the

Strongyloides hyperinfection syndrome, ivermectin is given at 200 μg/kg until the parasite can no longer be identified in clinical specimens for 2 weeks.

Ascaris lumbricoides (roundworm)

This pale yellow nematode is 20–35 cm long and the largest of the intestinal nematodes. Humans are infected by eating food contaminated with mature ova. *Ascaris* larvae hatch in the duodenum, migrate through the lungs, ascend the bronchial tree, are swallowed and mature in the small intestine. This tissue migration can provoke both local and general hypersensitivity reactions, with pneumonitis, eosinophilic granulomas, wheezing and urticaria.

Clinical features

Intestinal ascariasis causes symptoms ranging from vague abdominal pain to malnutrition. The large size of the adult worm and its tendency to aggregate and migrate result in obstructive complications. Tropical and subtropical areas are endemic for ascariasis, and here it causes up to 35% of all intestinal obstructions, most commonly in the terminal ileum. Obstruction can be complicated further by intussusception, volvulus, haemorrhagic infarction and perforation. Other complications include blockage of the bile or pancreatic duct and obstruction of the appendix by adult worms. Ascariasis in non-endemic areas has been associated with pig husbandry and may be caused by *Ascaris suum*, which is indistinguishable from *A. lumbricoides*.

Investigations

The diagnosis is made microscopically by finding ova in the faeces. Adult worms are frequently expelled rectally or orally. Occasionally, the worms are demonstrated radiographically by a barium examination. There is eosinophilia.

Management

A single dose of albendazole (400 mg), pyrantel pamoate (11 mg/kg; maximum 1 g), or ivermectin (150–200 μg/kg), or alternatively mebendazole (100 mg twice daily for 3 days) treats intestinal ascariasis. Treatment is best given between meals. Patients should be warned that they might expel numerous whole, large worms. Obstruction due to ascariasis should be treated with nasogastric suction, piperazine and intravenous fluids. Complete intestinal obstruction and its complications require urgent surgical intervention.

Prevention

Community chemotherapy programmes reduce *Ascaris* infection. The whole community can be treated every 3 months for several years. Alternatively treatment targets schoolchildren to lower the prevalence of ascariasis in the community.

Enterobius vermicularis (threadworm, pinworm)

This helminth is common worldwide and affects mainly children. After the ova are swallowed, development takes place in the small intestine but the adult worms are found chiefly in the colon.

Clinical features

The female lays ova around the anus, causing intense itching, especially at night. The ova are carried to the mouth on the fingers and so reinfection or human-to-human infection occurs (Fig. 14.65). In females, the genitalia may be involved. The adult worms may be seen moving on the buttocks or in the stool.

Investigations

Ova are detected in stool samples or by applying the adhesive surface of cellophane tape to the perianal skin in the morning. This is then examined on a glass slide under the microscope. A perianal swab, moistened with saline, also allows diagnosis.

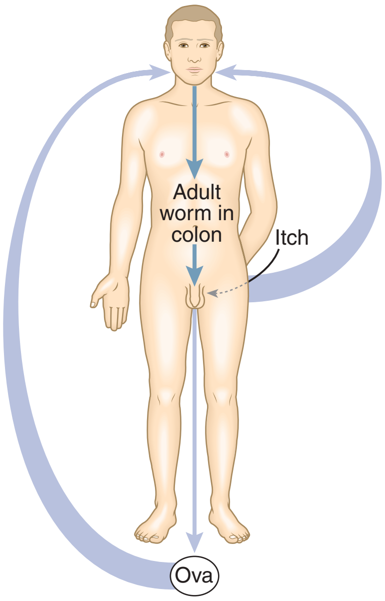

Fig. 14.65 **Threadworm.** Life cycle of *Enterobius vermicularis*.

Management

A single dose of albendazole (400 mg), mebendazole (100 mg), or pyrantel pamoate (11 mg/kg) treats infection and is repeated after 2 weeks to control auto-reinfection. If infection recurs in a family, each member should be treated. All nightclothes and bed linen are laundered during treatment. Fingernails must be kept short and hands washed carefully before meals. Subsequent therapy is reserved for family members with recurrent infection.

Trichuris trichiura (whipworm)

Whipworm infections are common worldwide with poor hygiene. Infection follows ingestion of earth or food contaminated with ova, which have become infective after lying for 3 weeks or more in moist soil. The adult worm is 3–5 cm long and has a coiled anterior end resembling a whip. Whipworms inhabit the caecum, lower ileum, appendix, colon and anal canal. There are usually no symptoms, but intense infections in children may cause persistent diarrhoea or rectal prolapse, and growth retardation. The diagnosis is readily made by identifying ova in faeces. Treatment is a single dose of albendazole 400 mg alone or in combination with ivermectin (200 μg/kg) or mebendazole in doses of 100 mg twice daily or albendazole 400 mg daily for 3 days for patients with light infections, and for 5–7 days for those with heavy infections.

Tissue-dwelling human nematodes

Filarial worms are tissue-dwelling nematodes. The larval stages are inoculated by biting mosquitoes or flies, each specific to a particular filarial species. The larvae develop into adult worms (2–50 cm long), which, after mating, produce millions of microfilariae (170–320 μm long) that migrate in blood or skin. The life cycle is completed when the vector takes up microfilariae by biting humans. In the insect, ingested microfilariae develop into infective larvae for inoculation in humans, normally the only host.

Disease is due to the host's immune response to the worms (both adult and microfilariae), particularly dying worms, and its pattern and severity vary with the site and stage of each species (Box 14.80). The worms are long-lived: microfilariae survive 2–3 years and adult worms 10–15 years. The infections are chronic and worst in individuals constantly reinfected.

14.80 Pathogenicity of filarial infections depending on site and stage of worms

Lymphangitis and lymphoedema

Fig. 14.66 ***Wuchereria bancrofti* and *Brugia malayi*.** Life cycle of organisms and pathogenesis of lymphatic filariasis.

Lymphatic filariasis

The filarial worms *Wuchereria bancrofti* and *Brugia malayi* infect approximately 120 million people globally, whose features range from subclinical infection to hydrocele and elephantiasis.

W. bancrofti is usually transmitted by night-biting culicine or anopheline mosquitoes (Fig. 14.66). The adult worms, 4–10 cm in length, live in the lymphatics, and the females produce microfilariae that circulate in large numbers in the peripheral blood, usually at night. The infection is widespread in tropical Africa, on the North African coast, in coastal areas of Asia, Indonesia and northern Australia, the South Pacific islands, the West Indies and also in North and South America.

B. malayi usually causes less severe disease than *W. bancrofti* and is transmitted by *Mansonia* or *Anopheles* mosquitoes in Indonesia, Borneo, Malaysia, Vietnam, South China, South India and Sri Lanka.

Pathology

Toxins released by adult worms cause lymphangiectasia; this dilatation of the lymphatic vessels leads to lymphatic dysfunction and the chronic clinical manifestations of lymphatic filariasis, lymphoedema and hydrocele. Death of the adult worm results in acute filarial lymphangitis. The filariae are symbiotically infected with rickettsia-like bacteria (*Wolbachia* spp.), and lipopolysaccharide released from *Wolbachia* triggers inflammation. Lymphatic obstruction persists after death of the adult worm. Secondary bacterial infections cause tissue destruction.

Clinical features

Acute filarial lymphangitis presents with fever, pain, tenderness and erythema along the course of inflamed lymphatic vessels. Inflammation of the spermatic cord, epididymis and testis is common. Episodes last a few days but may recur several times a year. Temporary oedema becomes more persistent and regional lymph nodes enlarge. Progressive enlargement, coarsening, corrugation, fissuring and bacterial infection of the skin and subcutaneous tissue develop gradually, causing irreversible 'elephantiasis'. The scrotum may reach an enormous size. Chyluria and chylous effusions are milky and opalescent; on standing, fat globules rise to the top.

Acute lymphatic manifestations of filariasis must be differentiated from thrombophlebitis and infection. Oedema and lymphatic obstructive changes must be distinguished from congestive cardiac failure, malignancy, trauma and idiopathic abnormalities of the lymphatic system. Silicates absorbed from volcanic soil can also cause elephantiasis (podoconiosis).

Tropical pulmonary eosinophilia is a complication and is the result of the host response to microfilariae. It is seen mainly in India, due to microfilariae trapped in the pulmonary capillaries that are destroyed by allergic inflammation. Patients present with paroxysmal cough, wheeze and fever. If untreated, this may progress to debilitating chronic interstitial lung disease.

Investigations

Early in filariasis lymphangitis is a clinical diagnosis, supported by eosinophilia and sometimes by positive filarial serology. Filarial infections cause the highest eosinophil counts of all helminthic infections.

Microfilariae can be found in the peripheral blood at night; motile in a wet blood film or detected by microfiltration in lysed blood. They are usually present in hydrocele fluid, which may occasionally yield an adult filaria. By the time elephantiasis develops, microfilariae become difficult to find. Calcified filariae may sometimes be demonstrable by radiography. Movement of adult worms can be seen on scrotal ultrasound. PCR-based tests for detection of *W. bancrofti* and *B. malayi* DNA from blood have been developed.

Indirect fluorescence and ELISA detect antibodies in over 95% of active cases and 70% of established elephantiasis. The test becomes negative 1–2 years after cure. Serological tests cannot distinguish the different filarial infections. Highly sensitive and specific, commercially available, immunochromatographic card tests detect circulating *W. bancrofti* antigen using finger-prick blood samples taken at any time of the day.

In tropical pulmonary eosinophilia, serology is strongly positive and IgE levels are massively elevated but circulating microfilariae are not found. The chest X-ray shows miliary changes or mottled opacities. Pulmonary function tests show a restrictive picture.

Management

Treatment is aimed at halting and reversing disease progression. Diethylcarbamazine (DEC; 2 mg/kg orally 3 times daily for 21 days, or 6 mg/kg as a single dose) kills microfilariae and adult worms. Most adverse effects seen with DEC treatment are due to the host response to dying microfilariae, which is directly proportional to the microfilarial load. The main symptoms are fever, headache, nausea, vomiting, arthralgia and prostration, usually within 24–36 hours of the first dose of DEC. Antihistamines or glucocorticoids treat these allergic phenomena. Combining albendazole (400 mg) with ivermectin (200 µg/kg) in a single dose, with or without DEC (300 mg), is also highly effective in clearing the microfilariae. Treatment of *Wolbachia* with doxycycline (200 mg/day) for 4–8 weeks provides additional benefit by eliminating the bacteria; this leads to interruption of parasite embryogenesis, enhancing killing of macrofilariae. For tropical pulmonary eosinophilia, DEC for 14 days is the treatment of choice.

Co-infections

Patients co-infected with lymphatic filariasis and onchocerciasis with eye involvement should be treated with doxycycline before ivermectin. Co-infection with lymphatic filariasis and loiasis depends on the *Loa loa* microfilarial load. If high, an agent such as albendazole should be given first before DEC to reduce microfilarial load as DEC can result in severe encephalitis/shock. Management of these scenarios is complex and should be performed with specialist input experienced in manging these infections.

Chronic lymphatic pathology

Active management of chronic lymphatic pathology can alleviate symptoms. Patients should be taught meticulous skin care for lymphoedema to prevent secondary bacterial and fungal infections. Tight bandaging, massage and bed rest with elevation of the affected limb help to control the lymphoedema. Prompt diagnosis and antibiotic therapy of bacterial cellulitis prevent further lymphatic damage and worsening of existing elephantiasis. Plastic surgery to remove excess tissue may offer relief in established elephantiasis, but without establishment of new lymphatic drainage, recurrence is likely. Hydroceles and chyluria can be repaired surgically.

Prevention

Treatment of the whole population (mass drug administration, MDA) in endemic areas with annual single-dose DEC (6 mg/kg), either alone or in combination with albendazole and ivermectin (triple drugs), can reduce filarial transmission. MDA should be combined with mosquito control programmes.

Loiasis

Loiasis is caused by infection with the filaria *Loa loa*. The disease is endemic in forested and swampy parts of Western and Central Africa. The adult worms, 3–7 cm × 4 mm, chiefly parasitise the subcutaneous tissue of humans, releasing larval microfilariae into the peripheral blood in the daytime. The vector is *Chrysops*, a forest-dwelling, day-biting fly.

The host response to *Loa loa* is usually absent or mild. From time to time a short-lived, inflammatory, oedematous swelling (a Calabar swelling) is produced around an adult worm. Heavy infections, especially when treated, may cause encephalitis.

Clinical features

The infection is often symptomless. The incubation period ranges from 3 months to over a year. The first sign is usually a Calabar swelling: an irritating, tense, localised swelling that may be painful, especially if beside a joint. The swelling is generally on a limb; it measures a few centimetres in diameter but may be diffuse and extensive. It usually disappears after a few days but may persist for 2–3 weeks. Several swellings may appear at irregular intervals, often in adjacent sites. Sometimes, there is urticaria and pruritus elsewhere. Occasionally, a worm may be seen wriggling under the skin, especially that of an eyelid, and may cross the eye under the conjunctiva, taking many minutes to do so.

Investigations

Diagnosis is by demonstrating microfilariae in blood taken during the day, but they may not always be found in patients with Calabar swellings. Quantitative blood smears are required before initiating treatment. Antifilarial antibodies are positive in 95% of patients and there is massive eosinophilia. Occasionally, a calcified worm may be seen on X-ray.

Management

DEC (see above) is curative, in a dose of 9–12 mg/kg daily, continued for 21 days. Albendazole may be an alternative and it has been suggested that pretreatment with albendazole may reduce the risk of severe reactions to DEC. It is used as first treatment with high microfilarial loads, since treatment with DEC may precipitate a severe ('Mazzotti') reaction in patients with a heavy microfilaraemia. This is characterised by fever, joint and muscle pain, and encephalitis; microfilaraemic patients should be given glucocorticoid cover. Apheresis followed by DEC has also been used in some experienced centres as an approach for patients with high microfilarial loads. Before DEC treatment, screen for onchocerciasis as it may cause a very severe reaction and worsen eye disease. Treatment for onchocerciasis with ivermectin or moxidectin may precipitate loa loa encephalopathy or death. Loa loa does not contain *Wolbachia*, so doxycycline is not effective.

Prevention

Building houses away from trees and having dwellings wire-screened reduce infections. Protective clothing and insect repellents are also useful. DEC in a dose of 5 mg/kg daily for 3 days each month is partially protective. Co-infection with onchocerciasis is common.

Onchocerciasis (river blindness)

Onchocerciasis results from infection by the filarial *Onchocerca volvulus*. The infection is conveyed by flies of the genus *Simulium*, which breed in rapidly flowing, well-aerated water. Adult flies inflict painful bites during the day, both inside and outside houses. While feeding, they pick up the microfilariae, which mature into the infective larva and are transmitted to a new host in subsequent bites. Humans are the only known hosts (Fig. 14.67).

Onchocerciasis is endemic in sub-Saharan Africa, Yemen and a few foci in Central and South America. It is estimated that 15 million people are infected and 1 million have vision loss. Due to onchocerciasis, huge tracts of fertile land lie virtually untilled and individuals and communities are impoverished.

Pathology

After inoculation of larvae by a bite, the worms mature in 2–4 months and live for up to 17 years in subcutaneous and connective tissues. At sites of trauma, over bony prominences and around joints, fibrosis may form nodules around adult worms, which otherwise cause no direct damage. Innumerable microfilariae, discharged by the female *O. volvulus*, move actively in these nodules and in the adjacent tissues. The microfilariae are widely distributed in the skin and may invade the eye. Live microfilariae elicit little tissue reaction, but dead ones may cause severe allergic inflammation, leading to hyaline necrosis and loss of collagen and elastin. Death of microfilariae in the eye causes inflammation and may lead to blindness.

Clinical features

The infection may remain symptomless for months or years. The first symptom is usually itching, localised to one quadrant of the body and later becoming generalised and involving the eyes. Transient oedema of part or all of a limb is an early sign, followed by papular urticaria, spreading gradually from the site of infection. In dark skins the most common signs are papules excoriated by scratching, spotty hyperpigmentation from resolving inflammation, and chronic changes of a rough, thickened and wrinkled skin. Both infected and uninfected superficial

Fig. 14.67 ***Onchocerca volvulus.*** Life cycle of organism and pathogenesis of onchocerciasis.

lymph nodes enlarge and may hang down in folds of loose skin in the groin. Hydrocele, femoral hernias and scrotal elephantiasis can occur. Firm subcutaneous nodules ≥ 1 cm in diameter (onchocercomas) occur in chronic infection.

Eye disease is most common in highly endemic areas and is associated with chronic heavy infections and nodules on the head. Early manifestations include itching, lacrimation and conjunctival injection. These cause conjunctivitis; sclerosing keratitis with pannus formation; uveitis, which may lead to glaucoma and cataract; and, less commonly, choroiditis and optic neuritis. Classically, 'snowflake' deposits are seen in the edges of the cornea.

Investigations

The finding of nodules or characteristic lesions of the skin or eyes in a patient from an endemic area, associated with eosinophilia, is suggestive. Skin snips or shavings, taken with a corneoscleral punch or scalpel blade from calf, buttock and shoulder, are placed in saline under a cover slip on a microscope slide and examined after 4 hours. Microfilariae are seen wriggling free in all but the lightest infections. Slit-lamp examination may reveal microfilariae moving in the anterior chamber of the eye or trapped in the cornea. An excised nodule may reveal a coiled, thread-like adult worm.

Filarial antibodies are positive in up to 95% of patients. Rapid strip tests to detect antibody or antigen are under clinical evaluation. When there is a strong suspicion of onchocerciasis but tests are negative, a provocative Mazzotti test, in which administration of 0.5–1.0 mg/kg of DEC exacerbates pruritus or dermatitis, strongly suggests onchocerciasis. PCR, though highly sensitive and specific, is not available commercially.

Management

Ivermectin is recommended, in a single dose of 100–200 µg/kg, repeated several times at 3-monthly intervals to prevent relapses. It kills microfilariae and has minimal toxicity. In the rare event of a severe reaction causing oedema or postural hypotension, prednisolone 20–30 mg may be given daily for 2 or 3 days. Ivermectin has little macrofilaricidal effect so that, 1 year after ivermectin treatment, skin microfilarial densities regain at least 20% of pre-treatment levels; repeated treatments are required for the lifespan of the adult worm. Eradication of *Wolbachia* with doxycycline (100 mg daily for 6 weeks) prevents worm reproduction. See above for interaction with loa loa treatment, in which case a strategy such as first treating with albendazole to lower the loa loa microfilarial load may be required if this is found to be high.

Prevention

Mass treatment with ivermectin reduces community morbidity and slows the progression of eye disease, but it does not clear worm infection. *Simulium* can be destroyed in its larval stage by the application of insecticide to streams. Long trousers, skirts and sleeves discourage the fly from biting. Co-infection with loa loa is common.

Dracunculiasis (Guinea worm)

Infestation with the Guinea worm *Dracunculus medinensis* manifests when the female worm, over a metre long, emerges from the skin. Humans are infected by ingesting a small crustacean, *Cyclops*, which inhabits wells and ponds, and contains the infective larval stage of the worm. Global programmes have almost eradicated this disease. However, recent findings of dracunculiasis in animals pose a challenge to eradication efforts. This is especially the case for dogs in Chad. In 2023 there were only 14 cases predominantly in Chad.

Management and prevention

Traditionally, the protruding worm is extracted by winding it out gently over several days on a matchstick. The worm must never be broken. Antibiotics for secondary infection and prophylaxis of tetanus are also required.

The global eradication campaign aims to provide clean drinking water and eradicate water fleas from drinking water by simple filtration of water through a plastic mesh filter and chemical treatment of water supplies.

Other filariases

Mansonella perstans

This filarial worm is transmitted by the midges *Culicoides austeni* and *C. grahami*. It is common throughout equatorial Africa, as far south as Zambia, and also in Trinidad and parts of northern and eastern South America.

M. perstans has never been proven to cause disease but it may be responsible for a persistent eosinophilia and occasional allergic manifestations. *M. perstans* is resistant to ivermectin and DEC; however, anti-*Wolbachia* treatment (doxycycline 200 mg daily for 6 weeks) can cure this infection.

Dirofilaria immitis

This dog heartworm infects humans, causing skin and lung lesions. It is not uncommon in the USA, Japan and Australia.

Zoonotic nematodes

Trichinosis (trichinellosis)

Trichinella spiralis is a nematode that parasitises rats and pigs, and is transmitted to humans by ingestion of partially cooked infected pork, particularly sausage or ham, or occasionally by bear meat. Symptoms result from invasion of intestinal submucosa by ingested larvae, which develop into adult worms, and the secondary invasion of striated muscle by fresh larvae produced by these adult worms. Outbreaks have occurred in countries where pork is eaten.

Clinical features

The clinical features of trichinosis are determined by the larval numbers. A light infection with a few worms may be asymptomatic; a heavy infection causes nausea and diarrhoea 24–48 hours after the infected meal. A few days later, the symptoms associated with larval invasion predominate: there is fever and oedema of the face, eyelids and conjunctivae; invasion of the diaphragm may cause pain, cough and dyspnoea; and involvement of the muscles of the limbs, chest and mouth causes stiffness, pain and tenderness in affected muscles. Larval migration may cause acute myocarditis and encephalitis. Eosinophilia, which can be very high, is observed after 10 days. An intense infection may prove fatal but those who survive recover completely.

Investigations

Frequently, people who have eaten infected pork from a common source develop symptoms at about the same time. Biopsy from the deltoid or gastrocnemius muscle after the third week of symptoms may reveal encysted larvae. Serological tests are also helpful.

Management

Treatment is with albendazole (400 mg twice daily for 8–14 days) or mebendazole (200–400 mg 3 times daily for 3 days, followed by 400–500 mg 3 times daily for 10 days). Treatment commenced early in infection kills newly formed adult worms in the submucosa and reduces the number of larvae reaching the muscles. Glucocorticoids are necessary to control the serious effects of acute inflammation.

Anisakiasis (herring worm)

This infection is caused by the larvae of a fish nematode (*Anisakis simplex* or *Pseudoterranova decipiens*) and is associated with consumption of under-cooked fish or squid. The parasite cannot complete its life cycle in humans but larval ingestion is associated with pharyngeal tingling, abdominal pain, diarrhoea and vomiting. Diagnosis is made by identification of the larva by patients or endoscopists, and albendazole (400 mg twice a day for 5 days) treats larvae that are not manually removed.

Cutaneous larva migrans

Cutaneous larva migrans (CLM) is the most common linear lesion seen in travellers (Fig. 14.68). Intensely pruritic, linear, serpiginous lesions result from the larval migration of the dog hookworm (*Ancylostoma caninum*). The track moves across the skin at a rate of 2–3 cm/day. This contrasts with the fast-moving transient rash of *Strongyloides*. Although the larvae of dog hookworms frequently infect humans, they do not usually develop into the adult form. The most common site for CLM is the foot but elbows, breasts and buttocks may be affected. Most patients with CLM have recently visited a beach where the affected part was exposed. The diagnosis is clinical. Treatment may be local with 12-hourly application of 15% thiabendazole cream, or systemic with a single dose of albendazole (400 mg) or ivermectin (150–200 µg/kg).

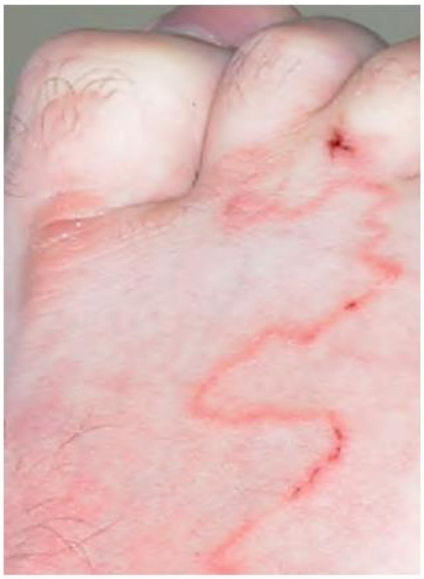

Fig. 14.68 **Cutaneous larva migrans.** *Courtesy of Dr Ravi Gowda, Royal Hallamshire Hospital, Sheffield.*

Angiostrongylus cantonensis

The rat lungworm infects humans in Asia and the Pacific basin, via ingestion of infected snails or contaminated water. It causes eosinophilic meningitis. The role of combination therapy with glucocorticoids and albendazole remains controversial.

Gnathostomiasis

Gnathostomiasis occurs predominantly in South-east Asia and is due to *Gnathostoma spinigerum*. It also occurs in other parts of Asia, Central and South America, and Africa. Humans are infected by the larvae from intermediate hosts (raw or under-cooked freshwater fish, shrimps and frogs) and are not definitive hosts, so the life cycle is incomplete. Pruritic, painful, migratory nodules appear 3–4 weeks after ingestion due to larval migration. Complications include cough, visual disturbance, eosinophilic meningitis or encephalitis. Serology confirms diagnosis and the preferred treatment is albendazole (400 mg twice daily) for 21 days, but its role in visual or neurological disease is uncertain as it may increase larval migration.

Trematodes (flukes)

These leaf-shaped worms are parasitic to humans and animals. Their complex life cycles may involve one or more intermediate hosts, often freshwater molluscs.

Schistosomiasis

Schistosomiasis is a major cause of morbidity in the tropics. The species commonly causing disease in humans are: *Schistosoma haematobium*, *S. mansoni*, *S. japonicum*, *S. mekongi* and *S. intercalatum*. *S. haematobium* is sometimes called bilharzia or bilharziasis. Schistosome eggs have been found in Egyptian mummies.

The life cycle is shown in Figure 14.69A. The ovum is passed in the urine or faeces of infected individuals and gains access to fresh water,

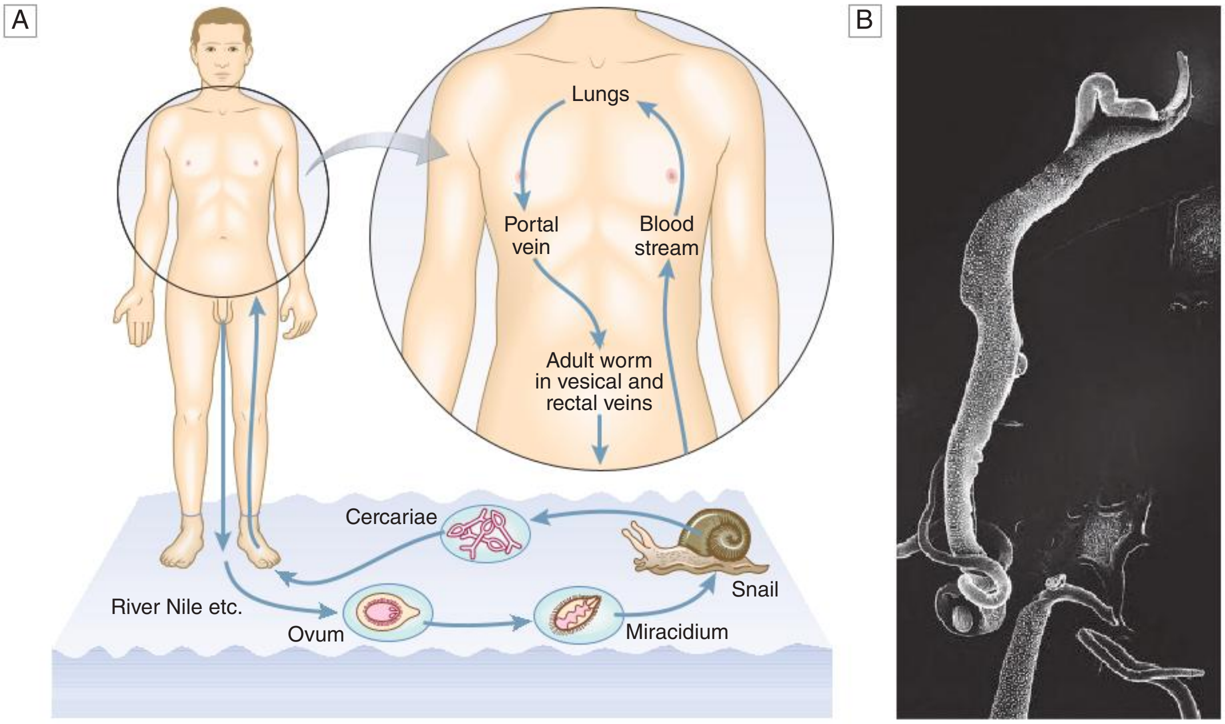

Fig. 14.69 ***Schistosoma.*** **A** Life cycle. **B** Scanning electron micrograph of adult schistosome worms, showing the larger male worm embracing the longer thinner female.

where the ciliated miracidium is liberated; it enters its intermediate host, a species of freshwater snail, and multiplies. Large numbers of fork-tailed cercariae are then liberated into the water, where they may survive for 2–3 days. Cercariae can penetrate the skin or the mucous membrane of the mouth of humans. They transform into schistosomulae and moult as they pass through the lungs; then they are carried by the blood stream to the liver, and so to the portal vein, where they mature. The male worm is up to 20 mm in length and the slenderer cylindrical female, usually enfolded longitudinally by the male, is longer (Fig. 14.69B). Within 4–6 weeks of infection, they migrate to the venules draining the pelvic viscera, where the females deposit ova.

Pathology

The passage of eggs through mucosa and the granulomatous reaction to eggs deposited in tissues causes disease. The eggs of *S. haematobium* pass mainly through the bladder wall but may also involve the rectum, seminal vesicles, vagina, cervix and uterine tubes. *S. mansoni* and *S. japonicum* eggs pass mainly through the wall of the lower bowel or are carried to the liver. The most serious, although rare, site of ectopic egg deposition is the CNS. Granulomas are composed of macrophages, eosinophils, and epithelioid and giant cells around an ovum. Later, there is fibrosis and eggs calcify, which is often visible radiologically. Eggs of *S. haematobium* may leave the vesical plexus and be carried directly to the lung. Those of *S. mansoni* and *S. japonicum* may also reach the lungs after the development of portal hypertension and consequent portasystemic collateral circulation. Egg deposition in the pulmonary vasculature, and the resultant host response, can lead to pulmonary hypertension.

Clinical features

Recent travellers, especially those overlanding through Africa, may present with allergic manifestations and eosinophilia; residents of schistosomiasis-endemic areas are more likely to present with chronic urinary tract pathology or portal hypertension.

During early infection, there may be itching lasting 1–2 days at the site of cercarial penetration ('swimmer's itch'). After a symptom-free period of 3–5 weeks, acute schistosomiasis (Katayama syndrome) may present with allergic manifestations: urticaria, fever, muscle aches, abdominal pain, headaches, cough and sweating. On examination, hepatomegaly, splenomegaly, lymphadenopathy and pneumonia may be present. These allergic phenomena may be severe in infections with *S. mansoni* and *S. japonicum*, but are rare with *S. haematobium*. The features subside after 1–2 weeks.

Chronic schistosomiasis is due to egg deposition and occurs months to years after infection. The symptoms and signs depend on the intensity of infection and the species of infecting schistosome (Box 14.81).

Schistosoma haematobium

Humans are the only natural hosts of *S. haematobium*, which is highly endemic in Egypt and East Africa, and occurs throughout Africa and the Middle East (Fig. 14.70). Infection can be acquired after a brief exposure, such as swimming in freshwater lakes in Africa.

Painless terminal haematuria is usually the first and most common symptom. Frequency of micturition follows, due to bladder neck obstruction. Later, frequent urinary tract infections, bladder or ureteric stones, hydronephrosis and ultimately renal failure with a contracted calcified bladder may occur. Pain is often felt in the iliac fossa or in the loin, and radiates to the groin. In several endemic areas, there is a strong epidemiological association of *S. haematobium* infection with squamous cell carcinoma of the bladder. Disease of the seminal vesicles may lead to haematospermia. Females may develop schistosomal papillomas of the vulva, and schistosomal lesions of the cervix may be mistaken for cancer. Intestinal symptoms may follow involvement of the bowel wall. Ectopic worms cause skin or spinal cord lesions.

The severity of *S. haematobium* infection varies greatly; light infections are often asymptomatic. However, as adult worms can live for 20 years or more and lesions may progress, these patients should always be treated.

14.81 Pathogenesis of schistosomiasis

Time	*Schistosoma haematobium*	*S. mansoni* and *S. japonicum*
Cercarial penetration		
Days	Papular dermatitis at site of penetration	As for *S. haematobium*
Larval migration and maturation		
Weeks	Pneumonitis, myositis, hepatitis, fever, 'serum sickness', eosinophilia, seroconversion	As for *S. haematobium*
Early egg deposition		
Months	Cystitis, haematuria	Colitis, granulomatous hepatitis, acute portal hypertension
	Ectopic granulomatous lesions: skin, CNS etc. Immune complex glomerulonephritis	As for *S. haematobium*
Late egg deposition		
Years	Fibrosis and calcification of ureters, bladder: bacterial infection, calculi, hydronephrosis, carcinoma	Colonic polyposis and strictures, periportal fibrosis, portal hypertension
	Pulmonary granulomas and pulmonary hypertension	As for *S. haematobium*

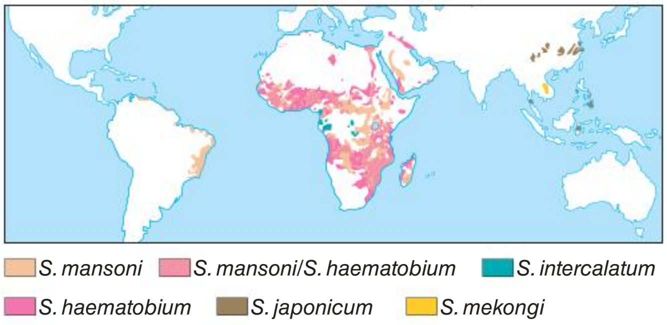

Fig. 14.70 Geographical distribution of schistosomiasis. Map lines delineate study areas and do not necessarily depict accepted national boundaries. *From Gryseels B, Polman K, Clerinx J, Kestens L. Human schistosomiasis. Lancet. 2006;368(9541):1106–1118.*

Schistosoma mansoni

S. mansoni is endemic throughout Africa, the Middle East, Venezuela, Brazil and the Caribbean (see Fig. 14.70).

Characteristic symptoms begin from 2 months after infection. They may be minimal (e.g. malaise) or consist of abdominal pain and frequent stools that contain blood-stained mucus. With severe advanced disease, increased discomfort from rectal polyps may be experienced. The early hepatomegaly is reversible but portal hypertension may cause massive splenomegaly, fatal haematemesis from oesophageal varices, or progressive ascites. Liver function is initially preserved because the pathology is fibrotic rather than cirrhotic. *S. mansoni* and other schistosome infections predispose to the carriage of *Salmonella*, in part because *Salmonella* may attach to the schistosomes and in part because shared antigens on schistosomes may induce immunological tolerance to *Salmonella*.

Schistosoma japonicum, S. mekongi and *S. intercalatum*

In addition to humans, the adult worm of *S. japonicum* infects the dog, rat, field mouse, water buffalo, ox, cat, pig, horse and sheep. Although other *Schistosoma* spp. can infect species other than humans, the non-human reservoir seems to be particularly important only in transmission for *S. japonicum*. *S. japonicum* is prevalent in the Yellow River and Yangtze–Jiang basins in China, where the infection is a major public health problem. It also has a focal distribution in the Philippines, Indonesia and Thailand (see Fig. 14.70). The related *S. mekongi* occurs in Laos, Thailand and Myanmar, and *S. intercalatum* in West and Central Africa.

The pathology of *S. japonicum* is similar to that of *S. mansoni*, but as this worm produces more eggs, the lesions tend to be more extensive and widespread. The clinical features resemble those of severe infection with *S. mansoni*, with added neurological features. The small and large bowel may be affected, and hepatic fibrosis with splenic enlargement is usual. Deposition of eggs or worms in the CNS, especially in the brain or spinal cord, causes symptoms in about 5% of infections, notably epilepsy, blindness, hemiplegia or paraplegia.

Investigations

There is marked eosinophilia. Serological tests (ELISA) are useful as screening tests but remain positive after treatment.

In *S. haematobium* infection, dipstick urine testing shows blood and albumin. The eggs can be found by microscopic examination of the centrifuged deposit of terminal stream urine (Fig. 14.71). Ultrasound assesses the urinary tract; bladder wall thickening, hydronephrosis and bladder calcification can be detected. Cystoscopy reveals ‘sandy’ patches, bleeding mucosa and later distortion.

In a heavy infection with *S. mansoni* or *S. japonicum*, the characteristic egg with its lateral spine can usually be found in the stool. When the infection is light or of long duration, a rectal biopsy can be examined. Sigmoidoscopy may show inflammation or bleeding. Biopsies should be examined for ova. PCR, though highly sensitive and specific, is not widely available.

Management

Therapy aims to kill the adult schistosomes and stop egg-laying. Praziquantel (20 mg/kg orally twice daily for 1 day) is the drug of choice for all forms of schistosomiasis except *S. japonicum* and *S. mekongi*, for which 20 mg/kg for 3 doses is recommended. The drug produces parasitological cure in 80% of treated individuals and over 90% reduction in egg counts in the remainder. Side-effects are uncommon but include nausea and abdominal pain. Praziquantel therapy in early infection reverses hepatomegaly, bladder wall thickening and granulomas.

Surgery may be required to deal with residual lesions such as ureteric stricture, small fibrotic urinary bladders, or granulomatous masses in the brain or spinal cord. Removal of rectal papillomas by diathermy or by other means may provide symptomatic relief.

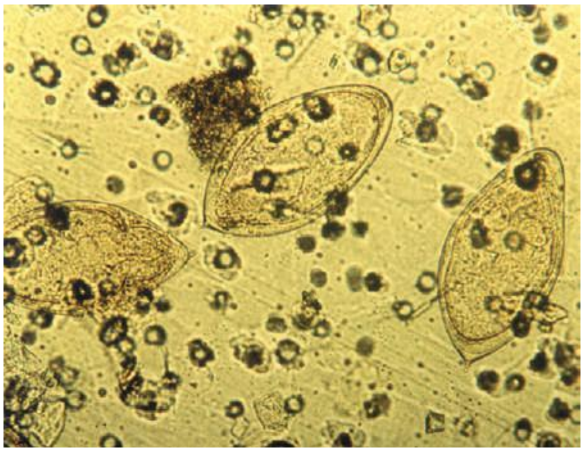

Fig. 14.71 Ova of *Schistosoma haematobium* in urine. *Note the terminal spike.*

Prevention

No single means of controlling schistosomiasis has been established to date. The life cycle is terminated if fresh water containing the snail host is not contaminated by ova-containing urine or faeces. The provision of latrines and of a safe water supply, however, remains challenging in rural areas throughout the tropics. Furthermore, *S. japonicum* has multiple hosts besides humans; therefore, latrines would have little impact. Population mass treatment annually helps prevent *S. haematobium* and *S. mansoni* infection but so far has had little success with *S. japonicum*. Targeting the intermediate host, the snail, is problematic and has not, on its own, proved successful. For personal protection, contact with infected water must be avoided.

Liver flukes

Liver flukes infect at least 20 million people and remain public health priorities in endemic areas. Clinical symptoms are abdominal pain, hepatomegaly and relapsing cholangitis. *Clonorchis sinensis* and *Opisthorchis felineus* are major aetiological agents of bile duct cancer. The three major liver flukes have similar life cycles and pathologies, as outlined in Box 14.82.

Other flukes of medical importance include lung and intestinal flukes (see Box 14.78).

i 14.82 Diseases caused by flukes in the bile duct

	Clonorchiasis	Opisthorchiasis	Fascioliasis
Parasite	*Clonorchis sinensis*	*Opisthorchis felineus*	*Fasciola hepatica*
Other mammalian hosts	Dogs, cats, pigs	Dogs, cats, foxes, pigs	Sheep, cattle
Mode of spread	Ova in faeces, water	As for *C. sinensis*	Ova in faeces on to wet pasture
1st intermediate host	Snails	Snails	Snails
2nd intermediate host	Freshwater fish	Freshwater fish	Encysts on vegetation
Geographical distribution	Far East, especially South China	Far East, especially North-east Thailand	Cosmopolitan, including UK
Pathology	*Escherichia coli* cholangitis, abscesses, biliary carcinoma	As for *C. sinensis*	Toxaemia, cholangitis, eosinophilia
Symptoms	Often symptom-free, recurrent jaundice	As for *C. sinensis*	Unexplained fever, tender liver, may be ectopic, e.g. subcutaneous fluke
Diagnosis	Ova in stool or duodenal aspirate	As for *C. sinensis*	As for *C. sinensis*, also serology
Prevention	Cook fish	Cook fish	Avoid contaminated watercress
Treatment	Praziquantel 25 mg/kg 3 times daily for 2 days	As for *C. sinensis* but for 1 day only	Triclabendazole 10 mg/kg single dose; repeat treatment may be required*

*In the UK, available from the Hospital for Tropical Diseases, London.

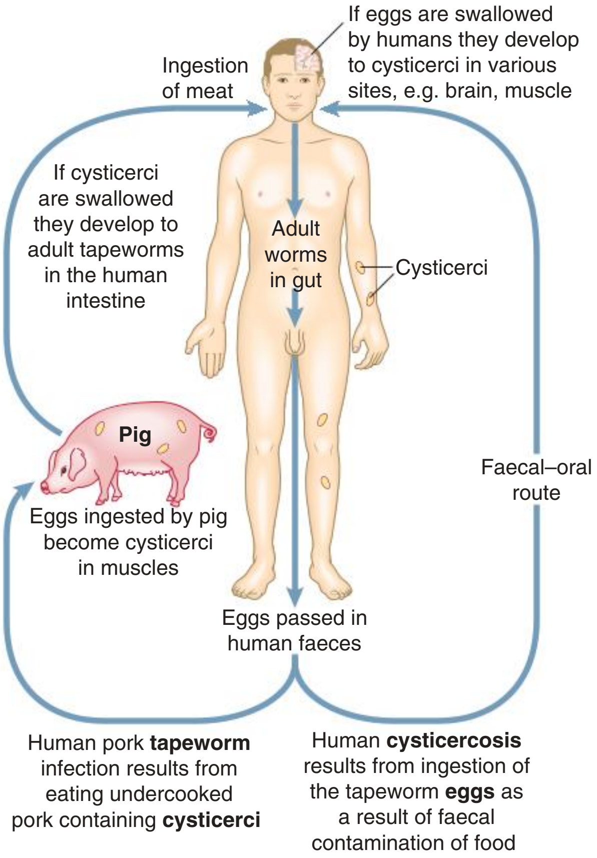
Cestodes (tapeworms)

Cestodes are ribbon-shaped worms that inhabit the intestinal tract. They have no alimentary system and absorb nutrients through the tegumental surface. The anterior end, or scolex, has suckers for attaching to the host. From the scolex, a series of progressively developing segments arise, the proglottides, which may continue to show active movements when shed. Cross-fertilisation takes place between segments. Ova, present in large numbers in mature proglottides, remain viable for weeks, and during this period they may be consumed by the intermediate host. Larvae liberated from the ingested ova pass into the tissues of the intermediate host, forming larval cysticerci.

Tapeworms cause two distinct patterns of disease: either intestinal infection or systemic cysticercosis (see Fig. 14.72). *Taenia saginata* (beef tapeworm), *Taenia asiatica* and *Diphyllobothrium latum* (fish tapeworm) cause only intestinal infection in humans, following ingestion of intermediate hosts. *Taenia solium* causes intestinal infection if a cysticerci-containing intermediate host is ingested, and cysticercosis (systemic infection from larval migration) if ova are ingested. *Echinococcus granulosus* (dog tapeworm) does not cause human intestinal infection, but causes hydatid disease (which is analogous to cysticercosis) following ingestion of ova and subsequent larval migration.

Intestinal tapeworm

Humans acquire tapeworm by eating under-cooked beef infected with the larval stage of *T. saginata*, under-cooked pork containing the larval stage of *T. solium* or *T. asiatica*, or under-cooked freshwater fish containing larvae of *D. latum*. Usually, only one adult tapeworm is present in the gut but up to 10 have been reported. The ova of all the three *Taenia* are indistinguishable microscopically. However, examination of scolex and proglottids can differentiate them: *T. solium* has a rostellum and two rows of hooklets on the scolex, and discharges multiple proglottids (3–5) attached together with lower degrees of uterine branching (approximately 10); *T. saginata* has only four suckers in its scolex, and discharges single proglottids with greater uterine branching (up to 30); *T. asiatica* has a rostellum without hooks on its scolex and is difficult to differentiate from *T. saginata*, except that there are fewer uterine branches (16–21).



If eggs are swallowed by humans they develop to cysticerci in various sites, e.g. brain, muscle
Ingestion of meat
If cysticerci are swallowed they develop to adult tapeworms in the human intestine
Adult worms in gut
Cysticerci
Pig
Faecal–oral route
Eggs ingested by pig become cysticerci in muscles
Eggs passed in human faeces
Human pork **tapeworm** infection results from eating undercooked pork containing **cysticerci**
Human **cysticercosis** results from ingestion of the tapeworm **eggs** as a result of faecal contamination of food

Fig. 14.72 Cysticercosis. Life cycle of *Taenia solium.*

Taenia solium

T. solium, the pork tapeworm, is common in central Europe, South Africa, South America and parts of Asia. It is smaller than *T. saginata*. The adult worm is found only in humans following the ingestion of pork containing cysticerci. Intestinal infection is treated with praziquantel (5–10 mg/kg) or niclosamide (2 g), both as a single dose, or alternatively with nitazoxanide (500 mg twice daily for 3 days). These are followed by a mild laxative (after 1–2 hours) to prevent retrograde intestinal autoinfection. Cooking pork well prevents intestinal infection. Great care must be taken while attending a patient harbouring an adult worm to avoid ingestion of ova or segments.

Taenia saginata

Infection with *T. saginata* occurs in all parts of the world. The adult worm may be several metres long and produces minimal intestinal upset in human beings, but identification of segments in the faeces or on underclothing distresses patients. Ova may be found in the stool. Praziquantel is the drug of choice; niclosamide or nitazoxanide are alternatives. Prevention depends on efficient meat inspection and thorough cooking of beef.

Taenia asiatica

T. asiatica is a newly recognised species of *Taenia*, restricted to Asia. It is acquired by eating uncooked meat or viscera of pigs. Clinical features and treatment are similar to those of *T. saginata*.

Cysticercosis

Human cysticercosis is acquired by ingesting *T. solium* tapeworm ova, from either contaminated fingers or food (Fig. 14.72). The larvae are liberated from eggs in the stomach, penetrate the intestinal mucosa and are carried to many parts of the body, developing into cysticerci, 0.5–1 cm cysts that contain the head of a young worm. They do not grow further or migrate. Common locations are subcutaneous tissue, skeletal muscles and brain (Fig. 14.73).

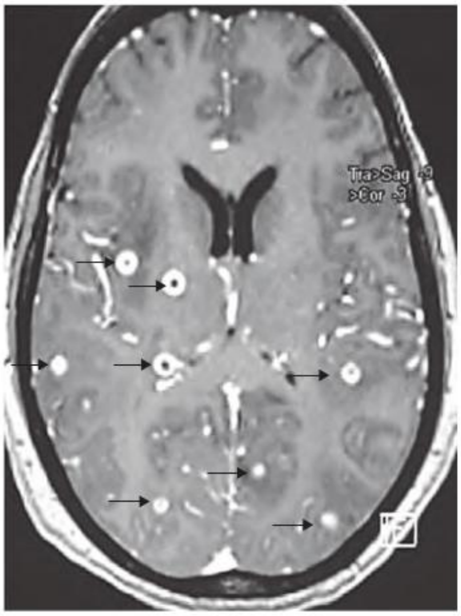


Fig. 14.73 Gadolinium enhanced T1 axial image demonstrating multiple ring-enhancing lesions typical of neurocysticercomas (neurocysticercomata). Arrows show the largest lesions.

Clinical features

Superficial cysts can be palpated under the skin or mucosa as pea-like ovoid bodies, but cause few or no symptoms and eventually die and calcify.

Heavy brain infections, especially in children, may cause features of encephalitis. More commonly, however, cerebral signs do not occur until the larvae die, 5–20 years later. Epilepsy, including new-onset focal seizures, stroke-like syndromes, personality changes, staggering gait and signs of hydrocephalus, are the most common features. Neurocysticercosis is a common cause of seizures in developing countries and may present with features referred to psychiatrists because of changes in personality.

Investigations

Calcified cysts in muscles can be recognised radiologically. In the brain, however, less calcification takes place and larvae are only occasionally visible by plain X-ray; CT or magnetic resonance imaging (MRI) will usually show them. Epileptic fits starting in adult life suggest the possibility of cysticercosis if the patient has lived in or travelled to an endemic area. The subcutaneous tissue should be palpated and any nodule excised for histology. Radiological examination of the skeletal muscles may be helpful. Antibody detection is available for serodiagnosis.

Management and prevention

Albendazole (15 mg/kg daily for a minimum of 8 days) is recommended for parenchymal neurocysticercosis. Praziquantel (50 mg/kg in 3 divided doses daily for 10 days) is another option. Prednisolone (10 mg 3 times daily) is also given for 14 days, starting 1 day before anti-cysticercosis therapy. Antiepileptic drugs are often prescribed until the reaction in the brain has subsided. Operative intervention is indicated for hydrocephalus. Studies from India and Peru suggest that most small, solitary cerebral cysts will resolve without treatment.

Echinococcus granulosus (*Taenia echinococcus*) and hydatid disease

Dogs are the definitive hosts of the tiny tapeworm *E. granulosus*. The larval stage, a hydatid cyst, normally occurs in sheep, cattle, camels and other animals exposed to contaminated pastures or water. By handling a dog or drinking contaminated water, humans may ingest eggs (Fig. 14.74). The embryo is liberated from the ovum in the small intestine and invades the blood stream, spreading to the liver. The resultant cyst grows very slowly, sometimes intermittently. It is composed of an enveloping fibrous pericyst, laminated hyaline membrane (ectocyst) and inner germinal layers (endocyst) that give rise to daughter cysts, or a germinating cystic brood capsule in which larvae (protoscolices) develop. Over time, some cysts calcify and become non-viable. The disease is common in the Middle East, North and East Africa, Australia and Argentina. Foci of infection persist in the UK in rural Wales and Scotland. *E. multilocularis*, which has a cycle between foxes and voles, causes a similar but more severe infection, 'alveolar hydatid disease', which invades the liver like cancer.

Clinical features

A hydatid cyst is typically acquired in childhood and, after growing for years, may cause site-specific pressure symptoms. In nearly 75% of patients the right lobe of the liver is invaded and contains a single cyst. In others, a cyst may be found in lung, bone, brain or elsewhere.

Investigations

The diagnosis depends on the clinical, radiological and ultrasound findings in a patient that has close contact with dogs in an endemic area. Complement fixation and ELISA are positive in 70%–90% of patients.

Management and prevention

Hydatid cysts should be excised wherever possible. Great care is taken to avoid spillage and cavities are sterilised with 0.5% silver nitrate or 2.7% sodium chloride. Albendazole (400 mg twice daily for 3 months) should also be used and is often combined with PAIR (percutaneous puncture, aspiration, injection of scolicidal agent and re-aspiration). Praziquantel (20 mg/kg twice daily for 14 days) also kills protoscolices perioperatively.

Prevention is difficult when there is a close association with dogs. Personal hygiene, satisfactory disposal of carcasses, meat inspection and deworming of dogs reduces disease prevalence.

Other tapeworms

Other cestodes' adult or larval stages may infect humans. In sparganosis an immature worm develops, usually subcutaneously, as a result of eating or applying to the skin the secondary or tertiary intermediate host, such as frogs or snakes.

Ectoparasites

Ectoparasites only interact with the outermost surfaces of the host; see also page 1122.

Jiggers (tungiasis)

This is widespread in tropical America and Africa and is caused by the sand flea *Tunga penetrans*. The pregnant flea burrows into the skin around toes and produces large numbers of eggs. The burrows are intensely irritating and the whole inflammatory nodule should be removed with a sterile needle. Secondary infection of lesions is common.

Myiasis

Myiasis is due to skin infestation with larvae of the South American botfly, *Dermatobia hominis*, or the African tumbu fly, *Cordylobia anthropophaga*. The larvae develop in a subcutaneous space with a central sinus (see Fig. 14.8A). This orifice is the air source for the larvae, and periodically the larval respiratory spiracles protrude through the sinus (see Fig. 14.8B). Patients with myiasis feel movement within the larval burrow and can experience intermittent sharp, lancinating pains. Myiasis is diagnosed clinically and should be suspected with any furuncular lesion accompanied by pain and a crawling sensation in the skin. The larva may be suffocated by blocking the respiratory orifice with petroleum jelly and gently removing it with tweezers. Secondary infection of myiasis is rare and rapid healing follows removal of intact larvae.

Fungal infections

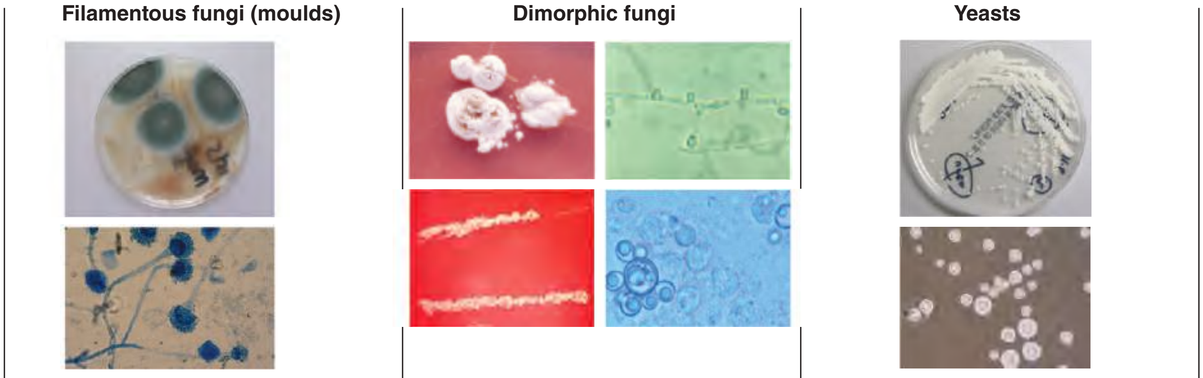
Fungal infections, or mycoses, are classified as superficial, subcutaneous or systemic (deep), depending on the degree of tissue invasion. They are caused by filamentous fungi (moulds), by yeasts or by fungi that vary between these two forms, depending on environmental conditions (dimorphic fungi; Fig. 14.75). Following changes to the International Code of Nomenclature for algae, fungi and plants, the practice of giving different names to teleomorph (sexual state) and anamorph (asexual) forms of the same fungus was discontinued, meaning, for example, that *Filobasidiella neoformans* became a synonym of the earlier name *Cryptococcus neoformans*.

Superficial mycoses

Superficial cutaneous fungal infections caused by dermatophyte fungi are described in Chapter 26. Increasing rates of *Trichophyton* spp. resistance to terbinafine are reported in countries such as India and are placing greater reliance on azole-based therapies.

Candidiasis (thrush)

Superficial candidiasis is caused by *Candida* spp., mainly *C. albicans*. Manifestations include oropharyngeal and vaginal candidiasis ('thrush'), intertrigo and chronic paronychia. Superficial candidiasis often follows antibiotic therapy. Intertrigo is characterised by inflammation in skin folds with surrounding 'satellite lesions'. Chronic paronychia is associated with frequent wetting of the hands. Superficial candidiasis is treated mainly with topical azoles (p. 151), oral azoles being reserved for refractory or recurrent disease. For oropharyngeal candidiasis in PWH, topical antifungals are usually effective. Antifungal lozenges are more effective than antifungal solutions. Systemic azole therapy, usually fluconazole, should be given if topical therapy fails or if there are oesophageal symptoms. Severe oropharyngeal and oesophageal candidiasis is seen with T-cell immunodeficiency, including HIV infection, and anti-IL-17 therapy. Recurrent vaginal or penile candidiasis may be a manifestation of diabetes. Rarely, mutations in the autoimmune regulator gene (*AIRE*) or signal



Filamentous fungi (moulds)

Characterised by the production of elongated, cylindrical, often septate cells (hyphae) and conidia (spores)

Examples:
- *Aspergillus* spp. (*A. fumigatus* shown here)
- *Fusarium* spp.
- Dermatophyte fungi (*Tricophyton* spp., *Microsporum* spp. etc.)
- Mucorales

Dimorphic fungi

Exist in filamentous (top) or yeast (bottom) form, depending on environmental conditions

Examples:
- *Histoplasma capsulatum*, *Coccidioides immitis*, *Paracoccidioides brasiliensis* (shown here), *Blastomyces dermatidis*
- *Sporothrix schenkii*
- *Talaromyces marneffei*
- *Malassezia* spp.

Yeasts

Characterised by the production of oval or round cells, which reproduce by binary fission (budding)

Examples:
- *Candida* spp.*
- *Cryptococcus* spp. (*C. neoformans* shown here)

Fig. 14.75 Classification of medically important fungi. Fungal classification is based on simple morphological characteristics. *Pneumocystis jirovecii* is morphologically distinct from other fungi and does not fit into this classification. *Although *Candida albicans* exists in a number of forms, including filamentous (hyphae and pseudohyphae), it is generally encountered in its yeast form so is classified in this category. *Insets (dimorphic fungi) Courtesy of Beatriz Gomez and Angela Restrepo, CIB, Medellín, Colombia.*

transducer and activator of transcription 1 (*STAT1*) cause a syndrome of chronic mucocutaneous candidiasis, resulting in chronic *Candida* infections of skin, mucosa and nails, with hyperkeratotic nails and erythematous periungual skin. Patients have cell-mediated immune defects against *Candida* and may have polyendocrinopathy and autoimmune features.

Subcutaneous mycoses

Chromoblastomycosis

Chromoblastomycosis is a predominantly tropical or subtropical disease caused by environmental dematiaceous (dark-pigmented) fungi, most commonly *Fonsecaea pedrosoi*. Other causes include *F. compacta, Cladophialophora carrionii* and *Phialophora verrucosa*. The disease is a cutaneous/subcutaneous mycosis acquired by traumatic inoculation, particularly in the foot, ankle and lower leg. Several months after inoculation, lesions develop. Medical attention is often sought several years later. The initial lesion is a papule. Further papules develop and coalesce to form irregular plaques. Nodular lesions may produce a characteristic 'cauliflower' appearance.

Diagnosis is by histopathological examination of infected material, revealing dematiaceous, rounded, thick-walled 'sclerotic bodies' with septa at right-angles to each other. The aetiological agent is confirmed by culture. Therapeutic approaches include antifungal agents, cryosurgery and surgical excision, alone or in combination, but the optimal therapy is unknown. Itraconazole and terbinafine are the most effective antifungal agents. However, posaconazole has also been used with a good outcome.

Mycetoma (eumycetoma and actinomycetoma)

Mycetoma is a chronic suppurative infection of the deep soft tissues and bones, notably the limbs but also the abdominal or chest wall or head. It is caused by either filamentous fungi, Eumyces (eumycetoma – 40%) or aerobic Actinomycetes (actinomycetoma – 60%). Many fungi cause eumycetomas, the most common being *Madurella mycetomatis*, *M. grisea*, *Leptosphaeria senegalensis* and *Scedosporium apiospermum*; causes of actinomycetoma include *Nocardia*, *Streptomyces* and *Actinomadura* spp. Both groups produce characteristically coloured 'grains' (microcolonies), the colour depending on the organism (black grains – eumycetoma, red and yellow grains – actinomycetoma, white grains – either). The disease occurs mostly in the tropics and subtropics.

Clinical features

The disease is acquired by inoculation (e.g. from a thorn), usually of the foot (Madura foot). A painless swelling at the inoculation site becomes chronic and progressive, spreads steadily within the soft tissues, and eventually penetrates bone. Subepidermal nodules mature and rupture, revealing sinuses that may discharge grains. Sinuses heal with scarring, while fresh sinuses appear elsewhere. Deeper tissue invasion and bone involvement are less rapid and extensive in eumycetoma than actinomycetoma. There is little pain and usually no fever or lymphadenopathy, but there is progressive disability.

Investigations

Diagnosis of mycetoma involves identification of grains in pus, and/or histopathological examination of tissue. Culture is necessary for species identification and susceptibility testing. Serological tests are not available.

Management

Eumycetoma is usually treated with a combination of surgery and antifungal therapy. Antifungal susceptibility testing, if available, is recommended, although clinical outcome does not necessarily correspond to in vitro test results. Itraconazole and ketoconazole (both 200–400 mg/day) are used most commonly. Success has also been reported with terbinafine monotherapy, and for some cases with liposomal amphotericin B. Refractory cases have responded to voriconazole or posaconazole. Therapy is continued for 6–12 months or longer. In extreme cases, amputation may be required. Recent studies have shown a new oral treatment, fosravuconazole, is safe, tolerated and effective in treating the fungal form. Actinomycetoma is treated with prolonged antibiotic combinations, most commonly streptomycin and dapsone. Dapsone is replaced by co-trimoxazole with intolerance or refractory disease. Success has also been reported with co-trimoxazole plus amikacin, with rifampicin added in difficult cases and to prevent recurrence.

Phaeohyphomycosis

Phaeohyphomycoses are a heterogeneous group of fungal diseases caused by a large number (> 70) of dematiaceous fungi. In phaeohyphomycosis, the tissue form of the fungus is predominantly mycelial (filamentous), as opposed to eumycetoma (grain) or chromoblastomycosis (sclerotic body). Disease may be superficial, subcutaneous or deep. The most serious manifestation is cerebral phaeohyphomycosis, which presents with a ring-enhancing, space-occupying cerebral lesion. Optimal therapy for this condition is not established but usually includes neurosurgical intervention and antifungal (usually triazole) therapy. Causative agents are *Cladophialophora bantiana*, *Fonsecaea* spp. and *Rhinocladiella mackenziei*, which occurs mainly in the Middle East and is usually fatal.

Sporotrichosis

Sporotrichosis is caused by *Sporothrix schenckii*, a dimorphic fungal saprophyte of plants in tropical and subtropical regions. Disease is caused by dermal inoculation of the fungus, usually from a thorn (occasionally from a cat scratch). A subcutaneous nodule develops at the site of infection and subsequently ulcerates, with a purulent discharge. The disease may then spread along the cutaneous lymphatic channels, resulting in multiple cutaneous nodules that ulcerate and discharge (lymphocutaneous sporotrichosis). Rarer forms include cutaneous disease presenting with arthritis. Later, draining sinuses may form. Pulmonary sporotrichosis occurs as a result of inhalation of the conidia (spores) and causes chronic cavitary fibronodular disease with haemoptysis and constitutional symptoms. Disseminated disease may occur, especially in immunocompromised hosts.

Investigations

Typical yeast forms detected on histology confirm diagnosis but are rarely seen; the fungus can also be cultured from biopsy specimens. ELISA detection of antibodies can be helpful.

Management

Cutaneous and lymphocutaneous disease is treated with itraconazole (200–400 mg daily, prescribed as the oral solution, which has better bioavailability than the capsule formulation) for 3–6 months. Alternative agents include a saturated solution of potassium iodide (SSKI, given orally), initiated with 5 drops and increased to 40–50 drops 3 times daily, or terbinafine (500 mg twice daily). Localised hyperthermia may be used in pregnancy (to avoid azole use). Osteoarticular disease requires a longer course of therapy (at least 12 months). Severe or life-threatening disease is treated with amphotericin B (lipid formulation preferred).

Systemic mycoses

Aspergillosis

Aspergillosis is an opportunistic systemic mycosis, which affects the respiratory tract predominantly. It is described on page 564.

Candidiasis

Systemic candidiasis is an opportunistic mycosis caused by *Candida* spp. The most common cause is *Candida albicans*. Other fungi include

Candida dubliniensis, *Nakaseomyces glabratus* (previously known as *Candida glabrata)*, *Candida krusei*, *Candida parapsilosis* and *Candida tropicalis*. *Candida* species identification often predicts susceptibility to fluconazole: *Candida krusei* is universally resistant, many *Nakaseomyces glabrata* isolates have reduced susceptibility or are resistant, and other species are mostly susceptible. Candidiasis is usually an endogenous disease that originates from oropharyngeal, genitourinary or skin colonisation, although nosocomial spread occurs. *Candida auris* is an emerging species, which has a particular propensity for nosocomial transmission.

Syndromes of systemic candidiasis

Acute disseminated candidiasis

This usually presents as candidaemia (isolation of *Candida* spp. from the blood). The main predisposing factor is the presence of a central venous catheter. Other major factors include recent abdominal surgery, total parenteral nutrition (TPN), recent antimicrobial therapy and localised *Candida* colonisation. Up to 40% of cases will have ophthalmic involvement, with characteristic retinal 'cotton wool' exudates. As this is a sight-threatening condition, all candidaemic patients should have a full ophthalmoscopy review. Skin lesions (non-tender pink/red nodules) may be seen. Although predominantly a disease of intensive care and surgical patients, acute disseminated candidiasis and/or *Candida* endophthalmitis is seen occasionally in injection drug-users, due to candidal contamination of citric acid or lemon juice used to dissolve heroin.

Chronic disseminated candidiasis (hepatosplenic candidiasis)

Persistent fever in a neutropenic patient, despite antibacterial therapy and neutrophil recovery, associated with the development of abdominal pain, raised alkaline phosphatase and multiple lesions in abdominal organs (e.g. liver, spleen and/or kidneys) on radiological imaging, suggests a diagnosis of hepatosplenic candidiasis. This represents a form of immune reconstitution syndrome in patients recovering from neutropenia and usually lasts for several months, despite appropriate therapy.

Other manifestations

Renal tract candidiasis, osteomyelitis, septic arthritis, peritonitis, meningitis and endocarditis may occur and are usually sequelae of acute disseminated disease. Diagnosis and treatment of these conditions require specialist mycological advice.

Management

Blood cultures positive for *Candida* spp. must never be ignored. Acute disseminated candidiasis is treated with antifungal therapy, removal of any in-dwelling central venous catheter (whether known to be the source of infection or not) and removal of any documented source. Candidaemia should be treated initially with an echinocandin (p. 151), with subsequent adjustment (usually to intravenous or oral fluconazole) guided by clinical response, species identification and susceptibility testing. Treatment should continue for a minimum of 14 days. Alternative therapies include voriconazole and amphotericin B formulations.

Chronic disseminated candidiasis requires prolonged treatment over several months with fluconazole or other agents, depending on species and clinical response. The duration of the condition may be reduced by adjuvant therapy with systemic glucocorticoids.

Cryptococcosis

Cryptococcosis is a systemic mycosis caused by two environmental yeast species, *Cr. neoformans* and *Cr. gattii*. *Cr. neoformans* (also known as *Filobasidiella neoformans*) is distributed worldwide and is primarily an opportunistic pathogen, most commonly associated with HIV infection or other immunocompromised hosts. *Cr. gattii* is a primary pathogen with a widespread distribution, including Australasia, Africa, Canada (Vancouver Island) and the north-western USA.

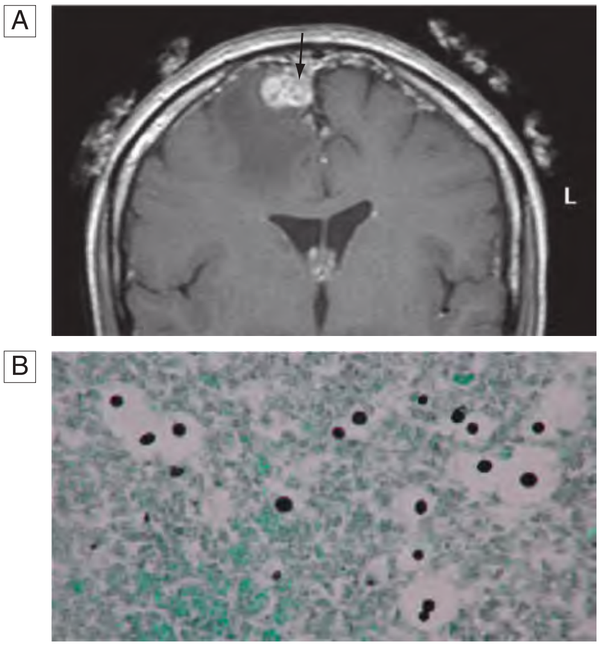


Fig. 14.76 Cryptococcal disease. A 23-year-old HIV-positive male developed headache and left-sided weakness. **A** MRI scan of the brain showed a space-occupying lesion (arrow) with surrounding oedema. **B** Histopathological examination of the lesion stained with Grocott silver stain showed encapsulated yeasts. *Cryptococcus neoformans* was cultured.

Cryptococcosis is acquired by inhalation of yeasts. These may disseminate to any organ, most commonly the CNS and skin. The manifestations of *Cr. neoformans* are most severe in immunocompromised individuals. Conversely, *Cr. gattii* causes severe disease in immunocompetent hosts. Disseminated cryptococcosis (sepsis with cryptococci present in the blood stream or at multiple sites) is largely restricted to immunocompromised patients. CNS manifestations of cryptococcosis include meningitis and cryptococcoma (Fig. 14.76), the latter more likely with *Cr. gattii* infection. Manifestations of pulmonary cryptococcosis range from severe pneumonia (in more immunocompromised patients) to asymptomatic disease with single or multiple pulmonary nodules, sometimes exhibiting cavitation (in patients with lesser immunosuppression). Cryptococcal nodules may mimic other causes of lung pathology, such as tuberculosis or malignancy, and diagnosis requires histopathology and/or culture.

Treatment of severe cryptococcosis is the same as for cryptococcal meningitis, initially with liposomal amphotericin B. Mild pulmonary disease, without any evidence of systemic disease, is usually treated with fluconazole, although for asymptomatic nodules resection of the lesions is likely to be sufficient.

Fusariosis

Fusarium spp. cause disseminated disease in patients with prolonged neutropenia. The disease presents with antibiotic-resistant fever and evidence of dissemination (e.g. skin nodules, endophthalmitis, septic arthritis, pulmonary disease; Fig. 14.77). Unlike *Aspergillus* spp., *Fusarium* spp. are often recovered from blood cultures. Treatment is challenging because of resistance to antifungal agents; voriconazole, posaconazole or lipid-formulated amphotericin B is usually prescribed.

Mucormycosis

Mucormycosis is a severe but uncommon opportunistic systemic mycosis caused by a number of 'mucoraceous' moulds, most commonly *Lichtheimia* spp., *Rhizomucor* spp., *Mucor* spp. and *Rhizopus* spp. Disease patterns include rhinocerebral/craniofacial, pulmonary,

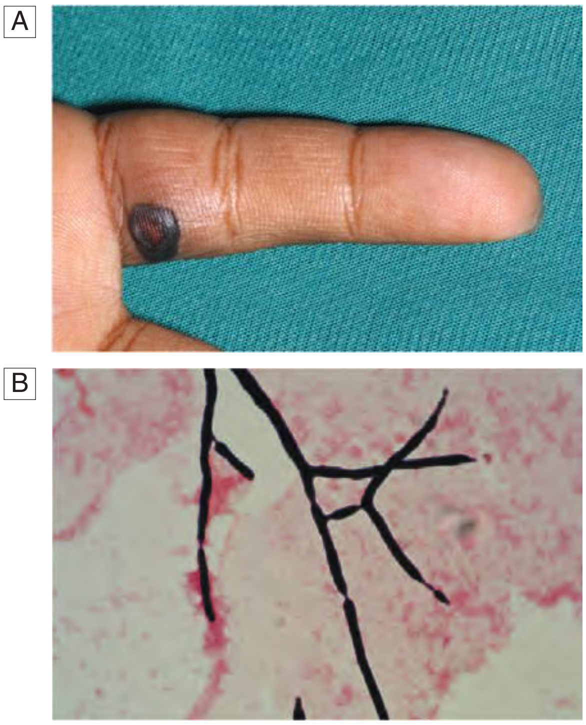

Fig. 14.77 ***Fusarium*** **infection.** A patient presented with fever and skin nodules after developing neutropenia secondary to haematopoietic stem cell transplantation and chemotherapy for relapsed leukaemia. *Fusarium solani* was cultured from skin lesions and blood cultures. **A** Tender, erythematous papule/nodule on the finger. **B** Gram stain of *Fusarium* in blood culture medium.

cutaneous and systemic disease. All are characterised by the rapid development of severe tissue necrosis, which is usually fatal if left untreated. The most common predisposing factors are profound immunosuppression from neutropenia and/or haematopoietic stem cell transplantation, uncontrolled diabetes, iron chelation therapy with desferrioxamine and severe burns. During the COVID-19 pandemic, mucormycosis emerged as a specific complication of COVID-19, reported mainly from India.

Definitive diagnosis is by culture but histopathological confirmation is required, as the fungi may be environmental contaminants. Treatment requires a combination of antifungal therapy and surgical débridement, with correction of predisposing factor(s) if possible. High-dose lipid-formulated amphotericin B is most commonly used. Posaconazole is active against many mucoraceous moulds in vitro and may be used as a second-line agent or as oral ‘step-down’ therapy.

Talaromyces marneffei infection

T. marneffei is a thermally dimorphic pathogen (filamentous in environmental conditions and yeast at body temperature), which causes disease in South-east Asia, mainly in association with HIV infection (although immunocompetent patients may also be infected). Acquisition is usually by inhalation of environmental spores, with primary lung infection followed by haematogenous dissemination. A generalised papular rash, which progresses to widespread necrosis and ulceration, is a characteristic feature. Skin lesions may resemble molluscum contagiosum. Diagnosis is by histopathology and/or culture of respiratory secretions, blood or any infected clinical material (e.g. skin lesions, bone marrow, biopsies). Treatment involves an amphotericin B formulation followed by itraconazole (in severe infection), or itraconazole alone.

Histoplasmosis

Histoplasmosis is a primary systemic mycosis caused by the dimorphic fungus *Histoplasma capsulatum*. *H. capsulatum* var. *capsulatum* is endemic to east-central USA (especially the Mississippi and Ohio river valleys), parts of Canada, Latin America, the Caribbean, East and South-east Asia, and Africa. It occurs sporadically in Australia and India and is very rare in Europe. Recent reports, however, describe a growing number of cases all around India, but primarily from Bengal, Assam, the west of India and the Gangetic plains. *H. capsulatum* var. *duboisii* is found in West Africa and Madagascar.

The primary reservoir of *H. capsulatum* is soil enriched by bird and bat droppings, in which the fungus remains viable for many years. Infection is by inhalation of infected dust. Natural infections are found in bats, which represent a secondary reservoir of infection. Histoplasmosis is a specific hazard for explorers of caves and people who clear out bird (including chicken) roosts.

Pathology

The organism is inhaled in the form of conidia or hyphal fragments and transforms to the yeast phase during infection. Conidia or yeasts are phagocytosed by alveolar macrophages and neutrophils, and this may be followed by haematogenous dissemination to any organ. Subsequent development of a T-lymphocyte response brings the infection under control, resulting in a latent state in most exposed individuals.

Clinical features

Disease severity depends on the quantity of spores inhaled and the immune status of the host. In most cases, infection is asymptomatic. Pulmonary symptoms are the most common presentation, with fever, non-productive cough and an influenza-like illness. Erythema nodosum, myalgia and joint pain frequently occur, and chest radiography may reveal a pneumonitis with hilar or mediastinal lymphadenopathy.

Patients with pre-existing lung disease, such as chronic obstructive pulmonary disease (COPD) or emphysema, may develop chronic pulmonary histoplasmosis (CPH). The predominant features of this condition, which mimics tuberculosis, are fever, cough, dyspnoea, weight loss and night sweats. Radiological findings include fibrosis, nodules, cavitation and hilar/mediastinal lymphadenopathy.

Disease caused by *H. capsulatum* var. *duboisii* presents more commonly with papulonodular and ulcerating lesions of the skin and underlying subcutaneous tissue and bone (sometimes referred to as ‘African histoplasmosis’). Multiple lesions of the ribs are common and the bones of the limbs may be affected. Lung involvement is relatively rare. Radiological examination may show rounded foci of bone destruction, sometimes associated with abscess formation. Other disease patterns include a visceral form with liver and splenic invasion, and disseminated disease.

Acute disseminated histoplasmosis is seen with immunocompromise, including HIV infection. Features include fever, pancytopenia, hepatosplenomegaly, lymphadenopathy and often a papular skin eruption. Chronic disseminated disease presents with fever, anorexia and weight loss. Cutaneous and mucosal lesions, lymphadenopathy, hepatosplenomegaly and meningitis may develop. *Emergomyces africanus* is a dimorphic fungus described in South Africa that causes a disseminated histoplasmosis-like illness, mainly associated with HIV infection. Histopathologically, yeast forms appear similar to histoplasmosis and can be distinguished only by PCR.

Investigations

Histoplasmosis should be suspected in endemic areas with every undiagnosed infection in which there are pulmonary signs, enlarged lymph nodes, hepatosplenomegaly or characteristic cutaneous/bony lesions. Radiological examination in long-standing cases may show calcified lesions in the lungs, spleen or other organs. In the more acute phases of the disease, single or multiple soft pulmonary shadows with enlarged tracheobronchial nodes are seen on chest X-ray.

Laboratory diagnosis is by direct detection (histopathology or antigen detection), culture and serology; although antigen detection is the most effective method, it is not widely available. Serology utilises complement fixation testing or immunodiffusion; interpretation is complex and requires a specialist. *Histoplasma* antigen may be detectable in blood or urine. Culture is definitive but slow (up to 12 weeks). Histopathology may show characteristic intracellular yeasts. Diagnosis of subcutaneous or bony infection is mainly by histopathological examination and/or culture.

Management

Mild pulmonary disease does not require treatment. However, if prolonged, it may be treated with itraconazole. More severe pulmonary disease is treated with an amphotericin B formulation for 2 weeks, followed by itraconazole for 12 weeks, with methylprednisolone added for the first 2 weeks of therapy if there is hypoxia or ARDS. CPH is treated with itraconazole oral solution for 12–24 months and disseminated histoplasmosis with an amphotericin B formulation followed by itraconazole for at least 3 months and for longer in more immunocompromised patients. Lipid formulations of amphotericin B are preferred, but their use is subject to availability. In subcutaneous and bone infection, patterns of remission and relapse are more common than cure. A solitary bony lesion may require local surgical treatment only.

Coccidioidomycosis

This is a primary systemic mycosis caused by the dimorphic fungi *Coccidioides immitis* and *C. posadasii*, found in the south-western USA and Central and South America. The disease is acquired by inhalation of conidia (arthrospores). In 60% of cases it is asymptomatic but in the remainder it affects the lungs, lymph nodes and skin. Rarely (in approximately 0.5%), it may spread haematogenously to bones, adrenal glands, meninges and other organs, particularly in those with immunocompromise.

Pulmonary coccidioidomycosis has two forms: primary and progressive. If symptomatic, primary coccidioidomycosis presents with cough, fever, chest pain, dyspnoea and (commonly) arthritis and a rash (erythema multiforme). Progressive disease presents with systemic upset (e.g. fever, weight loss, anorexia) and features of lobar pneumonia, and may resemble tuberculosis with cavitation.

Coccidioides meningitis (which may be associated with CSF eosinophils) is the most severe disease manifestation; it is fatal if untreated.

Investigations and management

Diagnosis is by direct histopathological detection in specimens, culture of infected tissue or fluids, or antibody detection. IgM may be detected after 1–3 weeks of disease by precipitin tests. IgG appears later and is detected with the complement fixation test. Change in IgG titre may be used to monitor clinical progress.

Treatment depends on specific disease manifestations and ranges from regular clinical reassessment without antifungal therapy (in mild pulmonary, asymptomatic cavitary or single nodular disease) to high-dose treatment with an antifungal azole (typically fluconazole), which may be continued indefinitely (e.g. in meningitis). Amphotericin B is used in diffuse pneumonia, disseminated disease and, intrathecally, in meningitis. Posaconazole has been used successfully in refractory disease.

Paracoccidioidomycosis

This is a primary systemic mycosis caused by inhalation of the dimorphic fungus *Paracoccidioides brasiliensis*, which is restricted to South America. The disease affects the lungs, mucous membranes (painful destructive ulceration in 50% of cases), skin, lymph nodes and adrenal glands (hypoadrenalism). Diagnosis is by microscopy and culture of lesions, and antibody detection. Oral itraconazole solution (200 mg/day) has demonstrated 98% efficacy and is currently the treatment of choice (mean duration 6 months). Ketoconazole, fluconazole, voriconazole and 2- to 3-year courses of sulphonamides are alternatives. Amphotericin B is used in severe or refractory disease, followed by an azole or sulphonamide.

Blastomycosis

Blastomyces dermatitidis is a dimorphic fungus endemic to restricted parts of North America, mainly around the Mississippi and Ohio rivers. Very occasionally, it is reported from Africa. The disease usually presents as a chronic pneumonia similar to pulmonary tuberculosis. Bones, skin and the genitourinary tract may also be affected. Diagnosis is by culture of the organism or identification of the characteristic yeast form in a clinical specimen. Antibody detection is rarely helpful. Treatment is with amphotericin B (severe disease) or itraconazole.

Pneumocystis

Pneumocystis is a yeast-like organism. The trophozoite is the vegetative form and is a single cell multilobed form. Thick-walled cysts contain the fungal spore. *Pneumocystis jirovecii* is the form found in humans. It is extracellular and found in the lungs after inhalation. It is commonly found in healthy lungs but appears to only cause disease with significant impairment to T-cell immunity. Clinical features are usually of dry cough, shortness of breath, fever and weight loss. Onset is subacute over several weeks. *Pneumocystis* pneumonia (PCP) may be more insidious in onset in PWH than other immunocompromised groups. Hypoxia develops and the radiological features are highly variable but most often result in interstitial infiltrates on chest X-ray or ground-glass features on CT of the chest.

Investigations and management

Diagnosis involves identification of the organism on induced sputum, bronchoalveolar lavage or rarely a tissue biopsy, using an immunofluorescence stain, silver stain or alternative to identify cysts or increasingly by identification using PCR. Sensitivity is lowest with induced sputum, but as this is least invasive, it is usually the first test employed. Serum β-D-glucan is also positive in PCP but is not specific. High-dose therapy with co-trimoxazole (20/100 mg/kg/day in four divided doses) is the treatment of choice for moderate–severe PCP (PO_2 < 9.3 kPa in PWH), combined with corticosteroids (prednisolone 40 mg twice daily orally × 5 days then 20 mg twice daily × 5 days then 20 mg once a day to complete a 21-day course. To limit toxicity, the co-trimoxazole dose is often reduced to 15/75 mg/kg/day after the first 3 days. For mild–moderate disease (PO_2 > 9.3 kPa, O_2 saturation > 92%), co-trimoxazole 2 double-strength tablets (1920 mg total dose) is used 3 times daily orally. The alternative therapy is clindamycin 1920 mg total dose 3 times daily intravenously combined with primaquine 30 mg orally for 21 days. When the patient is improving, those on intravenous therapy can switch to oral therapy co-trimoxazole 960 mg 3 times daily orally or clindamycin 600 mg 3 times daily combined with primaquine 20 mg once a day orally. Complications of PCP in PWH include pneumothoraces and acute respiratory distress syndrome (ARDS) with respiratory failure. Immunocompromised patients at risk of PCP, including PWH with a CD4 count < 200 cells/mm^3, or those recovering after initial treatment with PCP should receive prophylaxis until they are no longer at risk of PCP. Co-trimoxazole 480-960 mg once a day orally is preferred but pentamidine 300 mg given by nebuliser once a month or atovaquone 1500 mg once a day orally with food are alternatives.

Multiple Choice Questions

14.1. A 35-year-old conservationist returns from an extended stay in Central Africa. They have had recurrent fevers and lymphadenopathy. They failed to respond to a self-administered course of malaria treatment and have been increasingly bothered with headaches. They have also started to note some memory problems. A card agglutination trypanosomiasis test is positive for *Trypanosoma brucei gambiense* and a lymph node aspirate identifies trypanosomes. A lumbar puncture is performed and reveals white blood cells of 0.7×10^9/L and an elevated protein and reduced glucose are noted. Recommended treatment for this condition is with:

A. Eflornithine
B. Melarsoprol
C. Suramin
D. Nifurtimox and eflornithine combination therapy
E. Nifurtimox

Answer: D.

Nifurtimox and eflornithine combination therapy (NECT) is now the preferred therapy for *Trypanosoma brucei gambiense* stage 2 infection causing nervous system disease. It should be used when the CSF exam shows $\geq 0.1 \times 10^9$/L white blood cells or where a lumbar puncture is indicated but cannot be performed. Melarsoprol was used in the past but treatment was associated with significant mortality while NECT reduces the number of injections and side-effects associated with eflornithine monotherapy, which was used before the introduction of NECT. The other agents listed are used for other forms of trypanosomiasis.

14.2. A 35-year-old geologist returns from a 4-week period working in Siberia. Two weeks into his illness he developed fever and myalgia. Since then he has had low-grade symptoms until he developed severe headache and neck stiffness 2 days ago after returning from Siberia. This illness originated after a 3-day field trip when he camped in a wooded area with other colleagues. He has had no skin rash. He is admitted to hospital. Initial lumbar puncture reveals a raised white cell count, primarily lymphocytes and elevated protein. He is placed on ceftriaxone but after 3 days has noted no improvement. Initial investigations include negative Lyme disease serology and negative Lyme disease PCR. An HIV test is also negative. A dengue serology was sent from the accident and emergency room and is reportedly positive. Which of the following is most likely to establish the diagnosis?

A. Dengue PCR
B. Follow-up HIV serology
C. Rocky Mountain spotted fever serology and PCR
D. Follow-up lumbar puncture for Lyme disease serology in CSF
E. Tick-borne encephalitis virus serology and PCR

Answer: E.

Tick-borne encephalitis is the most likely cause of this syndrome. After a tick bite the initial illness occurs after a mean of 7 days, while emergence of meningitis or encephalitis can take up to a further 28 days. The causative agent is a flavivirus and cross-reactivity with other flavivirus infections, including dengue, is common. Lyme disease is also a consideration, but there has been no response to initial therapy. While this remains in the differential, serological testing on CSF is not a standard test. HIV should always be considered but the initial test was negative, although its interpretation relies on knowing when the individual last had unprotected sexual intercourse. Dengue and Rocky Mountain spotted fever infections are not located in the region visited.

14.3. A 74-year-old man with obesity and hypertension presents to the accident and emergency department with fever, loss of smell and respiratory distress in early December 2020. He is up to date on all vaccinations as of November 2020. A D-dimer test is elevated. A CT pulmonary angiogram is performed, which shows multiple pulmonary clots. A PCR performed on an upper respiratory sample is positive for a virus. Which virus is most likely to explain this combination of symptoms?

A. Adenovirus
B. Cytomegalovirus
C. Influenza A virus
D. Respiratory syncytial virus
E. SARS-CoV-2

Answer: E.

The symptoms are most likely caused by SARS-CoV-2. The development of pulmonary emboli has been particularly reported with COVID-19 though it can occur during many other infections. Although in some seasons the influenza A virus may evolve such that there is reduced vaccine efficacy, this only occurs in occasional flu seasons. Other respiratory virus infections would be less likely in this scenario and cytomegalovirus would only be likely if there was a history of very significant T-cell immunosuppression.

14.4. A 55-year-old woman is admitted with respiratory distress and an oxygen saturation of 88%. She was previously fit and well, but she works in a care home and recently many of the residents have been sick with COVID-19. An antiviral therapeutic that may have some activity against the causative SARS-CoV-2 is:

A. Oseltamivir
B. Remdesivir
C. Tenofovir
D. Palivizumab
E. Tocilizumab

Answer: B.

Remdesivir has antiviral activity against several viruses in vitro and some clinical trials show activity against SARS-CoV-2. Oseltamivir is used against influenza A, tenofovir against HIV and hepatitis B virus, and palivizumab is a monoclonal antibody used against respiratory syncytial virus. Tocilizumab is an anti-IL-6 monoclonal antibody that has shown anti-inflammatory activity in COVID-19, but it is not an antiviral. Tenofovir use in HIV may be associated with lower rates of hospitalisation with COVID-19, but there is no evidence this reflects antiviral activity against SARS-CoV-2.

14.5. A 76-year-old woman with diabetes mellitus is admitted with pyelonephritis and acute kidney injury. She has had multiple previous infections. Despite initial antimicrobial therapy she remains febrile and blood cultures now reveal *Klebsiella pneumoniae* resistant to multiple antimicrobials. The laboratory informs you that the strain is a KPC-2 carbapenemase-producing microorganism with a high meropenem minimum inhibitory concentration (MIC). She has previously been treated for a multidrug-resistant infection with colistin but developed renal impairment and encephalopathy. Subject to supportive sensitivities, which agent would you initially consider switching this patient onto?

A. Colistin
B. Ceftazidime–avibactam
C. Fosfomycin
D. Meropenem
E. Tigecycline

Answer: B.

Ceftazidime–avibactam is a β-lactam/β-lactamase inhibitor combination that can be used against many multidrug-resistant bacteria, sometimes in combinations. Although avibactam is not active against some carbapenemases, e.g. New Delhi metallo-β-lactamase, it is active against many, including the *K. pneumoniae*-producing β-lactamase (KPC-2) enzyme produced here. Although colistin may be required, her previous problems suggest other options should be considered first. Fosfomycin is primarily reserved for uncomplicated urinary tract infections and tigecycline or meropenem, when resistance is not associated with high minimum inhibitory concentrations, are reserved for combination therapy, often with colistin or aminoglycosides.

14.6. HIV infects cells bearing the CD4 receptor. Which co-receptor is required for HIV to enter the cell?

A. CD8
B. Chemokine receptor 5 (CCR5)
C. CD20
D. Major histocompatibility complex (MHC)
E. CD3

Answer: B.

Entry of HIV into the cell commences with binding of the envelope glycoprotein gp120 to the CD4 receptor. This results in a conformational change in gp120 that permits binding to one of two chemokine co-receptors, CCR5 or CXCR4. The chemokine co-receptor CCR5 is utilised during initial infection, but subsequently the virus may adapt to use CXCR4. Individuals who are homozygous for the CCR5 delta 32 mutation do not express CCR5 on CD4 cells and are immune to HIV infection.

14.7. Select the most important measure of the efficacy of antiretroviral therapy.

A. CD4 lymphocyte count
B. Weight gain
C. Viral load
D. Resolution of HIV symptoms
E. Absence of opportunistic infections

Answer: C.

The most important measure of effective antiretroviral therapy (ART) is a decrease in the level of HIV viraemia measured by quantitative PCR of HIV RNA, or ‘viral load’. Baseline viral load should be measured prior to initiating ART, and this should be repeated 4 weeks after starting ART, when there should be at least a 10-fold decrease. Once the viral load is suppressed (as defined according to local guidance) measurement should be repeated every 6–12 months.

The CD4 count is the most important laboratory indicator of the degree of immune suppression in HIV infection and CD4 counts usually increase rapidly in the first month after starting ART. However, CD4 responses are highly variable among patients and do not provide a rapid, sensitive and reliable measurement of the effectiveness of ART.

Weight gain, resolution of HIV symptoms and absence of opportunistic infections are all clinical markers of effective ART. However, as these are dependent on recovery of effective immune function, they change too slowly to provide a rapid, sensitive and reliable measurement of the initial and ongoing effectiveness of ART.

14.8. Access to antiretroviral therapy has markedly changed the epidemiology of HIV. Which of the following statements is correct about global epidemiology of HIV over the 5-year period 2014–2019?

A. Prevalence has decreased and incidence has decreased
B. Prevalence has decreased and incidence has increased
C. Prevalence has remained similar and incidence has decreased
D. Prevalence has increased and incidence has decreased
E. Prevalence has decreased and incidence has remained similar

Answer: D.

The incidence and prevalence of HIV infection are measures of the number of new infections per year and the total number of people living with HIV (PWH), respectively.

In 2024 it was estimated that there were 1.3 million new HIV infections, compared with 3.1 million in 2001 and 2.6 million in 2009; and there were 40.8 million PWH, compared with 28.6 million in 2001 and 33.3 million in 2009.* Therefore, the incidence of HIV infection has decreased but the prevalence has increased.

Although behavioural modification is likely to have contributed to the decrease in new infections, the main influence on both incidence and prevalence has been expansion of access to effective antiretroviral therapy (ART). ART reduces the incidence of new infections by reducing the likelihood of PWH infecting other people and increases the prevalence by prolonging the survival of PWH.

Sexually transmitted infections

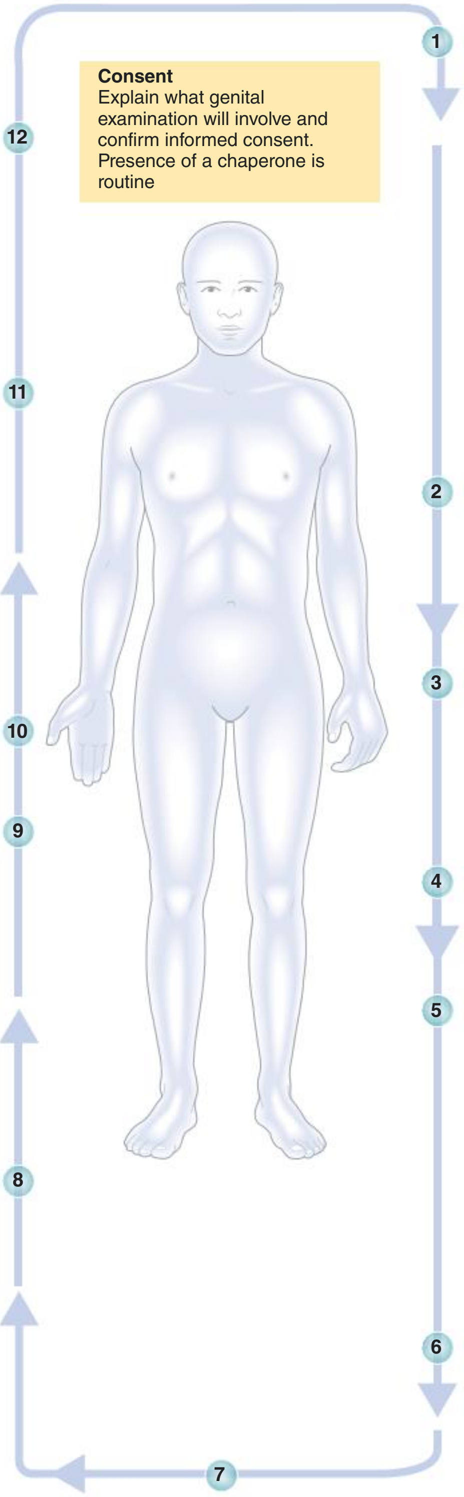
Clinical examination in sexually transmitted infection 406
Aetiology 408
Clinical assessment 408
Presenting problems 408
- Urethral discharge 408
- Genital itch, rash and discomfort 409
- Vaginal discharge 410
- Genital ulceration 410
- Genital lumps 411
- Proctitis 411
- Lower abdominal pain 411

Epidemiology 411
Prevention 412
Sexually transmitted bacterial infections 413
- Syphilis 413
- Gonorrhoea 415
- Chlamydial infection 416
- *Mycoplasma genitalium* 416
- Other sexually transmitted bacterial infections 416

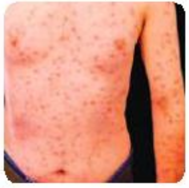
Sexually transmitted viral infections 416
- Genital herpes simplex 416
- Human papillomavirus and anogenital warts 418
- Molluscum contagiosum 419
- Mpox 419
- Viral hepatitis 419

Clinical examination in sexually transmitted infection

Consent
Explain what genital examination will involve and confirm informed consent. Presence of a chaperone is routine



1 Systemic signs on examination
Rash – HIV seroconversion, scabies, secondary syphilis, Mpox
Generalised lymphadenopathy – secondary syphilis, HIV
Extragenital chancres – primary syphilis
Polyarthritis – SARA
Septic monoarthritis – gonorrhoea
Peripheral/cranial neuropathies, psychosis or dementia – late syphilis



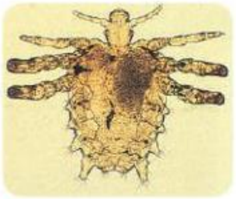
Syphilis rash

2 Head and neck
Meningism – meningovascular secondary syphilis/ severe primary HSV
Mouth – oral HSV lesions/syphilitic gumma/oral hairy leukoplakia in late presentation of HIV
Cervical lymphadenopathy – HIV

3 Abdomen
Right upper quadrant tenderness – chlamydial perihepatitis, acute viral hepatitis
Hepatosplenomegaly – secondary syphilis (abnormal LFTs)
Lower abdominal/pelvic tenderness – ascending bacterial infection (pelvicin flammatory disease)

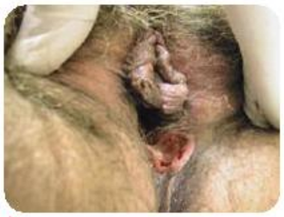
4 Inguinal glands
Generalised lymphadenopathy – secondary syphilis, HIV
Inguinal lymphadenopathy – HSV, primary syphilis, LGV

5 Skin of pubic area
Warts
Tinea cruris
Pthirus pubis



Pthirus pubis (crab louse)

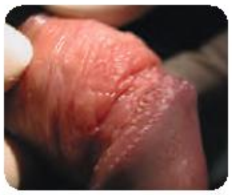
6 Labia majora and minora
Ulcers
Vulvitis
Note normal vestibular papillae and sebaceous glands



Vulval carcinoma

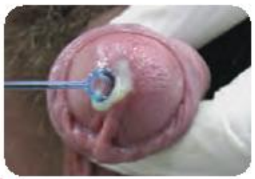
7 Vagina and cervix
Abnormal discharge
Warts
Ulcers
Inflammation
In women with lower abdominal pain, bimanual examination for adnexal tenderness (pelvic inflammatory disease)

8 Skin of penis
(Retract foreskin if present)
Genital warts
Ulcers
Be aware of normal anatomical features such as coronal papillae, or prominent sebaceous or parafrenal glands



Coronal papillae

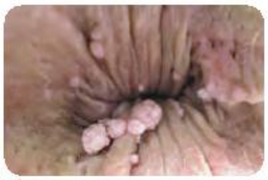
9 Urethral meatus
Mucoid/purulent discharge
Intrameatal ulcers or genital warts



Sampling discharge at urethral meatus

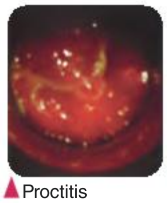
10 Scrotal contents
Abnormal masses or tenderness (epididymo-orchitis)

11 Perineum and perianal skin
Viral warts (condylomata acuminata)
Condylomata lata
Ulcers
Inflammation



Perianal warts

12 Rectum



Proctitis

Insets (Syphilis rash) From Woodward PJ, Kennedy A, Sohaey R, Eds. Diagnostic imaging: Obstetrics. ed 5. Philadelphia: Elsevier Inc.; 2026. (Coronal papillae, Discharge at urethral meatus, Perianal warts, Vulval carcinoma) From Clutterbuck DJ. Specialist training in sexually transmitted infections and HIV. St Louis: Mosby, Elsevier Inc.; 2004. (Proctitis) From McMillan A, Young H, Ogilvie MM, Scott GR. Clinical practice in sexually transmissible infections. Philadelphia: Saunders, Elsevier Inc.; 2002.

Identifying STIs in the population

- Testing for STIs in people who present to a clinic with symptoms identifies only a small minority of prevalent infections, and other methods of case-finding, including population screening programmes and opportunistic testing are widely employed.
- Online-ordered postal self-sampling (OPSS), where samples are taken at home and posted to a laboratory, is now a mainstay of testing provision for those without symptoms. NAAT testing platforms allow testing for an increasing range of organisms in addition to *N. gonorrhoea* and *C. trachomatis*, including *Mycoplasma genitalium*, other mycoplasmas and *Trichomonas vaginalis*. Microtube samples for blood serology allow testing for HIV, syphilis and viral hepatitis.
- Point-of-care testing (PoCT) in the community and home-based self-testing (where the test is performed at home) are used internationally for HIV and syphilis testing and may be provided in non-clinical outreach settings such as prisons, youth groups or sex-on-premises venues such as gay saunas.

Investigations for STIs

- Samples for combined nucleic acid amplification tests (NAATs) for gonorrhoea and chlamydia are taken from anatomical sites at risk – these may be identified by face-to-face or online assessment of gender, partner gender and sexual practices.
- First-void urine (FVU) is the specimen of choice to test for infection of the male urethra and a self-taken swab is preferred for vaginal samples. Clinician-obtained urethral, cervical or vaginal swabs are alternatives. Pharyngeal and rectal swabs may be indicated by sexual history and are often offered universally to GBMSM.
- For gonorrhoea, either as an alternative or adjunct to NAAT testing, swabs from the pharynx, urethra, cervix or rectum plated directly on a selective medium such as modified New York City (MNYC), or sent in an appropriate transport medium, can be cultured for assessment of antimicrobial sensitivities. NAAT-based sensitivity testing is increasingly available.
- Blood for serological tests including syphilis (STS), e.g. enzyme immunoassay (EIA) for antitreponemal immunoglobulin G (IgG) ± IgM antibody. Repeat testing may be necessary in the event of negative test results in the first few weeks following exposure.
- Human immunodeficiency virus (HIV) test. HIV testing should always be offered as part of STI testing. Informed consent is required, but extensive pre-test discussion is not.
- Serological tests for hepatitis B (and sometimes hepatitis A and/or C) are offered to those at epidemiological risk.
- Additional tests routinely used in the investigation of symptomatic patients in sexual health clinics include direct microscopy of Gram-stained samples from the male urethra for the diagnosis of urethritis, or of wet-mount and Gram-stained samples from the vagina for the diagnosis of *Trichomonas vaginalis*, bacterial vaginosis, aerobic vaginitis or candidiasis.

Examples of risk factors for STIs

Demographic factors

- Younger age (< 25)*
- Gay, bisexual and other men who have sex with men (GBMSM)
- Prior STI diagnosis

Behavioural factors

- Frequent partner change or concurrent partners
- Non-use of condoms, condom errors
- Use of drugs during sex (‘chemsex’)
- Use of geospatial mobile phone dating applications (‘dating apps’)

*But note that the possibility of STI should never be excluded on the grounds of older age alone.

Sexual health and gender identity

- Medical care in all settings must be inclusive of all patients regardless of sexual orientation or gender identity. This has particular relevance in sexual health.
- Gender identity is a characteristic protected by law in the UK and many other jurisdictions.
- Definitions of terms commonly used:
  - Gender identity: an individual’s innate sense of their own gender, which may or may not be congruent with the sex they were assigned at birth.
  - Cisgender/Cis: a cis person’s gender identity is generally congruent with the sex they were assigned at birth.
  - Trans: an umbrella term to describe people whose gender identity differs from the sex they were assigned at birth. There is a spectrum of trans identities, including but not limited to: trans woman, trans man, transgender, genderqueer, non-binary, agender.
  - Non-binary (genderqueer): a term for individuals whose gender identity does not align with either of the binary categories of ‘man’, ‘woman’, or ‘male’, ‘female’.
- Long-established social norms, health-care structures, clinical practice and teaching may create barriers to inclusive care for trans and non-binary individuals (for example, by failing to provide cervical screening to trans men who have a cervix, or providing only male and female options in waiting rooms, services or on registration forms).
- Clinicians and services can ensure inclusivity by asking about gender identity, preferred pronouns and gender of partners and providing tests and investigations on the basis of anatomical sites at risk rather than by binary gender.

Tips on sexual history-taking

1. A simple framing statement before taking the sexual history helps avoid any sense of apology or embarrassment. ‘So, thinking about your sex life …’; ‘Some questions about your sex life …’.
2. Use open language to avoid the impression of being judgemental; inclusive words such as ‘partner’ rather than ‘boyfriend’.
3. Avoid euphemisms (‘down below’). Straightforward anatomical terms are advisable (in the UK ‘vagina’ is generally understood but ‘vulva’ often is not). ‘So, you mean on the lips of your vagina?’
4. Focusing on events helps to avoid labels and generalisations. ‘When did you last have sex, any sort of sex …?’, ‘When did you last have sex with anyone else/any other partner?’
5. Use permission-giving in questioning (explicit permission for a range of answers). ‘Have your partners been men, women or both?’
6. Invite the ‘non-acceptable’ or non-sanctioned answer. ‘So was that without a condom …?’
7. Understand and mitigate the ways in which your own values might affect your questioning. ‘When was your last previous partner?’ (assumes serial monogamy – so avoid).

Aetiology

Sexually transmitted infections (STIs) are infections usually but not exclusively transmitted via the moist mucous membranes of the penis, vulva, vagina, cervix, anus, rectum, mouth and pharynx during sexual activity. STIs include syphilis, gonorrhoea, genital herpes, genital warts, chlamydia, *Mycoplasma genitalium*, trichomoniasis and lymphogranuloma venereum (LGV). Chancroid and granuloma inguinale are STIs seen in tropical countries but are rare in the UK. Sexually transmissible blood-borne viruses including human immunodeficiency virus (HIV) and hepatitis B and C (Ch. 14) are those in which sexual contact is an important, but not the only mode of transmission. Enteric hepatitis virus A and sexually transmitted enteric infections (STEI) including *Salmonella* and *Shigella* may be spread by oro-anal sexual contact, although this is responsible for only a minority of cases. Mpox virus transmission is very frequently associated with sexual activity and it may be considered as an STI. Other viruses, including Zika virus, are found in semen and may be sexually transmitted, and any virus transmitted during close physical contact (e.g. SARS-CoV-2 – causing COVID-19) may be passed on during sexual activity. Untreated STIs can lead to chronic pain or infertility and can progress to genital cancers such as cervical and anal carcinoma. Ulcerative STIs increase the risk of transmission of untreated HIV about threefold and up to a third of worldwide HIV transmissions are thought to be attributable to herpes simplex virus (HSV) type 2. STIs in pregnancy can cause serious complications, including stillbirth, neonatal death, prematurity, neonatal sepsis, low birth weight and congenital abnormalities (Box 15.1), or disseminated infection in the mother. Other conditions, including bacterial vaginosis (BV) and genital candidiasis, are not regarded as STIs, although they are common causes of vaginal discharge. Genital itch, discomfort or rash with a wide variety of underlying causes in sexually active individuals also present to sexual health clinicians.

Clinical assessment

The use of a recognisable set of signs and symptoms to identify the likely infective cause and guide antimicrobial treatment without diagnostic testing is termed syndromic management and has been a mainstay of clinical care of STIs worldwide for several decades. The risk of widespread antimicrobial resistance (AMR) is currently one of the greatest challenges in STI control, so syndromic management is increasingly supported by improvements in availability, reliability and speed of diagnostic testing technologies, in particular nucleic acid amplification testing (NAAT). However, diagnosis on the basis of observed syndromes (e.g. vaginal discharge) remains valuable even in resource-rich settings where sophisticated tests are widely available. The majority of those presenting with genital syndromes do not have STI. Conversely, around 50% of all gonorrhoea and syphilis and 80% of chlamydial infections are asymptomatic and many of those who are symptomatic do not seek care. A detailed understanding of symptoms and of social and behavioural risk factors for STI in an individual directs examination, investigations indicated and anatomical sites sampled. For example, rectal samples are indicated in those who have had condomless receptive anal sex. A good sexual history is key to identifying these factors (Box 15.2).

STI in children

The presence of an STI in a child may be indicative of sexual abuse, although vertical transmission may explain some presentations in the first 2 years. In an older child and in adolescents, STI may be the result of voluntary sexual activity. Specific issues regarding the management of STI and other infections in adolescence are discussed in Box 14.23.

Presenting problems

Urethral discharge

Discharge from the male urethra is common whereas discharge from the female urethra alone is rare. Male urethral discharge caused by gonorrhoea (gonococcal urethritis) is distinguished from the more frequently seen non-gonococcal urethritis (NGU). Causes of NGU include *Chlamydia trachomatis*, *Mycoplasma genitalium* and less frequently *Trichomonas vaginalis*, HSV, other mycoplasmas, urea plasmas or adenoviruses. Some cases are thought not to have an infectious aetiology and are termed non-specific urethritis (NSU).

Gonococcal urethritis usually causes symptoms within 7 days of exposure. The discharge is typically profuse and purulent. Chlamydial urethritis has an incubation period of 1–4 weeks, and tends to result in milder symptoms than gonorrhoea. However, a confirmed microbiological diagnosis should always be the aim.

15.2 History-taking for STI

- **Symptoms**: genital ulceration, rash, irritation, pain, swelling and urinary symptoms, especially dysuria. Urethral discharge, vaginal discharge, pelvic pain or dyspareunia. Testicular pain, abdominal and systemic symptoms.
- **Medical history**: medical problems including previous STI, allergies, medication (prescribed, over the counter, recreational drugs including 'chemsex'), HIV PrEP and post-exposure antibiotic prophylaxis (Doxy-PEP), vaccinations (hepatitis A and B, HPV, Mpox); obstetric and gynaecological history, cervical smears and contraception*.
- **Sexual history**: last sexual contact, partner gender, partner status (one off/regular/other), partner geographical origin, consent to sex, payment/transactional sex, other recent partners.
- **Sexual practices**: digital or penile insertive or receptive vaginal or anal, orogenital or oro-anal, protection (condom use).

*In any sexual health consultation with a woman of reproductive age, contraception should always be discussed and, where possible, provided.

(HPV = human papilloma virus; PrEP = pre-exposure prophylaxis)

15.1 Possible outcomes of STI in pregnancy

Organism	Mode of transmission	Outcome for fetus/neonate	Outcome for mother
Treponema pallidum	Transplacental	Ranges from no effect to severe stigmata or miscarriage/stillbirth	None directly relating to the pregnancy
Neisseria gonorrhoeae	Intrapartum	Severe conjunctivitis	Possibility of ascending infection post partum
Chlamydia trachomatis	Intrapartum	Conjunctivitis, pneumonia	Possibility of ascending infection post partum
Herpes simplex	Usually intrapartum, but transplacental infection may occur rarely	Ranges from no effect to severe disseminated infection	Rarely, primary infection during 2nd/3rd trimesters becomes disseminated, with high maternal mortality
Human papillomaviruses	Intrapartum	Anogenital warts or laryngeal papillomas are very rare	Warts may spread and enlarge during pregnancy, but usually regress post partum

Investigations

If microscopy facilities are available, a Gram-stained smear of urethral exudate (Fig. 15.1) reveals significant numbers of polymorphonuclear leucocytes (PMNL). Urethritis is defined as ≥5 PMNL per high-power field in the UK (the US Centers for Disease Control and Prevention recommends a lower threshold of ≥2). If gram-negative intracellular diplococci (GNDC) are also seen, a working diagnosis of gonorrhoea is made and further investigations for gonorrhoea are undertaken; if no GNDC are seen, a label of NGU is applied. In all settings, an FVU sample or swab should be taken for a combined nucleic acid amplification test (NAAT) for gonorrhoea, chlamydia and, where available, *M. genitalium*.

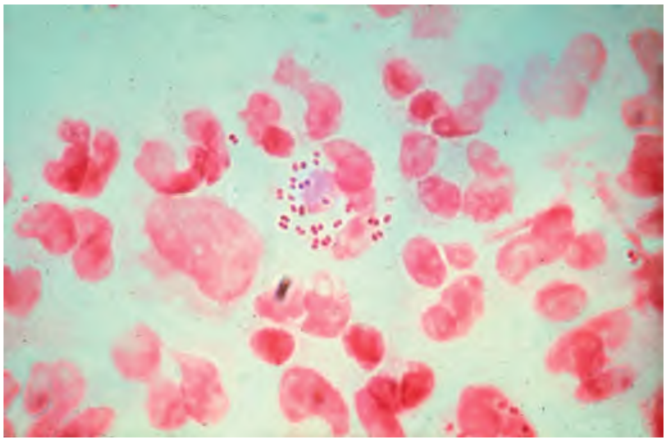


Fig. 15.1 A Gram-stained urethral smear from a man with gonococcal urethritis. Gram-negative diplococci are seen within polymorphonuclear leucocytes.

Management

Syndromic management with prescription of multiple antimicrobials to cover the possibility of chlamydia, *M. genitalium* and sometimes gonorrhoea may occasionally be unavoidable where diagnostic tests are unavailable or results delayed. Antibiotic use and selection is influenced by concerns about antibiotic resistance in both *N. gonorrhoeae* and *M. genitalium*. Microscopy findings allow a more accurate presumptive diagnosis. Additional treatment for gonorrhoea may be given on receipt of sensitivity results obtained by culture or NAAT technology (p. 132).

Genital itch, rash and discomfort

Genital symptoms including itch, irritation or discomfort may present acutely or as chronic problems with or without rash. Causes are infectious, non-infectious or multifactorial. Box 15.3 provides a guide to diagnosis.

Balanitis usually presents acutely and refers to inflammation of the glans penis, often extending to the under-surface of the prepuce (foreskin), in which case it is called balanoposthitis. Candidiasis affecting the glans penis or vulvovagina is sometimes associated with immune deficiency, diabetes mellitus and the use of broad-spectrum antimicrobials, glucocorticoids or antimitotic drugs. Chronic persistent or recurrent itch, commonly affecting the vulva, may be due to recurrent candidiasis with hypersensitivity to candidal antigens. Avoiding irritants such as scented hygiene products, soaps and detergents may be helpful in any case of chronic itch or discomfort.

15.3 Differential diagnosis of genital itch and/or rash

Likely diagnosis	Acute or chronic	Itch	Pain	Discharge	Specific characteristics	Diagnostic test	Treatment
Candidiasis	Acute	✓	–	White, typically curdy	Post-coital in men	Microscopy	Antifungal cream, e.g. clotrimazole or single dose oral antifungal, e.g. fluconazole 150 mg
Candidiasis	Chronic/ recurrent	✓	±	White, typically curdy	Usually cyclical, rare in men	Microscopy (culture for yeasts other than *Candida albicans* in recurrent/refractory disease)	Oral antifungal, e.g. fluconazole 150 mg weekly for 6 months
Dermatoses, e.g. eczema or psoriasis	Either	✓	–	–	Similar to lesions elsewhere on skin	Clinical	Mild topical glucocorticoid, e.g. hydrocortisone
Genital herpes	Acute	±	✓	–	Atypical ulcers are not uncommon	Swab for HSV-1 & 2 NAAT	Oral antiviral, e.g. aciclovir
Pthirus pubis ('crab lice') infection	Either	✓	–	–	Lice and nits seen attached to pubic hairs	Can be by microscopy but usually visual	According to local sensitivities Often permethrin
Lichen planus (p. 1132)	Either	±	–	–	Violaceous papules ± Wickham striae	Clinical	None or mild topical glucocorticoid, e.g. hydrocortisone
Lichen sclerosus	Chronic	±	–	–	Ivory–white plaques, scarring	Clinical or biopsy	Strong topical glucocorticoid, e.g. clobetasol
Plasma cell balanitis of Zoon (penis)	Chronic	✓	–	±	Shiny, inflamed circumscribed areas	Clinical or biopsy	Strong topical glucocorticoid, e.g. clobetasol
Circinate balanitis (penis)	Either	–	–	–	Painless erosions with raised edges; usually as part of SARA (p. 1062)	Clinical	Mild topical glucocorticoid, e.g. hydrocortisone
Anaerobic (erosive) balanitis	Acute	±	–	Yellow	Offensive tight prepuce and poor hygiene may be aggravating factors	Clinical	Saline bathing ± metronidazole
Vulvodynia and vulvar vestibulitis	Chronic	–	✓	–	Dyspareunia common, pain on touching erythematous area	Clinical	Refer to specialist vulva clinic

(HSV = herpes simplex virus; NAAT = nucleic acid amplification test; SARA = sexually active reactive arthritis)

The importance of psychological issues such as relationship or STI concerns, or a psychiatric diagnosis as a cause or a consequence of chronic or recurrent genital symptoms should always be considered.

Vaginal discharge

The normal physiological vaginal discharge may vary considerably over the menstrual cycle and with other hormonal changes such as puberty, pregnancy or prescribed contraception. An increase or change in vaginal discharge may also be due to a number of infective and non-infective conditions (Box 15.4). Worldwide, the most common treatable STI causing vaginal discharge is trichomoniasis; other possibilities include gonorrhoea and chlamydia. However, even in areas of high STI prevalence, most of those presenting with vaginal discharge alone will not have STI, so syndromic management of first presentation of vaginal discharge is often appropriate. Symptoms can help to distinguish the causes and anatomical origin of a vaginal discharge including:

- an increased discharge without any itch or irritation accompanied by an unpleasant or fishy odour, worse after sexual intercourse and during menstruation, suggests BV
- vulval itching accompanied by a thick, white vaginal discharge, vulval burning, external dysuria and superficial dyspareunia may indicate candidiasis
- a purulent or mucopurulent discharge, with bloodstaining and/or post-coital or intermenstrual bleeding may originate from an inflamed cervix, more commonly associated with STI including chlamydia and gonorrhoea.

Testing for STI should usually be decided by risk assessment rather than symptoms and usually includes vulvovaginal swabs for NAATs for chlamydia, gonorrhoea and sometimes *Trichomonas vaginalis*. Speculum examination, supported by testing with narrow range pH paper and Gram-stain microscopy, allows rapid diagnosis in many cases. A homogeneous off-white discharge, vaginal pH greater than 4.5, and microscopy revealing reduced lactobacilli with gram-variable organisms coating vaginal squamous cells (so-called clue cells, Fig. 15.2), suggests BV. Vulval and vaginal erythema, a curdy discharge, vaginal pH less than 4.5, and fungal spores and pseudohyphae on microscopy indicate candidiasis. A profuse yellow or green discharge with significant vulvovaginal inflammation and a very high pH suggests trichomoniasis, confirmed by finding motile flagellate protozoa on a wet-mount microscopy slide, by culture or by NAAT testing.

A purulent discharge from an inflamed cervix may contain GNDC on Gram-stain microscopy, allowing presumptive treatment for gonorrhoea. However, clinical examination and microscopy has very low sensitivity for *N. gonorrhoeae* in women, so NAAT and/or culture tests for STI should always be taken in women with behavioural or demographic risk factors for STI.

Treatment of infections causing vaginal discharge is shown in Box 15.4.

15.4 Infections that cause vaginal discharge

Cause	Clinical features	Treatment (in pregnancy seek specialist advice)
Candidiasis	Vulval and vaginal inflammation	Fluconazole[1] 150 mg orally as a single dose *or*
	Curdy white discharge adherent to walls of vagina	Clotrimazole[2] 500 mg pessary once at night and clotrimazole cream twice daily
	Low vaginal pH	
Trichomoniasis	Vulval and vaginal inflammation	Metronidazole[3] 400 mg orally twice daily for 5–7 days *or*
	Frothy yellow/green discharge Very high vaginal pH	Metronidazole[3] 2 g orally as a single dose
Bacterial vaginosis	No inflammation	Metronidazole[3] 2 g single dose or 400 mg twice daily orally for 5–7 days *or*
	White homogeneous discharge	Metronidazole[3] vaginal gel 0.75% daily for 5 days *or*
	High vaginal pH	Clindamycin[1,4] vaginal cream 2% daily for 7 days
Aerobic vaginitis: streptococcal/staphylococcal infection	Purulent vaginal discharge	Choice of antibiotic depends on sensitivity tests

[1] Avoid in pregnancy and breastfeeding.
[2] Clotrimazole and clindamycin damage latex condoms and diaphragms.
[3] Avoid alcoholic drinks until 48 hours after finishing treatment. Avoid high-dose regimens in pregnancy or breastfeeding.
[4] *Clostridioides difficile* colitis has been reported with the use of clindamycin cream.

Genital ulceration

The most common cause of genital ulceration is genital herpes, but the possibility of other diagnoses including syphilis and LGV must be considered in all cases, with a higher index of suspicion if the patient is a GBMSM or is in, or has partners from, regions where these STIs are more prevalent. Clinical signs and symptoms can help to distinguish between herpes and syphilis, but certainty requires diagnostic testing. In herpes, multiple painful ulcers typically affect the introitus, labiae and perineum of the female genitalia and the glans, coronal sulcus or shaft of penis (Fig. 15.3). The presence of multiple lesions at different stages (erythematous, vesicular/blistering, ulcerating and resolving) is strongly supportive of a herpes diagnosis. Perianal herpes ulcers may be seen and are usually associated with receptive anal sex. Inguinal lymphadenopathy and systemic features, such as fever and malaise, are more common in women than in men.

In contrast, the classic lesion of primary syphilis (chancre) is single, painless and indurated; however, multiple (usually <5) lesions are commonly seen and anal chancres are often painful. Ulcers also occur in the primary stage of LGV and should be considered, especially if there is significant inguinal lymphadenopathy.

Diagnosis is made by gently swabbing the lesion(s) for detection of HSV and *Treponema pallidum* DNA by NAAT. A swab for testing for LGV

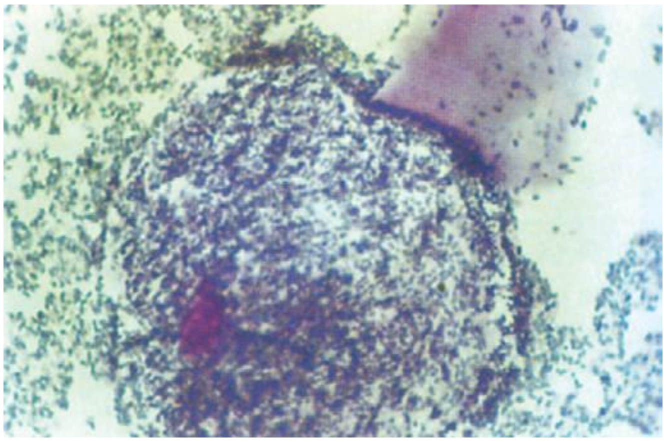

Fig. 15.2 Gram stain of a clue cell from a patient with bacterial vaginosis. The margin of this vaginal epithelial cell is obscured by a coating of anaerobic organisms. *From McMillan A, Young H, Ogilvie MM, Scott GR. Clinical practice in sexually transmissible infections. Philadelphia: Saunders, Elsevier Inc.; 2002.*

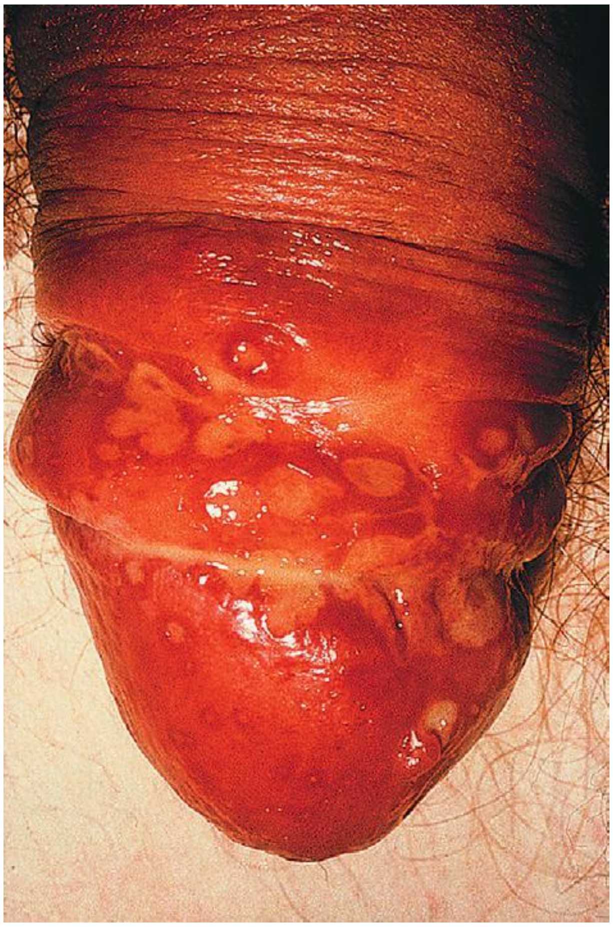

Fig. 15.3 **Penile herpes simplex (HSV-2) infection.**

(see Box 15.12) may be taken in GBMSM. Where available, syphilis may be diagnosed in-clinic by dark-ground microscopy of material obtained from a chancre. Serological tests for syphilis is mandatory in patients presenting with genital ulcer.

Other infective causes include varicella zoster virus (p. 337) and trauma with secondary infection. STIs such as chancroid and granuloma inguinale, are rare in the UK and are described in Box 15.12.

Non-infective inflammatory causes include lichen sclerosus, aphthosis, Stevens–Johnson syndrome (Ch. 26), Behçet disease (p. 1074) and fixed drug reactions. In older patients, squamous cell carcinoma and vulval or penile intra-epithelial neoplasia (VIN and PIN) should be considered and excluded by biopsy in cases of doubt. The possibility of a pre-existing underlying pathology with a co-incident infection should be considered if lesions recur or fail to resolve.

Genital lumps

The most common cause of genital 'lumps' is warts. These are classically found in areas of friction during sex, such as the parafrenal skin and prepuce of the penis, the inner aspect of the vulval labiae, the fourchette and perineum. Warts may also be seen on the keratinised epithelium of the shaft of the penis, pubis or inner thighs and less commonly in the urethral meatus. Perianal warts are relatively common even in the absence of a history of receptive anal sex.

The differential diagnosis includes molluscum contagiosum and skin tags. Normal anatomical features may be confused with warts by young men and women and occasionally by clinicians. These include coronal papillae, parafrenal glands or sebaceous glands (Fordyce spots) in men and vulval papillae and sebaceous glands in women.

Proctitis

Proctitis due to STI is most commonly diagnosed in GBMSM, but occasionally presents in others including trans and cis women. STIs that may cause proctitis include gonorrhoea, chlamydia, herpes and syphilis. Lymphogranuloma venereum (LGV), caused by sub strains L1–3 of *Chlamydia trachomatis*, and Mpox infection, are also causes of severe proctitis in GBMSM.

Symptoms include mucopurulent anal discharge, rectal bleeding, pain and tenesmus. Examination may show mucopus and erythema with contact bleeding (p. 406). In addition to the diagnostic tests listed on page 407, NAATs for HSV and Mpox should be performed, with NAAT for LGV subtypes if chlamydia NAAT is positive. Treatment is directed at the individual infections.

Gastrointestinal symptoms including diarrhoea may indicate sexually transmitted enteric infection (STEI) with organisms such as *Salmonella*, *Shigella*, *Campylobacter*, *Cryptosporidium* and *Entamoeba histolytica* (Ch. 14).

Lower abdominal pain

Lower abdominal and pelvic pain presenting in sexually active women of reproductive age has a wide differential diagnosis including complications of early pregnancy as well as those of STI. Pelvic inflammatory disease (PID) is usually the result of infection ascending from the endocervix to cause inflammation of the endometrium, Fallopian tubes and ovaries, sometimes extending to the parametrium and the pelvic peritoneum or causing tubo-ovarian abscess. A diagnosis of chlamydia, gonorrhoea or *M. genitalium* infection supports the diagnosis but PID commonly occurs without STI. A definitive diagnosis of PID can only be made by laparoscopy, which is not practical or appropriate in the majority of cases. Early treatment improves outcomes, so a clinical diagnosis is made with a low threshold for initiating empirical antibiotic treatment. Other symptoms suggesting PID include deep dyspareunia, abnormal vaginal discharge and/or bleeding and symptoms of systemic infection such as fever and malaise. On examination, lower abdominal tenderness is usually bilateral, and bimanual vaginal examination reveals adnexal tenderness with or without cervical motion tenderness. Diagnostic tests (p. 407) should include a pregnancy test because the differential diagnosis includes ectopic pregnancy.

If a clinical diagnosis of PID is thought likely, broad-spectrum antibiotics active against gonorrhoea, chlamydia and gram-negative organisms, such as ceftriaxone, doxycycline and metronidazole, should be initiated immediately. Hospital admission for intravenous therapy may be required in severe cases. Delaying treatment increases the likelihood of adverse sequelae, such as abscess formation, and tubal scarring that may lead to ectopic pregnancy, infertility or chronic pain.

Acute or chronic pain in the male pelvis may be attributable to infective prostatitis or abacterial prostatic pain syndromes. Infections are usually associated with organisms causing urinary infection and STI is not implicated.

Epidemiology

The World Health Organization (WHO) estimates that there were over 374 million cases of the four major curable STIs (syphilis, gonorrhoea, chlamydia and trichomoniasis) in adults aged 15–49 throughout the world in 2020, with 90% in lower-income countries. Most of the complications of untreated STI, including chronic pain, infertility, genital cancers and the increased risk of acquiring HIV infection, disproportionately affect women.

STI transmission depends partly on the number of sexual partners (high rates of partner change) and concurrency (having sex with more than one partner during the same time period) in any given population. Hence increases in STI prevalence are driven by changes in sexual

15.5 Examples of public health interventions to prevent STI in subpopulations with increased prevalence

	Primary prevention: Structural/societal	Primary prevention: Biomedical	Primary prevention: Behavioural	Secondary prevention	Tertiary prevention
Syphilis in MSM	Marriage equality Targeted MSM services	Post-exposure antibiotic prophylaxis (Doxy-PEP)	Inclusive schools sex and relationship education (SRE)	Free online syphilis self-testing provision	App-based partner notification, 1-to-1 behaviour change interventions
HPV-related cervical cancer in low-income women	Gender equal pay legislation Countering 'anti-vacc' propaganda through social media	HPV vaccination Smoking cessation medication	Condom skills demonstration in youth services	Cervical (pre) cancer screening	Surgical treatment for CIN (e.g. loop diathermy)
HIV in transgender women	Hate crime legislation Trans-inclusive health services	Promotion and provision of oral and injectable HIV PrEP	Safer sex advice in holistic gender services	Outreach HIV testing services	Treatment as prevention (TasP) PrEP for partners

(CIN = cervical intra-epithelial neoplasia; HPV = human papilloma virus; MSM = men who have sex with men; PrEP = pre-exposure prophylaxis)

behaviour, ways of increasing sexual mixing (finding new partners outside a social group or geographical area), such as travel or the use of mobile phone apps, and early sexual debut. Rates of different infections may also be affected by microbiological factors such as the emergence of strains carrying genetic mutations conferring antimicrobial resistance or causing asymptomatic infection. Human biological factors include changes in the prevalence of particular sexual behaviours (such as oral or anal sex), increased geographical mobility within and between countries, or the rates of vaccination and use of protection, for example condoms and pre-exposure HIV prophylaxis (PrEP). Consequently, STI incidence can vary dramatically by geography and over time, affected by structural changes such as economic decline, mass migration, legislation or changes in social mores and sexual behaviour, but also the availability of tests and services, treatment, prevention and vaccination programmes. In common with other infectious diseases, intersectional demographic risk factors relating to race, age, gender and sexual orientation combined with geography and social deprivation ('syndemics') are often associated with increased STI prevalence in subpopulations across the world. These factors are also commonly barriers to access to education, prevention, testing and treatment services. For those affected by intersectional risk factors, the population from whom they choose a sexual partner is likely to be a more significant determinant of STI risk than their individual sexual behaviours. The inability of individuals (in particular women) to make choices about consent to sex and reproductive health, including the necessity of transactional sex (exchange of sex for money, goods or protection), is an important additional factor for many such populations.

15.6 Management goals in diagnosed bacterial STI

Goal	Interventions
Prevention of onward transmission	Advice to abstain until treatment completed Notification of sexual partners for testing/epidemiological treatment
Prevention of antimicrobial resistance	Antibiotic selection based on current local resistance data Antimicrobial test-of-cure Culture/NAAT-based antimicrobial resistance testing
Identify other undiagnosed STI/BBV infection	Routine testing for other STIs, including HIV
Prevention of viral STIs for those at increased risk	Vaccination (HPV, hepatitis A, hepatitis B, Mpox) PrEP for HIV
Opportunistic health improvement	Contraceptive advice and provision Address problematic alcohol/recreational drug use Brief behaviour change interventions

(BBV = blood-borne virus; HPV = human papilloma virus; NAAT = nucleic acid amplification test; PrEP = pre-exposure prophylaxis)

Prevention

STI prevention involves making deliberate changes to affect the epidemiological factors described above at all levels to reduce the risk of acquisition of infection (Box 15.5). This may involve structural and legislative interventions (such as UK marriage equality, gender recognition laws) and deliberate social influencing (such as addressing HIV or trans stigma through TV drama). Primary biomedical and behavioural interventions (to prevent acquisition of infection) such as hepatitis B vaccination for GBMSM may be applied to populations or individuals at risk. Secondary prevention includes the early detection of infection to limit the period of infectivity and often involves designing services to provide equity of access to groups affected by higher prevalence of infection (e.g. chlamydia screening for young people, antenatal HIV testing in maternity services). Tertiary prevention includes biomedical interventions such as ensuring access to effective early treatment for the individual to prevent onward transmission. Partner notification (contact tracing) is a cornerstone of STI prevention (Box 15.6). It involves identifying recent sexual contacts at risk of infection to allow testing and sometimes giving treatment without confirming the individual is infected (termed epidemiological treatment). The benefits of provision of antibiotics for partners without a confirmed diagnosis must be carefully weighed against the risks of antibiotic resistance in the community. Partner notification may be undertaken by the patient, sometimes with professional help, or by the provider (clinician), requiring high levels of sensitivity and respect for confidentiality and anonymity. It is increasingly supported by technology such as dedicated partner notification apps and online systems. Behaviour change interventions, applied to populations or individuals at increased STI risk, sometimes following an initial STI diagnosis, have a good evidence base. However, proving or excluding a direct effect of population interventions that are 'distal' to the outcome measure (i.e. STI rates), such as schools sex and relationships education (SRE) or mass media campaigns, is extremely challenging due to multiple confounding factors.

PrEP and PEPSE

Pre-exposure prophylaxis for HIV (PrEP) taken as oral tablets (tenofovir disoproxil salts (TD) or tenofovir alafenamide (TAF) with emtricitabine (FTC)) are highly effective in reducing HIV incidence in populations of GBMSM and trans women worldwide. Biological efficacy of TD-FTC or TAF-FTC is the same in women, although in many populations stigma and gender inequality mean that oral PrEP use for women is particularly challenging. Oral PrEP is fully protective for exposures 2 hours after a dose of two tablets for all risk exposures in all populations, but seven single daily doses are required after exposure for receptive vaginal or neovaginal sex (a 2:7 regimen) as opposed to only two doses (a 2:1:1) for insertive or receptive anal sex or insertive vaginal sex. A long-acting injectable antiretroviral (cabotegravir) is licensed for use as PrEP in many countries and offers significant advantages, particularly for women, in whom 2-monthly injections avoid the disclosure issues associated with tablet-taking. A 6-monthly injectable (lenacapavir) may offer further benefits.

Post-exposure prophylaxis for sexual exposure (PEPSE), usually with daily TD- or TAF-FTC combined with a third agent such as an integrase inhibitor, is effective if given within 24 hours of exposure and may be beneficial if started up to 72 hours after risk. It is usually given as a 28-day course. Post-exposure prophylaxis for bacterial STI (as a self-administered patient-held single oral dose of doxycycline 200 mg) has been demonstrated to reduce the incidence of syphilis, chlamydia and, depending on local resistance patterns, gonorrhoea in subpopulations of GBMSM. It is routinely recommended for those at highest STI risk in some countries but due to concerns about AMR remains controversial in others.

Sexually transmitted bacterial infections

Syphilis

Syphilis is caused by infection, through abrasions in the skin or mucous membranes, with the spirochaete *Treponema pallidum* subspecies *pallidum*. In adults the infection is usually sexually acquired; however, transmission by kissing, blood transfusion and percutaneous injury has been reported. Congenital syphilis, caused by transplacental infection of the fetus, remains rare in the UK, but an estimated 1.1 million pregnant women worldwide had active syphilis in 2022, causing about 390 000 adverse birth outcomes including stillbirth and neonatal death. Rates of infectious syphilis in the UK have continued to rise annually to levels last seen in the 1940s. About 70% of syphilis cases in the UK are in GBMSM.

The natural history of untreated syphilis is variable. Primary and secondary syphilis symptoms resolve spontaneously without treatment, meaning that the disease may go unrecognised and untreated with a risk of late complications. Infection may remain latent throughout, or clinical features may develop at any time.

Acquired syphilis

Early syphilis

Primary syphilis

Following exposure, the incubation period is typically around 21 days, with a range of 9–90 days. A primary lesion or chancre (Fig. 15.4) develops at the site of infection, usually in the genital area. A dull red macule develops, becomes papular and then erodes to form an indurated ulcer (chancre). Chancres may be multiple or atypical. The draining inguinal lymph nodes may become moderately enlarged, mobile, discrete and rubbery. The chancre and the lymph nodes are both painless and non-tender, unless there is concurrent or secondary infection. Without treatment, the chancre will resolve within 2–6 weeks to leave a thin atrophic scar.

Chancres may develop on the vaginal wall and on the cervix. Extragenital chancres are found in up to a third of MSM, affecting sites such as the finger, lip, tongue, tonsil, nipple, anus or rectum. Anal chancres often resemble fissures and may be painful.

Secondary syphilis

This occurs 6–8 weeks after the development of the chancre, when treponemes disseminate to produce a multisystem disease. Constitutional symptoms, such as mild fever, malaise and headache, are common. Over 75% of patients present with a rash on the trunk and limbs that may later involve the palms and soles; this is initially macular but evolves to maculopapular or papular forms, which are generalised, symmetrical and non-irritable. Scales may form on the papules later. Lesions are red, changing to a 'gun-metal' grey as they resolve. Without treatment, the rash may last for up to 12 weeks and is easily confused with psoriasis, pityriasis rosea, scabies, allergic drug reaction, erythema multiforme or pityriasis (tinea) versicolor, particularly if risk factors for syphilis infection have not been identified. Primary HIV infection (Ch. 14) is an important differential diagnosis.

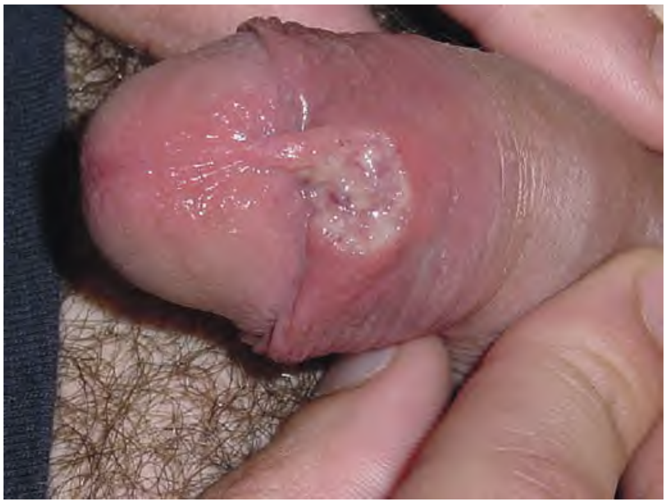

Fig. 15.4 Primary syphilis. A painless ulcer (chancre) is shown in the coronal sulcus of the penis. This is usually associated with inguinal lymphadenopathy. *From Clutterbuck DJ. Specialist training in sexually transmitted infections and HIV. St Louis: Mosby, Elsevier Inc.; 2004.*

Condylomata lata (papules coalescing to plaques) may develop in warm, moist sites such as the vulva or perianal area. Generalised non-tender lymphadenopathy is present in over 50% of patients. Mucosal lesions, known as mucous patches, may affect the genitalia, mouth, pharynx or larynx. Rarely, confluence produces characteristic 'snail track ulcers' in the mouth.

Other features of secondary syphilis may present with or without rash; these include meningitis, cranial nerve palsies, anterior or posterior uveitis, hepatitis, gastritis, glomerulonephritis or periostitis. Although neurosyphilis has often been regarded as a manifestation of late syphilis, the commonest presentation of neurosyphilis in the UK is meningovascular syphilis presenting in the secondary stage.

The clinical manifestations of secondary syphilis will resolve without treatment but relapse occurs in up to 25% of cases within the 2 years of infection. The disease then enters the phase of latency.

Latent syphilis

This is characterised by positive syphilis serology or the diagnostic cerebrospinal fluid (CSF) abnormalities of neurosyphilis in an untreated patient with no evidence of clinical disease. In early latency (within 2 years of infection), syphilis may be transmitted sexually. In late latent syphilis the patient is no longer sexually infectious. Transmission of syphilis from a pregnant woman to her fetus, and rarely by blood transfusion, is possible for several years following infection.

Late syphilis

Late latent syphilis

Over 60% of patients will suffer little or no ill health from untreated syphilis, although many of these have pathological changes identifiable at autopsy. This is termed late latent syphilis. Other manifestations of late syphilis are now rarely seen in the UK, partly because the prescription of antibiotics for other illnesses may unintentionally treat syphilis.

Cardiovascular syphilis

The commonest late manifestation of untreated syphilis is involvement of the ascending aorta and sometimes the aortic arch, presenting between 10 and 30 years after infection as aortic incompetence, angina and aortic aneurysm (p. 479).

Benign tertiary syphilis

A chronic granulomatous lesion called a gumma is characteristic and may be single or multiple, developing 3–10 years after infection. Mucosal lesions may occur in the mouth, pharynx, larynx or nasal septum, appearing as punched-out ulcers. Gummas of the tibia, skull, clavicle and sternum have been described, as has involvement of the brain, spinal cord, liver, testis and, rarely, other organs. Resolution of active disease should follow treatment, though some tissue damage may be permanent. Paroxysmal cold haemoglobinuria (p. 981) may be seen.

Neurosyphilis

This may also take years to develop. Asymptomatic infection is associated with CSF abnormalities in the absence of clinical signs. Meningovascular disease, tabes dorsalis and general paralysis of the insane constitute the symptomatic forms.

Congenital syphilis

Where antenatal serological screening is routinely implemented, congenital syphilis is rare. Antisyphilitic treatment in pregnancy treats the fetus, if infected, as well as the mother.

Treponemal infection may give rise to a variety of outcomes after 4 months of gestation, when the fetus becomes immunocompetent:

- miscarriage or stillbirth, prematurely or at term
- birth of a syphilitic baby (a very sick baby with hepatosplenomegaly, bullous rash and perhaps pneumonia)
- birth of a baby who develops signs of early congenital syphilis during the first few weeks of life (Box 15.7)
- birth of a baby with latent infection who either remains well or develops congenital syphilis/stigmata later in life (see Box 15.7).

15.7 Clinical features of congenital syphilis

Early congenital syphilis (neonatal period)

- Maculopapular rash
- Condylomata lata
- Mucous patches
- Fissures around mouth, nose and anus
- Rhinitis with nasal discharge (snuffles)
- Hepatosplenomegaly
- Osteochondritis/periostitis
- Generalised lymphadenopathy
- Choroiditis
- Meningitis
- Anaemia/thrombocytopenia

Late congenital syphilis

- Benign tertiary syphilis
- Periostitis
- Paroxysmal cold haemoglobinuria
- Neurosyphilis
- 8th nerve deafness
- Interstitial keratitis
- Clutton joints (painless effusion into knee joints)

Stigmata

- Hutchinson incisors (anterior–posterior thickening with notch on narrowed cutting edge)
- Mulberry molars (imperfectly formed cusps/deficient dental enamel)
- High arched palate
- Maxillary hypoplasia
- Saddle nose (following snuffles)
- Rhagades (radiating scars around mouth, nose and anus following rash)
- Salt and pepper scars on retina (from choroiditis)
- Corneal scars (from interstitial keratitis)
- Sabre tibia (from periostitis)
- Bossing of frontal and parietal bones (healed periosteal nodes)

Investigations in adult cases

Nucleic acid testing for *Treponema pallidum* is often available for the diagnosis of early syphilis on samples collected from chancres, or from moist or eroded lesions in secondary syphilis. Dark-field microscopy remains in use as the fastest near-patient test in many specialist sexual health services.

Serological tests for syphilis (STS) such as treponemal enzyme immunoassays (EIAs) for IgG and IgM antibodies are used for routine testing in most settings and for antenatal screening. Other treponemal and non-treponemal tests are usually done if an initial screening test is positive or for follow-up for positive cases; these are listed in Box 15.8. Syphilis IgM becomes positive at approximately 2 weeks, while non-treponemal tests become positive about 4 weeks after primary syphilis.

Following treatment, non-treponemal tests are routinely monitored for declining titres, usually to low or undetectable levels within 12–18 months for primary or secondary syphilis. In untreated late syphilis there may be high antibody titres with little change even after adequate treatment. Consequently, positive syphilis serology may be found during the investigation of other conditions (e.g. dementia), reflecting infection that has been treated deliberately or by accident, many years previously. Interpretation of results requires knowledge of any treatment, which may include antibiotics given for other indications.

Biological false-positive reactions occur occasionally; these are most commonly seen with Venereal Diseases Research Laboratory (VDRL) or rapid plasma reagin (RPR) tests, which do not require laboratory facilities so are used as screening tests in many countries. False positives are identified when treponemal tests are negative. Acute false-positive reactions may be associated with infections, such as infectious mononucleosis, chickenpox and malaria, or in pregnancy. Chronic false-positive reactions may be associated with autoimmune diseases.

The CSF may be examined in patients with clinical signs of neurosyphilis (p. 1223) and in both early and late congenital syphilis.

Chest X-ray, electrocardiogram (ECG) and echocardiogram are useful in the investigation of cardiovascular syphilis. Biopsy may be required to diagnose gumma.

Endemic treponematoses, such as yaws, endemic (non-venereal) syphilis (bejel) and pinta (Ch. 14), are caused by treponemes that are morphologically indistinguishable from *T. pallidum* and cannot be reliably differentiated by serological tests.

Investigations in suspected congenital syphilis

A newborn baby may have positive serological tests due to passively transferred maternal antibodies, but non-treponemal tests should become negative within 3–6 months of birth if the mother is adequately treated and child is uninfected. A diagnosis of congenital syphilis mandates investigation of the mother, her partner and any siblings.

Management

Penicillin is widely used for all stages of infection 80 years after its introduction. A single dose of 2.4 megaunits of long-acting intramuscular benzathine benzylpenicillin is recommended for early syphilis (< 2 years' duration), or three doses at weekly intervals for late syphilis. A 14-day course of intramuscular procaine penicillin 2.4 megaunits once daily with oral probenecid

15.8 Serological tests for syphilis

Non-treponemal tests: detect antibodies non-specific to syphilis antigens

- Venereal Diseases Research Laboratory (VDRL) test
- Rapid plasma reagin (RPR) test

Treponemal antibody tests: specific for antibody to syphilis antigens

- Treponemal antigen-based enzyme immunoassay (EIA) for IgG and IgM
- *Treponema pallidum* haemagglutination assay (TPHA)
- *T. pallidum* particle agglutination assay (TPPA)
- Fluorescent treponemal antibody-absorbed (FTA-ABS) test

500 mg 4 times daily is recommended for the treatment of neurosyphilis, supplemented by a 3-day course of prednisolone (see below). Oral doxycycline is indicated for patients allergic to penicillin, except in pregnancy (see below). Ceftriaxone given intravenously or intramuscularly daily for 10–14 days is increasingly accepted as an alternative. All patients must be followed up until clinical signs have resolved and for partner notification. Serology is usually repeated for a year following treatment.

Pregnancy

Penicillin is the treatment of choice in pregnancy. If there is penicillin hypersensitivity, options include intramuscular ceftriaxone 500 mg daily for 10 days (2 g daily for late infection/neurosyphilis).

Treatment reactions

- *Anaphylaxis*. Penicillin affects <1% of the population; adrenaline and resuscitation equipment should be immediately to hand (p. 219).
- *Jarisch–Herxheimer reaction*. This is an acute febrile reaction that follows treatment and is characterised by headache, malaise and myalgia; it resolves within 24 hours. It is common in early syphilis and rare in late syphilis. Fetal distress or premature labour can occur in pregnancy. The reaction may also cause worsening of neurological (cerebral artery occlusion) or ophthalmic (uveitis, optic neuritis) disease, myocardial ischaemia (inflammation of the coronary ostia) and laryngeal stenosis (swelling of a gumma). Prednisolone 40–60 mg daily for 3 days, started 24 hours before the first antibiotic dose, is recommended to prevent the reaction in patients with these forms of the disease. In high-risk situations the first antibiotic dose should be given in hospital.
- *Procaine reaction*. Fear of impending death occurs immediately after the accidental intravenous injection of procaine penicillin and may be associated with short-lived hallucinations or fits. Aspiration before any intramuscular injection is mandatory.

Gonorrhoea

Gonorrhoea is caused by the *Neisseria gonorrhoeae* gram-negative diplococcus and usually involves columnar epithelium in the lower genital tract, rectum, pharynx and eyes. Transmission is usually the result of vaginal, anal or oral sex. Gonococcal conjunctivitis may be caused by accidental infection from contaminated fingers. Untreated mothers may infect babies during delivery, resulting in ophthalmia neonatorum (Fig. 15.5).

Clinical features

The incubation period is usually 2–10 days. Infection of the male urethra causes urethral discharge and dysuria; only a minority are asymptomatic. The female urethra, paraurethral glands/ducts, Bartholin glands/ducts or endocervical canal may be infected, but about 80% of women are asymptomatic. Intermenstrual or post-coital bleeding suggests involvement of the cervix, and lower abdominal/pelvic pain and dyspareunia suggests that the infection has ascended to the upper genital tract (PID).

Rectal infection is due either to receptive anal sex or to contamination from a urogenital site. It is usually asymptomatic but may present with anal discomfort, discharge or rectal bleeding.

Clinical examination may show no abnormality, but mucopurulent or purulent urethral discharge may be seen at infected sites. This is often obvious at the male urethra (p. 408). Discharge may be expressed from the female urethra, paraurethral ducts or Bartholin ducts. The cervix may be inflamed, with mucopurulent discharge and contact bleeding. Proctoscopy may reveal either no abnormality, or clinical evidence of proctitis such as inflamed rectal mucosa and mucopus.

Pharyngeal gonorrhoea is usually symptomless and is largely attributed to receptive orogenital sex. Gonococcal conjunctivitis is an uncommon complication of adults and neonates, presenting with purulent discharge from the eye(s), severe inflammation of the conjunctivae and oedema of the eyelids, pain and photophobia. Conjunctivitis must be treated urgently to prevent corneal damage.

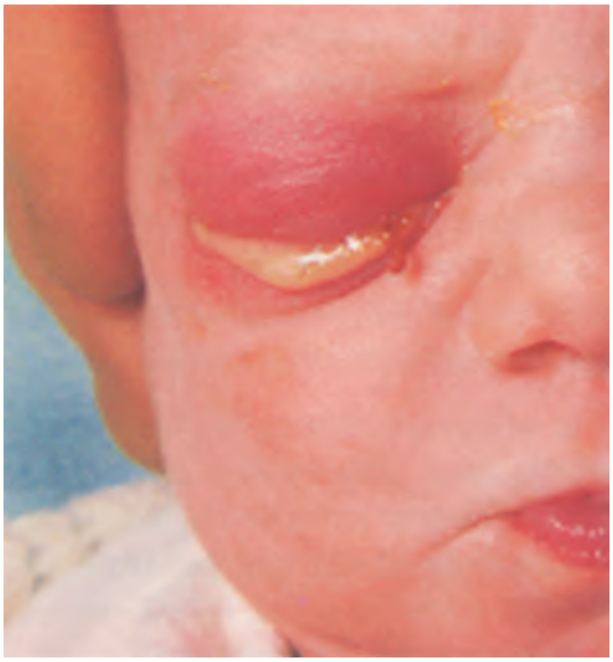

Fig. 15.5 **Gonococcal ophthalmia neonatorum.** *From McMillan A, Scott GR. Sexually transmitted infections: a colour guide. Edinburgh: Churchill Livingstone, Elsevier Ltd; 2000.*

15.9 Complications of delayed therapy in gonorrhoea

- Acute prostatitis
- Epididymo-orchitis
- Bartholin gland abscess
- Pelvic inflammatory disease (may lead to infertility or ectopic pregnancy)
- Disseminated gonococcal infection

Other complications arise if diagnosis or treatment is delayed (Box 15.9). Disseminated gonococcal infection (DGI) is rare. Symptoms include arthritis of one or more joints, pustular skin lesions, tenosynovitis and fever. Gonococcal endocarditis has been described.

Investigations

Gram-negative diplococci may be seen on microscopy of smears from infected sites (see Fig. 15.1). Pharyngeal smears are not helpful due to the presence of commensal *Neisseria* spp., which have the same microscopic appearance. *Neisseria meningitides* is increasingly identified as a cause of symptomatic urogenital infection and evidence suggests that strains of this organism have acquired from *N. gonorrhoea* genes conferring antibiotic resistance as well as those enabling survival in the anaerobic genital environment. Nucleic acid amplification tests (NAATs) are a widely used diagnostic test (see Box 15.1), with culture on selective medium in positive cases for antibiotic sensitivity surveillance. Nucleic acid probes for specific antibiotic resistance mutations (e.g. to ciprofloxacin) are increasingly available, with the future prospect of whole-genome sequencing.

Management of adults

Neisseria gonorrhoeae is a highly adaptable organism and has developed high-level resistance to a range of antibiotics over time, with frequent changes to recommended antibiotics and dosage. Multidrug-resistant gonorrhoea (MDRGC) has emerged as a significant concern in recent years. Current UK treatment recommendations are for a single 1 g dose of intramuscular ceftriaxone. Longer courses of antibiotics are required for complicated infection. NAAT-based antibiotic sensitivity testing available at the time of diagnosis offers the possibility of selective use of antibiotics previously rendered unsuitable for blind treatment (Box 15.10).

15.10 Treatment of uncomplicated anogenital gonorrhoea

Uncomplicated anogenital or pharyngeal infection

- Ceftriaxone 1 g IM as a single dose
- Ciprofloxacin 500 mg orally as a single dose[1,2]

Pregnancy and breastfeeding

- Ceftriaxone 1 g IM as a single dose
- Azithromycin 2g single dose[2]
- Spectinomycin 2 g IM stat[3]

Disseminated gonorrhoea

- Ceftriaxone 1 g IM or IV once daily or
- Cefotaxime 1 g IV 3 times daily
- Switched to an oral alternative according to sensitivities after 48 hrs and continued for 7 days

[1] Contraindicated in pregnancy and breastfeeding
[2] Only where nucleic acid amplification test (NAAT) or culture-based sensitivity testing shows sensitivity at all sites.
[3] Not routinely available.
(IM = intramuscular; IV = intravenous)

The partner(s) of patients with gonorrhoea should be seen as soon as possible.

Chlamydial infection

Chlamydia is transmitted and presents in a similar way to gonorrhoea. In women, the cervix and urethra are commonly involved. Infection is asymptomatic in about 80%, but may cause intermenstrual and/or post-coital bleeding, dysuria or vaginal discharge. Lower abdominal pain and dyspareunia are features of PID. Examination may reveal mucopurulent cervicitis, contact bleeding from the cervix, evidence of PID or no obvious clinical signs.

Other complications include perihepatitis (Fitz-Hugh–Curtis syndrome, p. 875), chronic pelvic pain, conjunctivitis and sexually acquired reactive arthritis (SARA) (p. 1062). Perinatal transmission may lead to ophthalmia neonatorum and/or pneumonia in the neonate. The majority of chlamydial infections clear spontaneously without treatment but others persist. The risk of ‘silent’ tubal damage and subsequent infertility or ectopic pregnancy following asymptomatic chlamydial infection is lower than had previously been understood and the impact of treatment on this risk is uncertain. Policies of mass screening for chlamydia have been reconsidered and in some countries have been abandoned.

In men, urethral symptoms are usually milder than those of gonorrhoea and may be absent in over 50% of cases. Conjunctivitis is also milder than in gonorrhoea; pharyngitis does not occur, although chlamydia is detected in pharyngeal samples in a small proportion of individuals. The incubation period varies from 1 week to a few months. Without treatment, symptoms may resolve but the patient remains infectious for several months. Complications, such as epididymo-orchitis and SARA are rare. Sexually transmitted pathogens, such as chlamydia or gonococci, are usually responsible for epididymo-orchitis in men aged less than 35 years, whereas bacteria such as gram-negative enteric organisms are more commonly implicated in older men.

Treatments for chlamydia (Box 15.11) are also used for empirical treatment of NGU. Antibiotic resistance has not yet been a significant issue. Sexual partners should be traced and may be tested and/or treated epidemiologically depending on circumstances. Technologies supporting testing, treatment and partner notification for chlamydia include app-based notification systems and electronic treatment vouchers which can be redeemed at community pharmacies.

15.11 Treatment of chlamydial infection

Uncomplicated infection

- First choice: Doxycycline 100 mg orally twice daily for 7 days[1]
- Second choice: Azithromycin 1 g orally as a single dose followed by 500 mg once daily for 2 days

Infection with possible complications (epididymo-orchitis, PID, SARA)[2]

- First choice: Doxycycline 100 mg orally twice daily for 14 days[1]
- Second choice: Ofloxacin 400 mg orally twice daily for 14 days[3]

[1] Contraindicated in pregnancy and breastfeeding.
[2] With additional antibiotics to cover other possible organisms.
[3] Quinolones are now less commonly used first line because of concerns about rare permanent and disabling side-effects.
(PID = pelvic inflammatory disease; SARA = sexually acquired reactive arthritis)

Mycoplasma genitalium

Mycoplasma genitalium is strongly associated with NGU (p. 408) and is implicated in the pathogenesis of PID. Its role in the development of other STI syndromes is not clear. A high proportion of *M. genitalium* isolates in the UK are resistant to macrolides. This has led to doxycycline replacing azithromycin as the first choice empirical treatment of chlamydial infection and NGU. Where azithromycin is used, a multiple-dose regimen shown in Box 15.11 is preferred over a single dose because this may be both more effective and reduce the risk of macrolide resistance developing in *M. genitalium*.

Other sexually transmitted bacterial infections

Chancroid, granuloma inguinale and LGV as causes of genital ulcers are described in Box 15.12. LGV now much more commonly presents as proctitis in GBMSM, having been acquired in Europe (p. 411).

Sexually transmitted viral infections

Genital herpes simplex

Infection with herpes simplex virus type 1 (HSV-1) or type 2 (HSV-2) produces a wide spectrum of clinical problems (p. 346), and facilitates the transmission of untreated HIV. Herpes is usually acquired sexually (vaginal, anal, orogenital or oro-anal), but perinatal transmission to the neonate may also occur. Primary infection at the site of HSV entry may be symptomatic or asymptomatic. HSV then establishes latency in local sensory ganglia, intermittently reactivating to cause either symptomatic or asymptomatic recurrences at the same site with viral shedding, during which transmission may occur. Most transmissions are thought to originate from people unaware of their infection. Although HSV-1 is classically associated with orolabial herpes and HSV-2 with anogenital herpes, HSV-1 accounts for more than 50% of anogenital infections in the UK.

Clinical features

Symptomatic episodes usually involve the external genitalia with irritable vesicles that soon rupture to form small, tender ulcers which scab and heal without scarring (Fig. 15.6, and see Fig. 15.3). A symptomatic episode at the time of acquisition is usually the most severe, but may occasionally be delayed following asymptomatic primary infection. Constitutional symptoms such as fever, headache and malaise are common. Complications, such as urinary retention due to autonomic neuropathy, and aseptic meningitis, are occasionally seen. Inguinal lymph nodes become enlarged and tender, and there may be nerve root pain in the 2nd and 3rd sacral dermatomes. Lesions at other sites (e.g. urethra, vagina, cervix, perianal area, anus or rectum) may cause dysuria, urethral or vaginal discharge, or anal, perianal or rectal pain. First episodes usually heal within 2–4 weeks without treatment; recurrences are similar but usually milder and of shorter duration than the initial attack.

Extragenital lesions may develop at other sites, such as the buttock, finger or eye, due to auto-inoculation.

15.12 Features of lymphogranuloma venereum, chancroid and granuloma inguinale (Donovanosis)

Infection and distribution	Organism	Incubation period	Genital lesion	Lymph nodes	Diagnosis	Management
Lymphogranuloma venereum (LGV)						
E/W Africa, India, SE Asia, S America, Caribbean	*Chlamydia trachomatis* types L1, 2, 3	3–30 days	Small, transient, painless ulcer, vesicle, papule; often unnoticed	Tender, usually unilateral, matted, suppurative bubo; inguinal/femoral nodes involved[1]	Swab from ulcer or bubo pus for *Chlamydia*, NAAT with LGV subtypes if positive	Doxycycline[2] 100 mg twice daily orally for 21 days *or* Erythromycin 500 mg orally 4 times daily
Chancroid						
Africa, Asia, Central and S America	*Haemophilus ducreyi* (short gram-negative bacillus)	3–10 days	Single or multiple painful ulcers with ragged undermined edges	As above but unilocular, suppurative bubo; inguinal nodes involved in ~50%	Microscopy and culture of scrapings from ulcer or pus from bubo	Azithromycin[3] 1 g orally once *or* Ceftriaxone 250 mg IM once *or* Ciprofloxacin[2] 500 mg orally twice daily for 3 days
Granuloma inguinale						
Australia, India, Caribbean, S Africa, S America, Papua New Guinea	*Klebsiella granulomatis* (Donovan bodies)	3–40 days	Ulcers or hypertrophic granulomatous lesions; usually painless[4]	Initial swelling of inguinal nodes, then spread of infection to form abscess or ulceration through adjacent skin	Microscopy of cellular material for intracellular bipolar-staining Donovan bodies	Azithromycin[3] 1 g orally weekly or 500 mg orally daily *or* Doxycycline[2] 100 mg orally twice daily *or* Ceftriaxone 1 g IM daily

N.B. Partners of patients with LGV, chancroid and granuloma inguinale should be investigated and treated, even if asymptomatic.

[1] LGV acquired as a rectal infection in GBMSM commonly presents as proctitis.

[2] Doxycycline and ciprofloxacin are contraindicated in pregnancy and breastfeeding.

[3] The safety of azithromycin in pregnancy and breastfeeding has not been fully assessed but it is very widely used.

[4] Mother-to-baby transmission of granuloma inguinale may rarely occur.

(IM = intramuscular; NAAT = nucleic acid amplification test)

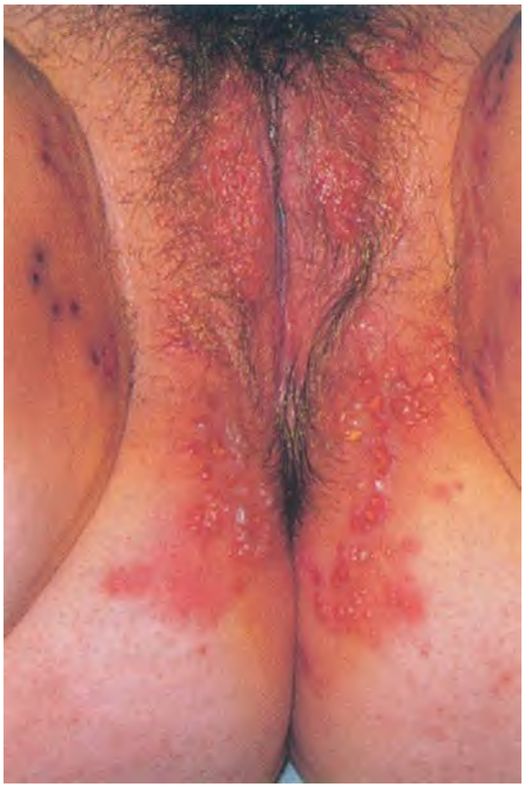

Fig. 15.6 **Herpetic ulceration of the vulva.** *From McMillan A, Scott GR. Sexually transmitted infections: a colour guide. Edinburgh: Churchill Livingstone, Elsevier Ltd; 2000.*

HSV-1 and HSV-2 episodes are clinically identical, but recurrences occur more often in HSV-2 infection and their frequency tends to decrease more slowly with time. Prodromal symptoms, such as irritation or burning at the affected site, or neuralgic pain affecting buttocks, legs or hips often occur prior to a symptomatic recurrence.

Diagnosis

Swabs are taken from vesicular fluid or ulcers for detection of HSV-1 and 2 DNA by NAAT. Type-specific antibody tests for HSV-1 and 2 are available but not routinely used for diagnosis.

Management

First episode

Oral antiviral treatment will shorten the duration of symptoms if started within 5 days of the beginning of the episode, or while lesions are still forming. Occasionally, intravenous therapy may be indicated if oral therapy is poorly tolerated or aseptic meningitis occurs. Many possible oral dosage regimens are used, including:

- aciclovir 400 mg 3 times daily for 5 days
- valaciclovir 500 mg twice daily for 5 days.

Topical and oral analgesia is helpful and patients are advised to use a warm shower spray to ease urination. Catheterisation via the suprapubic route is occasionally required for urinary retention. Treatment may be continued for longer than 5 days if new lesions develop.

Recurrent genital herpes

Symptomatic recurrences are usually mild and may require no specific treatment other than saline bathing, although the psychosexual impact of herpes stigma in a minority of patients should be considered. For more severe or prolonged episodes, patient-initiated treatment within 24 hours of onset, with one of the following oral regimens, should reduce the duration of the recurrence:

- aciclovir 800 mg 3 times daily for 2 days
- valaciclovir 500 mg twice daily for 5 days.

In a few patients, treatment started at the onset of prodromal symptoms may abort recurrence.

Those with recurrences that are severe and/or frequent may benefit from suppressive therapy, usually with aciclovir 400 mg twice daily. Daily treatment should be given for a minimum of 1 year before stopping to assess recurrence rate. The rate of decay in frequency of recurrence is low, so only about 20% of patients will experience significantly reduced rates. For others, resumption of suppressive therapy is justified.

Management in pregnancy

The risk of disseminated infection is increased in pregnancy, particularly in the third trimester. A pregnant woman with no previous anogenital herpes and a partner with a history of HSV infection should be advised on avoiding acquisition, which may include consistent condom use during pregnancy to reduce genital-to-genital transmission. Antibody testing can identify the type-specific HSV serostatus of a woman and her partner and inform the advice given. Treatment with aciclovir is usually offered for genital herpes acquired during pregnancy after appropriate discussion; although aciclovir is not licensed for use in pregnancy in the UK, there is considerable clinical evidence to support its safety.

Vaginal delivery is routine in most women with herpes in pregnancy. Caesarean section is sometimes considered if there is a recurrence at the beginning of labour, although the risk of neonatal herpes through vaginal transmission is very low. Caesarean section is often recommended if primary infection occurs after 34 weeks because the risk of viral shedding in labour is very high and the antibody response to HSV which develops in the mother and protects the neonate by transplacental transmission may not have fully developed.

Human papillomavirus and anogenital warts (Fig. 15.7)

Human papillomavirus (HPV) subtypes (p. 1120) that preferentially infect the genital skin and are mainly sexually transmitted include benign genotypes (HPV-6 and 11) causing anogenital warts as well as genotypes such as 16 and 18, which do not cause genital warts but are associated with cervical, vulval, penile and anal intra-epithelial neoplasia (CIN, VIN, PIN and AIN) and the associated invasive cancers, as well as with cancers of the oropharynx. HPV is commonly transmitted through non-penetrative sex so affects unvaccinated individuals from the early years of adolescence onwards. Asymptomatic infection without any clinical sequelae is usual with all subtypes and infection with multiple subtypes is common.

Clinical features

Anogenital warts caused by HPV may be single or multiple, exophytic, papular or flat. Rarely, a giant condyloma (Buschke–Löwenstein tumour) develops, with local tissue destruction. Because of the association with intra-epithelial neoplasia, warts with an atypical appearance should be biopsied. Perianal warts (p. 406) are more common in MSM, but are also found in women and in heterosexual men. In pregnancy, warts may dramatically increase in size and number, making treatment difficult. Rarely, they are large enough to obstruct labour so delivery by caesarean section is required. Perinatal transmission of HPV occasionally leads to anogenital warts and rarely to laryngeal papillomas in the neonate.

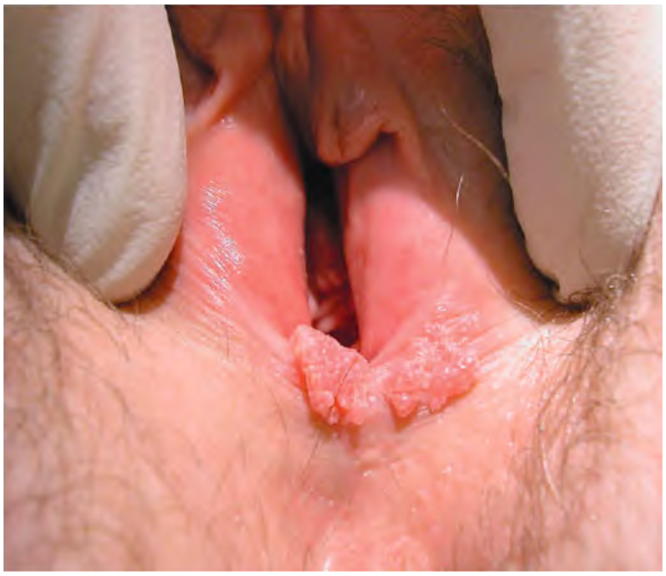

Fig. 15.7 Genital warts (condylomata acuminata) at the vaginal introitus. *From Clutterbuck DJ. Specialist training in sexually transmitted infections and HIV. St Louis: Mosby, Elsevier Inc.; 2004.*

Management

The use of condoms can help prevent the transmission of HPV to non-infected partners, but as condoms do not cover all of the genital skin, protection is incomplete. Vaccination is routine in many countries:

- *A bivalent vaccine* protects against HPV types 16 and 18, which account for approximately 75% of cervical cancers in the UK.
- *A quadrivalent vaccine* offers additional protection against HPV types 6 and 11, which account for over 90% of genital warts.
- *A nonavalent vaccine* protects against five additional high-risk types (31, 33, 45, 52 and 58).

All vaccines have been shown to be highly effective in the prevention of cervical intra-epithelial neoplasia in young women, and the quadrivalent and nonavalent vaccines have also been demonstrated to be highly effective in protecting against HPV-associated genital warts. HPV vaccination is usually administered prior to the onset of sexual activity, typically at age 11–13, in a course of two injections. In the UK, vaccination has been offered to girls since 2007 (with quadrivalent vaccine from 2012) and the recommendation was extended to boys from 2020.

Benign anogenital warts sometimes resolve spontaneously without treatment and in the vast majority of cases are a harmless, if sometimes distressing, inconvenience. Topical self-administered treatments commonly prescribed for use at home include:

- Podophyllotoxin, 0.5% solution or 0.15% cream (contraindicated in pregnancy)
- Imiquimod cream (contraindicated in pregnancy), also used in the treatment of HPV-associated intra-epithelial neoplasia
- Catephen, an extract of the green tea plant, *Camellia sinensis*.

Ablative therapies, usually performed by a clinician, are sometimes used first line or for warts that are keratinised, extensive or resistant to topical treatment.

- *Cryotherapy* using liquid nitrogen to freeze warty tissue often requires repeated clinic visits, although home cryotherapy is available. It is one of the few options for treatment of warts in pregnancy.

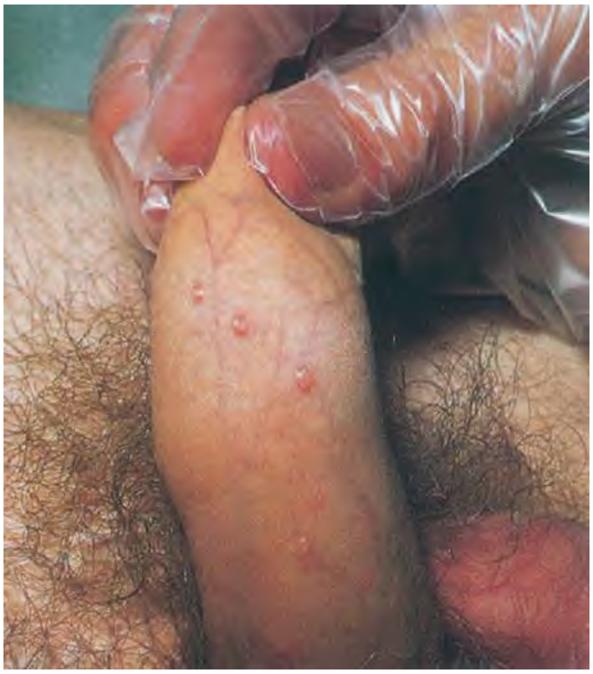

Fig. 15.8 **Molluscum contagiosum of the shaft of the penis.** *From McMillan A, Scott GR. Sexually transmitted infections: a colour guide. Edinburgh: Churchill Livingstone, Elsevier Ltd; 2000.*

- *Hyfrecation* – surgical electrofulguration using the heat from an electric current to destroy tissue – is suitable for external and internal warts.
- *Surgical removal* may be used to excise extensive and/or refractory warts, especially pedunculated perianal lesions, under local or general anaesthesia.

Molluscum contagiosum

Infection by molluscum contagiosum virus, both sexual and non-sexual, produces flesh-coloured, umbilicated, hemispherical papules usually up to 5 mm in diameter after an incubation period of 3–12 weeks (Fig. 15.8). Lesions are often multiple and, once established in an individual, may spread by auto-inoculation. Infection in childhood is common; many individuals are immune by adulthood. If not, sexually acquired infection causes lesions on the genitalia, lower abdomen and upper thighs. The diagnosis is usually clinical. Typically, lesions persist for several months before spontaneous resolution occurs. Treatment regimens are therefore cosmetic; they include cryotherapy, hyfrecation or topical applications of 0.15% podophyllotoxin cream (contraindicated in pregnancy). The hard, pearly central core of each lesion can be removed using a needle and results in resolution, but this carries a risk of scarring.

Mpox

A worldwide outbreak of clade II Mpox, the majority of cases affecting GBMSM, occurred in 2022–2023. Between 84% and 100% of cases followed sexual contact, often with an new partner, leading to the suggestion that Mpox is an STI. The case fatality rate was much lower than previously recorded outbreaks in Central and West Africa but severe cases and secondary bacterial infections may require hospitalisation. Symptoms include the development of painful ulcerative lesions on the genitals, limbs (including palms and soles) and the face with fever, fatigue, headache and myalgia and in some cases severe proctitis. Lesions usually resolve spontaneously without treatment over 3–4 weeks. Smallpox vaccines offer protection, and mass vaccination programmes for at-risk individuals were implemented in many countries. An outbreak of clade Ib Mpox began in 2024.

Viral hepatitis

The hepatitis viruses A–D (p. 903) may be sexually transmitted:

- *Hepatitis A (HAV)*. Enteric infection may be transmitted through insertive oro-anal, digital-anal sex or peno-anal sex. Outbreaks of hepatitis A occur in GBMSM populations, most recently across Europe in 2016–2018.
- *Hepatitis B (HBV)*. Hepatitis B is highly transmissible through all forms of penetrative sex, including oral sex, and is seen more commonly in groups with higher rates of partner change including sex workers and GBMSM, or with partners from endemic areas. Hepatitis D (HDV) may also be sexually transmitted.
- *Hepatitis C (HCV)*. Hepatitis C is much less transmissible through sex than HBV. Sex involving mucosal trauma (such as anal sex) carries a higher risk, and sexually transmitted HCV is seen more commonly in GBMSM, particularly those co-infected with HIV, than in other populations.

Active immunisation against HAV and HBV should be offered to susceptible people at risk of infection. Many STI clinics offer a combined HAV and HBV vaccine to all GBMSM and trans women.

Partner notification, for testing and advice on preventing onward transmission, is offered to all those diagnosed with sexually transmitted viral hepatitis, with vaccination for HAV and HBV. No active or passive immunisation is available for protection against HCV, but the consistent use of condoms is likely to protect susceptible partners until the index patient is able to complete treatment.

Multiple Choice Questions

15.1. The preferred treatment for uncomplicated chlamydial infection changed from single dose azithromycin to a 7-day course of doxycycline primarily because of concerns about the development of antimicrobial resistance in which organism?

A. *Chlamydia trachomatis*
B. *Mycoplasma genitalium*
C. *Haemophilus ducreyi*
D. *Treponema pallidum*
E. *Trichomonas vaginalis*

Answer: B.

The rates of macrolide resistance in *Mycoplasma genitalium* in the UK in 2023 were 62%, probably driven by the previous widespread use of single-dose azithromycin for the treatment of chlamydial infection in sexually active individuals. Treatment of antibiotic-resistant *M. genitalium* in symptomatic individuals such as men with non-gonococcal urethritis (NGU) can be difficult. Azithromycin has never been a first-line treatment for syphilis in the UK, but resistance does occur in *Treponema pallidum*. Azithromycin is a potential treatment for chancroid and resistance in *Haemophilus ducreyi* is not currently widely reported.

15.2. A 49-year-old woman who has had two new male partners in the past 4 weeks presents to her general practitioner with vaginal discharge having a 'fishy' smell which is worse after sex. She has had 3 days of intermenstrual bleeding which is unusual, but no abdominal or pelvic pain. On examination a thin grey discharge is seen without evidence of vulvitis. The optimal management plan is:

A. Empirical treatment for bacterial vaginosis (BV) with clindamycin cream and a cervical smear test
B. Swabs for NAAT for gonorrhoea and chlamydia and await results
C. High vaginal swab for microscopy for *Trichomonas vaginalis* (TV) and bacterial vaginosis and empirical treatment for bacterial vaginosis with oral metronidazole
D. Swabs for NAAT for gonorrhoea, chlamydia and *Trichomonas vaginalis* and empirical treatment with oral metronidazole
E. Treatment with IM ceftriaxone, oral doxycycline and metronidazole for possible gonococcal, chlamydial, TV or BV infection

Answer: D.

The commonest cause of a vaginal discharge with smell is bacterial vaginosis. BV does not cause inflammation or cervical bleeding. Intermenstrual bleeding is common in perimenopausal women. In a postmenopausal woman it may be a cause for concern but STIs should be excluded before investigating other causes. STIs have a much higher prevalence in young people but are seen in older sexually active individuals, particularly those with multiple partners. Both gonorrhoea and chlamydial infection cause cervicitis so should be excluded. *Trichomonas vaginalis* does not usually cause a cervicitis without significant vaginal inflammation and vulvitis, but should also be considered. NAAT testing for TV is not yet universal but is increasingly available as a routine test. Empirical treatment with metronidazole will usually cure both TV and BV. Syndromic management – giving treatment to cover all possible infections – would not usually be a preferred approach where testing is available unless there were symptoms and signs of ascending infection (pelvic inflammatory disease).

15.3. A 21-year-old woman presented to a walk-in sexual health clinic complaining of a painful rash on her vulva for the past 4 days, which she had not had before. She said that 7 days ago she had left her male partner because he had disclosed that he had been having sex with several other partners, both male and female, during their relationship, so she would like testing for other STIs. She uses recreational drugs and occasionally injects. She does not have a current sexual partner. On examination you identified a vesicular rash on her vulva that you diagnosed clinically as genital herpes, for which you treated her empirically with oral aciclovir 400 mg 3 times daily for 5 days. She had no symptoms or signs to suggest other STI or blood-borne virus (BBV) infection. You carried out relevant diagnostic tests and full testing for other STIs and BBVs. She returns to the clinic a few days later to see a health adviser, who telephones to ask your advice on management and advises of the following results:

Polymerase chain reaction (PCR) for *Chlamydia trachomatis* – positive
HIV-1 antigen/antibody (Ag/Ab) test – negative
PCR for *Neisseria gonorrhoeae* – negative
Hepatitis B surface antigen (HBsAg) – negative
Hepatitis B core antibody (anti-HBc) – positive
Hepatitis C antibody – positive
PCR of vesicle fluid for herpes simplex virus type 1 (HSV-1) – negative
PCR of vesicle fluid for herpes simplex virus type 2 (HSV-2) – positive
Treponema pallidum EIA – positive

Which one of the following actions would be appropriate on the basis of the above results?

A. Advise treatment with oral azithromycin 1 g orally followed by 500 mg once daily for 2 days
B. Send a further blood sample for hepatitis B PCR (viral load)
C. Send a further blood sample for hepatitis C PCR (viral load)
D. Initiate suppressive therapy for HSV-2 with aciclovir 400 mg 2 times per day for 3 months
E. Advise treatment with a single dose of 2.4 megaunits of long-acting intramuscular benzathine benzylpenicillin

Answer: C.

The positive *Chlamydia* PCR indicates current infection. However, the recommended treatment is with doxycycline rather than azithromycin, to take into account possible coexisting infection with macrolide-resistant *Mycoplasma genitalium*. The positive anti-HBc indicates past infection with hepatitis B and the negative HBsAg indicates an absence of current infection; there is therefore no indication to test her viral load. The positive hepatitis C antibodies are a marker of either current or past infection so should be investigated further by hepatitis C PCR, which, if positive, would indicate current infection. A first episode of genital herpes is usually treated with a 5-day course of aciclovir; longer-term suppressive therapy is reserved for patients who have severe and/or frequent recurrences. The *T. pallidum* EIA is a screening test for both IgG and IgM, so may indicate either past or current infection; therefore, further investigation is necessary (with *T. pallidum* IgM and a non-treponemal test) rather than treatment for syphilis.

15.4. A 23-year-old man presents for the first time to a specialist sexual health service with a 4-day history of dysuria and purulent urethral discharge. He has had condomless insertive vaginal, oral and anal sex with three female sexual partners over the last 3 weeks. Direct microscopy of a Gram-stained sample of urethral discharge shows many pus cells and gram-negative intracellular diplococci. The preferred management plan is:

A. Take samples for gonorrhoea NAAT testing and culture from the urethra, and blood for HIV and syphilis serology, treat empirically for urethral gonorrhoea with IM ceftriaxone 1 g single dose and notify the most recent female partner
B. Take samples for NAAT testing for *Neisseria gonorrhoea* and *Chlamydia trachomatis* from the urethra and pharynx, along with cultures for gonococcal antimicrobial sensitivities and HIV and syphilis serology. Treat for suspected gonorrhoea with IM ceftriaxone 1 g single dose. Obtain details of three recent partners for partner notification
C. Take samples for NAAT testing for *Neisseria gonorrhoea* and *Chlamydia trachomatis* from the urethra and pharynx, and blood for HIV and syphilis serology and treat with oral doxycycline 100 mg twice daily for 7 days for possible chlamydial infection. Treat for gonorrhoea and notify partners depending upon antimicrobial sensitivity results
D. Take samples for NAAT testing and culture for gonococcal antimicrobial sensitivities from the urethra, treat for both gonorrhoea and chlamydial infection and notify all three recent partners
E. Perform NAAT testing for *Neisseria gonorrhoea* and *Chlamydia trachomatis* from the urethra, pharynx and rectum along with cultures for gonococcal antimicrobial sensitivities and blood for HIV and syphilis serology. Treat for suspected gonorrhoea with IM ceftriaxone 1 g single dose. Obtain details of the most recent partner for partner notification

Answer: B.

Gram-stained microscopy has high sensitivity and specificity for the diagnosis of urethral gonorrhoea in men. Immediate treatment with ceftriaxone 1 g IM single dose on the basis of a presumptive diagnosis is appropriate but treatment for possible coexisting chlamydial infection is not routinely given. Resistance to ceftriaxone remains rare but is a major concern, so optimal management includes culture for antimicrobial sensitivity, which should be taken from all potentially exposed sites, and would usually include the rectum in women and MSM but not in men-who-have-sex-with-women (MSW). Testing for HIV and syphilis should be part of routine testing for STI in all cases in all individuals. Symptoms of urethral gonorrhoea in men usually develop within 7 days of contact with an infected individual; however, in symptomatic men, all partners within the last 4 weeks would usually be traced for testing and/or treatment.

15.5. An asymptomatic 19-year-old cis gay man attends a drop-in sexual health clinic for the first time requesting HIV post-exposure prophylaxis (PEP), reporting consensual condomless receptive anal sex with two new male partners on multiple occasions, the most recent being four days ago. He has been sexually active for 3 years and has previously accessed PEP through an emergency department over a year ago. The most appropriate approach is:

A. Initiate HIV PEP with oral tenofovir/emtricitabine and raltegravir immediately to continue for 28 days, arrange for serological testing for syphilis, HIV, hepatitis B and C, eGFR and NAATs for chlamydia and gonorrhoea
B. Initiate HIV PEP with oral tenofovir/emtricitabine and raltegravir immediately to continue for 28 days, arrange for serological testing for syphilis, HIV, hepatitis B and C, eGFR and NAATs for chlamydia and gonorrhoea and commence vaccinations for HPV (Gardasil), hepatitis A and B and Mpox
C. Initiate HIV PEP with oral tenofovir/emtricitabine and raltegravir to start immediately and continue for 28 days, with transition to oral daily PrEP (tenofovir/emtricitabine) after 28 days, arrange for serological testing for syphilis, HIV, hepatitis B and C, eGFR and NAATs for chlamydia and gonorrhoea and advise on Doxy-PEP
D. Initiate daily HIV PrEP with oral tenofovir/emtricitabine to start immediately, perform near-patient testing for HIV and syphilis, arrange for serological testing for syphilis, HIV, hepatitis B and C, eGFR and NAATs for chlamydia and gonorrhoea with follow-up for testing and vaccination in 28 days
E. Counsel regarding daily or event-based HIV PrEP with oral tenofovir/emtricitabine and regarding Doxy-PEP, perform near-patient testing for HIV and syphilis, arrange for serological testing for syphilis, HIV, hepatitis B and C, eGFR and NAATs for chlamydia and gonorrhoea and commence vaccinations for HPV (Gardasil), hepatitis A and B and Mpox, with follow-up for testing and PrEP start in 28 days

Answer: D.

HIV post-exposure prophylaxis (PEP) with a combination of three antiretroviral drugs is indicated only where a potential exposure to HIV has occurred within the preceding 72 hours. It is important to rule out recent HIV acquisition in those starting PrEP but this should not delay PrEP prescribing in those with repeated ongoing risk. ‘Quick start’ PrEP is appropriate in those with no symptoms of HIV seroconversion and near-patient testing for HIV is helpful in addition to serological testing in those who have not had an HIV test for some time. Testing for other STIs and infectious hepatitis, vaccinations (hepatitis A and B, Mpox, HPV) and Doxy-PEP are all appropriate interventions for individuals with elevated STI and BBV risk.

15.6. A 28-year-old woman presents to the sexual health clinic with a 3-month history of genital lumps. She is keen to have these lumps treated. She has been with a regular male partner for one year; he is asymptomatic. She uses a fertility app to avoid pregnancy and has decided against hormonal contraception. On examination there are a few small, scattered, flesh-coloured genital skin lumps at the vulva, with a papillary surface typical of genital warts. The most appropriate management is:

A. Offer wart treatment with liquid nitrogen cryotherapy, on the basis of clinical appearances
B. Refer for coloscopy examination prior to offering treatment with a self-applied topical podophyllotoxin cream
C. Undertake swab testing of the genital lesions for PCR testing for HSV, to confirm the diagnosis of benign genital warts, prior to offering treatment
D. Undertake swab testing of the genital lesions for PCR testing for HPV types 16 and 18, to exclude HPV-related vulval intra-epithelial neoplasia (VIN), prior to offering treatment with self-applied topical imiquimod
E. Undertake swab testing of the genital lesions for PCR testing for HPV types 6 and 11, to confirm the diagnosis of benign genital warts, prior to offering treatment with liquid nitrogen cryotherapy

Answer: A.

A clinical diagnosis of genital warts is sufficient in the vast majority of cases and liquid nitrogen cryotherapy is appropriate where self-applied topical treatments are unsuitable. Self-applied topical treatment with topical podophyllotoxin, imiquimod or green tea (*Camellia sinensis*) extract (Cataphen) is often preferred but is usually contraindicated in those at risk of pregnancy. App-based fertility trackers are not regarded as adequate contraception in this context. Herpes simplex virus does not cause warts. PCR testing for HPV subtypes is an important component of routine cervical cancer screening but is not used in wart diagnosis.

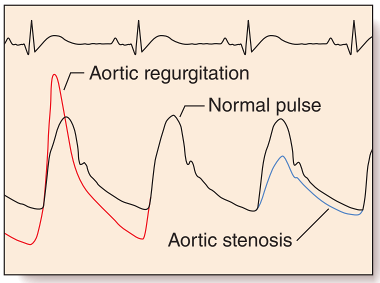
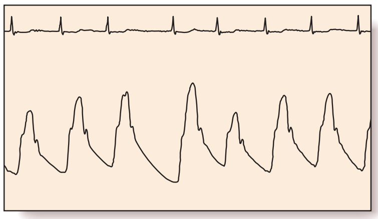
4 Examination of the arterial pulse

- The character of the pulse is determined by stroke volume and arterial compliance, and is best assessed by palpating a major artery, such as the carotid or brachial artery.
- Aortic regurgitation, anaemia, sepsis and other causes of a large stroke volume typically produce a bounding pulse with a high amplitude and wide pulse pressure (panel A).
- Aortic stenosis impedes ventricular emptying. If severe, it causes a slow-rising, weak and delayed pulse (panel A).
- Sinus rhythm produces a pulse that is regular in time and volume. Arrhythmias may cause irregularity. Atrial fibrillation produces a pulse that is irregular in time and volume (panel B).



A

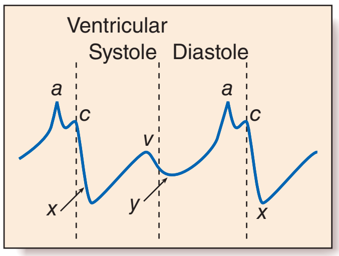


B

5 Examination of the jugular venous pulse

The internal jugular vein, superior vena cava and right atrium are in continuity, so the height of the jugular venous pulsation reflects right atrial pressure. When the patient is placed at 45°, with the head supported and turned to the left, the jugular venous pulse is visible along the line of the sternocleidomastoid muscle (see opposite). In health it is normally just visible above the clavicle.

- The height of the jugular venous pulse is determined by right atrial pressure and is therefore elevated in right heart failure and reduced in hypovolaemia.
- If the jugular venous pulse is not easily seen, it may be exposed by applying firm pressure over the abdomen.
- In sinus rhythm, the two venous peaks, the *a* and *v* waves, approximate to atrial and ventricular systole, respectively.
- The *x* descent reflects atrial relaxation and apical displacement of the tricuspid valve ring. The *y* descent reflects atrial emptying early in diastole. These signs are subtle.
- Tricuspid regurgitation produces giant *v* waves that coincide with ventricular systole.



i Distinguishing venous/arterial pulsation in the neck

- The venous pulse has two peaks in each cardiac cycle; the arterial pulse has one peak.
- The height of the venous pulse varies with respiration (falls on inspiration) and position.
- Abdominal compression causes the venous pulse to rise.
- The venous pulse is not easily palpable and can be occluded with light pressure.

7 Palpation of the precordium

Technique

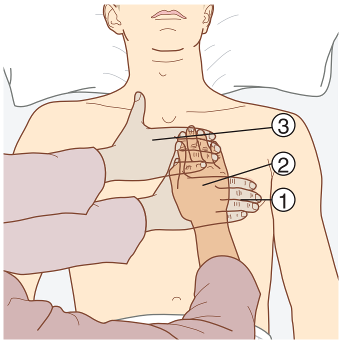
- Place fingertips over apex (1) to assess for position and character. Place heel of hand over left sternal border (2) for a parasternal heave or 'lift'. Assess for thrills in all areas, including the aortic and pulmonary areas (3). Normal position is the 5th or 6th intercostal space, at the mid-clavicular line.

Common abnormalities of the apex beat

- Volume overload, such as mitral or aortic regurgitation: displaced, thrusting
- Pressure overload, such as aortic stenosis, hypertension: discrete, heaving
- Dyskinetic, such as left ventricular aneurysm: displaced, incoordinate

Other abnormalities

- Palpable S1 (tapping apex beat: mitral stenosis)
- Palpable P2 (severe pulmonary hypertension)
- Left parasternal heave or 'lift' felt by heel of hand (right ventricular hypertrophy)
- Palpable thrill (aortic stenosis)



8 Auscultation of the heart

- Use the diaphragm to examine at the apex, lower left sternal border (tricuspid area) and upper left (pulmonary area) and right (aortic area) sternal borders.
- Use the bell to examine low-pitched noises, particularly at the apex for the mid-diastolic murmur of mitral stenosis.
- Time the sounds and murmurs by feeling the carotid pulse; the first heart sound (S1) just precedes the upstroke of the pulse and the second heart sound (S2) is out of step with it. If present, a third heart sound (S3) immediately follows S2, and a fourth heart sound (S4) just precedes S1. Systolic murmurs are synchronous with the pulse.
- Listen for radiation of systolic murmurs, over the base of the neck (aortic stenosis) and in the axilla (mitral incompetence).
- Listen over the left sternal border with the patient sitting forward (aortic incompetence), then at the apex with the patient rolled on to the left side (mitral stenosis).

The haemodynamic effects of respiration are discussed on page 427, and the analysis and interpretation of heart sounds and murmurs on page 436.

Cardiovascular disease is the commonest cause of death worldwide. The World Health Organization estimates that more people have died from cardiovascular disease since 1990 than any other category of illness, including infectious diseases. Strategies for the treatment and prevention of heart disease can be highly effective and have been subjected to rigorous evaluation by randomised trials. The evidence base for the treatment of cardiovascular disease is stronger than for almost any other disease group.

Coronary heart disease is the leading cause of death, with 3.8 million men and 3.4 million women dying each year. Although the incidence has been falling in some countries, it is rising in lower-income countries, where it accounts for more than 60% of the global burden of coronary heart disease. Valvular heart disease is also common, but the aetiology varies in different parts of the world. In South Asia and in Africa it is predominantly due to rheumatic fever, whereas calcific aortic valve disease is the commonest problem in high-income countries.

Prompt recognition of the development of heart disease is limited by two key factors. First, it is often clinically silent for prolonged periods and coronary heart disease can proceed to an advanced stage before the patient notices any symptoms. Second, the diversity of symptoms attributable to heart disease is limited, so different pathologies may frequently present with the same symptoms.

Functional anatomy and physiology

Anatomy

The heart acts as two serial pumps that share several electrical and mechanical components. The right heart circulates blood to the lungs where it is oxygenated, and the left heart circulates it to the rest of the body (Fig. 16.1). The atria are thin-walled structures that act as priming pumps for the ventricles, which provide most of the energy required to maintain the circulation. The atria are situated posteriorly within the mediastinum. The left atrium (LA) sits anterior to the oesophagus and descending aorta, and receives blood from four pulmonary veins, two from each of the left and right lungs. The right atrium (RA) receives blood from the superior and inferior venae cavae and the coronary sinus. The ventricles are thick-walled structures that pump blood through large vascular beds under pressure. The atria and ventricles are separated by the annulus fibrosus, which forms the skeleton for the atrioventricular (AV) valves, and which electrically insulates the atria from the ventricles. The right ventricle (RV) is about 2–3 mm thick and triangular in shape. It extends from the annulus fibrosus to near the cardiac apex and sits anterior and to the right of the left ventricle (LV). The anterosuperior surface of the RV is rounded and convex, and its posterior extent is bounded by the interventricular septum, which bulges into the chamber. Its upper extent forms the right ventricular outflow tract, from which the pulmonary artery arises. The LV is more conical in shape and in cross-section is nearly circular. It extends from the LA to the apex of the heart. The LV myocardium is approximately 10 mm thick because it pumps blood at a higher pressure than the RV through a larger vascular bed.

Normally, the heart occupies less than 50% of the transthoracic diameter in the frontal plane, as seen on a chest X-ray. On the patient's left, the cardiac silhouette is formed by the aortic arch, the pulmonary trunk, the left atrial appendage and the LV. On the right, the silhouette is formed by the RA and the superior and inferior venae cavae, and the lower right border is formed by the RV (Fig. 16.2). In disease states or congenital cardiac abnormalities, the silhouette may change because of hypertrophy or dilatation.

Coronary circulation

The left main and right coronary arteries arise from the left and right sinuses of the aortic root, superior to the aortic valve (Fig. 16.3). Within 2.5 cm of its origin, the left main coronary artery divides into the left anterior descending artery (LAD), which runs in the anterior interventricular groove, and the left circumflex artery (CX), which runs posteriorly in the atrioventricular groove. The LAD gives branches to supply the anterior part of the septum (septal perforators) and the anterior, lateral and apical walls of the LV. The CX gives marginal branches that supply the lateral, posterior and inferior segments of the LV. The right coronary artery (RCA) runs in the right atrioventricular groove, giving branches that supply the RA, RV and inferoposterior aspects of the LV. The posterior descending artery runs in the posterior interventricular groove and supplies the inferior part of the interventricular septum. This vessel is a branch of the RCA in approximately 90% of people (dominant right system) and is a branch of the CX in the remainder (dominant left system). The coronary anatomy varies greatly from person to person and there are many normal variants.

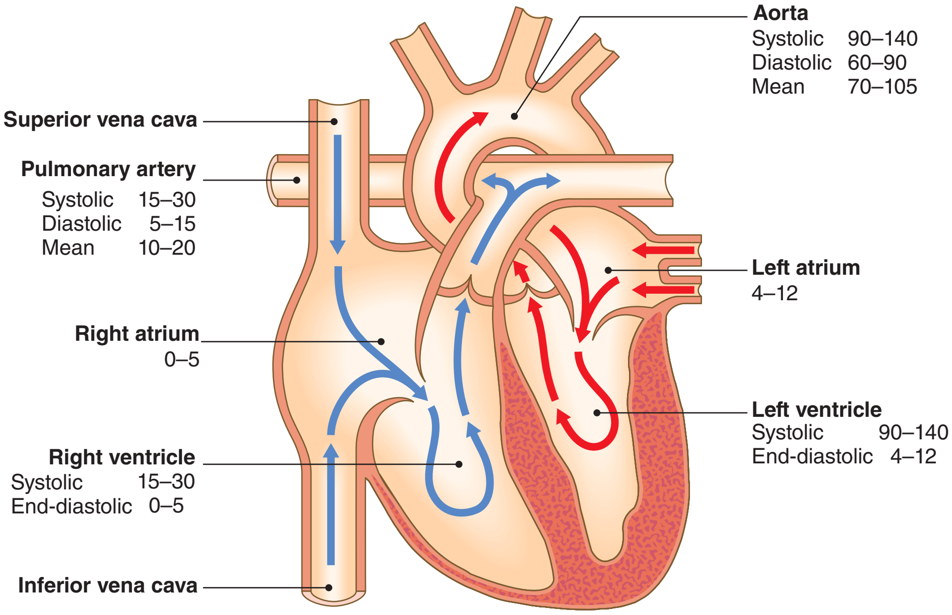


Fig. 16.1 Direction of blood flow through the heart. The blue arrows show deoxygenated blood moving through the right heart to the lungs. The red arrows show oxygenated blood moving from the lungs to the systemic circulation. The normal pressures are shown for each chamber in mmHg.

Fig. 16.3 The coronary arteries: anterior view.

The RCA supplies the sinoatrial (SA) node in about 60% of individuals and the AV node in about 90%. Proximal occlusion of the RCA therefore often results in sinus bradycardia and may also cause AV nodal block. Abrupt occlusion of the RCA, due to coronary thrombosis, results in infarction of the inferior part of the LV and often the RV. Abrupt occlusion of the LAD or CX causes infarction in the corresponding territory of the LV, and occlusion of the left main coronary artery is usually fatal.

The venous system follows the coronary arteries but drains into the coronary sinus in the atrioventricular groove, and then to the RA. An extensive lymphatic system drains into vessels that travel with the coronary vessels and then into the thoracic duct.

Conduction system

The SA node is situated at the junction of the superior vena cava and RA (Fig. 16.4). It comprises specialised atrial cells that depolarise at a rate influenced by the autonomic nervous system and by circulating catecholamines. During normal (sinus) rhythm, this depolarisation wave propagates through the atria via sheets of atrial myocytes. The annulus fibrosus forms a conduction barrier between atria and ventricles, preventing transmission of conduction except through the AV node. The AV node is a midline structure, extending from the right side of the interatrial septum, penetrating the annulus fibrosus anteriorly. It conducts relatively slowly, producing a necessary time delay between atrial and ventricular contraction. The His–Purkinje system is composed of the bundle of His extending from the AV node into the interventricular septum, the right and left bundle branches passing along the ventricular septum and into the respective ventricles, the anterior and posterior fascicles of the left bundle branch, and the smaller Purkinje fibres that ramify through the ventricular myocardium. The tissues of the His–Purkinje system conduct very rapidly and allow near-simultaneous depolarisation of the entire ventricular myocardium.

Fig. 16.4 The cardiac conduction system. Depolarisation starts in the sinoatrial node and spreads through the atria (blue arrows), and then through the atrioventricular node (black arrows). Depolarisation then spreads through the bundle of His and the bundle branches to reach the ventricular muscle (red arrows). Repolarisation spreads from epicardium to endocardium (green arrows).

Nerve supply of the heart

The heart is innervated by both sympathetic and parasympathetic fibres. Adrenergic nerves from the cervical sympathetic chain supply muscle fibres in the atria and ventricles, and in the electrical conducting system. Activation of β_1-adrenoceptors in the heart results in positive inotropic and chronotropic effects, whereas activation of β_2-adrenoceptors in vascular smooth muscle causes vasodilatation. Parasympathetic pre-ganglionic fibres and sensory fibres reach the heart through the vagus nerves. Cholinergic nerves supply the AV and SA nodes via muscarinic (M2) receptors. Under resting conditions, vagal inhibitory activity predominates, and the heart rate is slow. Exercise and other stressors such as emotional stress, fever and so on, cause the heart rate to increase through a decrease in parasympathetic activity and an increase in sympathetic stimulation. In disease states, the nerve supply to the heart may be affected. For example, in heart failure the sympathetic system may be upregulated, and in diabetes mellitus the nerves themselves may be damaged by autonomic neuropathy so that there is little variation in heart rate.

Physiology

Myocardial contraction

Myocardial cells (myocytes) are about 50–100 μm long; each cell branches and interdigitates with adjacent cells. An intercalated disc permits electrical conduction via gap junctions, and mechanical conduction via the fascia adherens, to adjacent cells (Fig. 16.5A). The basic unit of contraction is the sarcomere (2 μm long), which is aligned to those of adjacent myofibrils, giving a striated appearance due to the Z-lines (Fig. 16.5B and C). Actin filaments are attached at right angles to the Z-lines and interdigitate with thicker parallel myosin filaments. The cross-links between actin and myosin molecules contain myofibrillar adenosine triphosphatase (ATPase), which breaks down adenosine triphosphate (ATP) to provide the energy for contraction (Fig. 16.5E). Two chains of actin molecules form a helical structure, with a second molecule, tropomyosin, in the grooves of the actin helix, and a further molecule complex, troponin, attached to every seventh actin molecule (Fig. 16.5D).

During the plateau phase of the action potential, calcium ions enter the cell and are mobilised from the sarcoplasmic reticulum. They bind to troponin and thereby precipitate contraction by shortening of the sarcomere through the interdigitation of the actin and myosin molecules. The force of cardiac muscle contraction, or inotropic state, is regulated by the influx of calcium ions through 'slow calcium channels'. The extent to which the sarcomere can shorten determines stroke volume of the ventricle. It is maximally shortened in response to powerful inotropic drugs or marked exercise. However, the enlargement of the heart seen in heart failure is due to slippage of the myofibrils and adjacent cells rather than lengthening of the sarcomere.

Cardiac peptides

Cardiomyocytes secrete peptides that have humoral effects on the vasculature and kidneys. Atrial natriuretic peptide (ANP) is a 28-amino acid peptide that acts as a vasodilator, reducing blood pressure (BP), and as a diuretic, promoting renal excretion of water and sodium. It is released by atrial myocytes in response to stretch. B-type natriuretic peptide (BNP) is a 32-amino acid peptide produced by ventricular cardiomyocytes in response to stretch, as occurs in heart failure. Like ANP, it has diuretic properties. Neprilysin, an enzyme produced by the kidney and other tissues, breaks down ANP, BNP and other proteins and, in so doing, acts as a vasoconstrictor. It forms a therapeutic target in patients with heart failure.

Circulation

The RA receives deoxygenated blood from the superior and inferior venae cavae and discharges blood to the RV, which in turn pumps it into the pulmonary artery. Blood is oxygenated as it passes through the pulmonary alveolar capillary bed before draining into the pulmonary veins and LA. Blood then passes into the LV, which pumps it into the aorta (see Fig. 16.1). During ventricular contraction (systole), the tricuspid valve in the right heart and the mitral valve in the left heart close, and the pulmonary and aortic valves open. In diastole, the pulmonary and aortic valves close, and the two AV valves open. Collectively, these atrial and ventricular events constitute the cardiac cycle of filling and ejection of blood from one heart beat to the next. Blood passes from the heart through the large central elastic arteries into muscular arteries before encountering the resistance vessels (arterioles), and ultimately the capillary bed, where there is exchange of nutrients, oxygen and waste products of metabolism. The central arteries, such as the aorta, are predominantly composed of elastic tissue with little or no vascular smooth muscle cells. When blood is ejected from the heart, the compliant aorta expands to accommodate the volume of blood before the elastic recoil sustains BP and blood flow following cessation of cardiac contraction. This 'Windkessel' effect prevents excessive rises in systolic BP while sustaining diastolic BP, thereby reducing cardiac afterload and maintaining coronary perfusion.

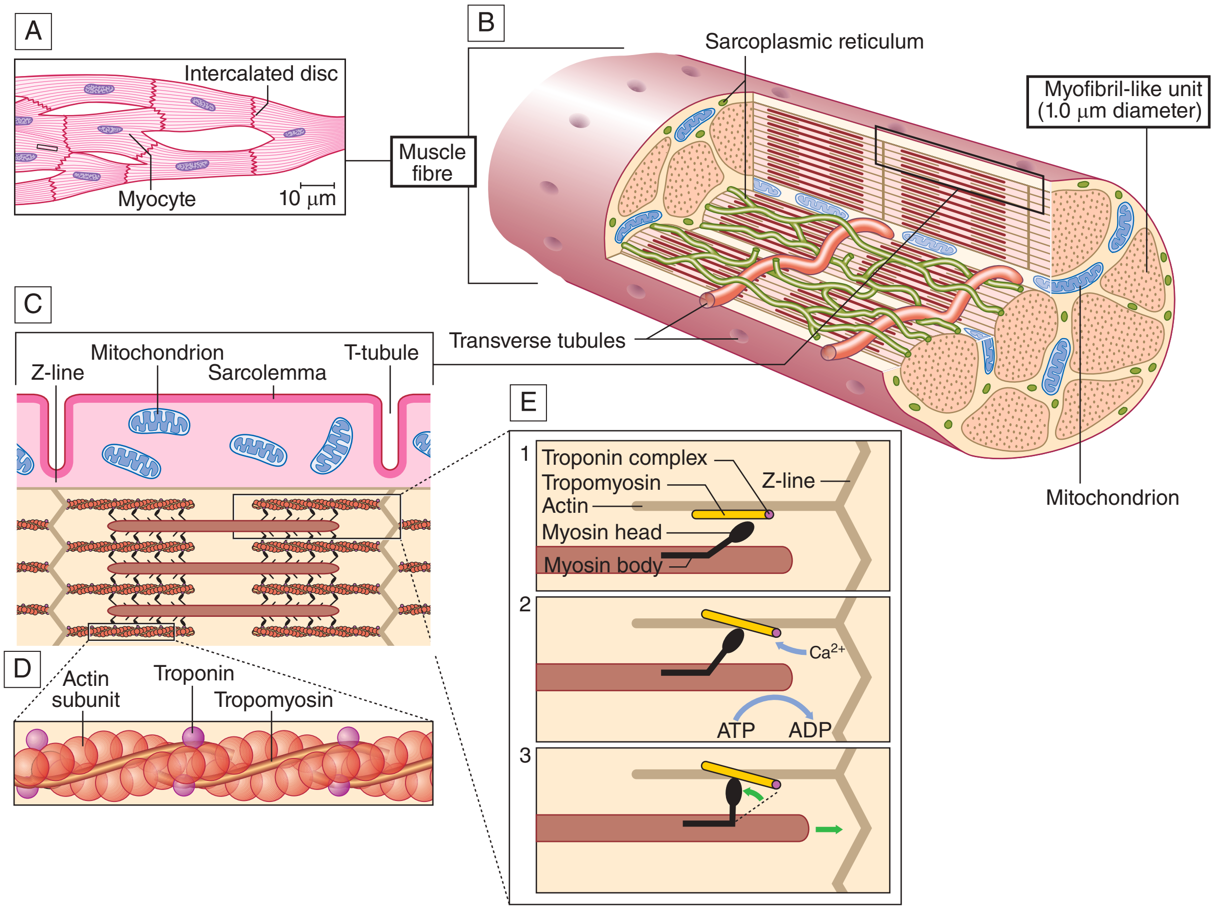

Fig. 16.5 Schematic of myocytes and the contraction process within a muscle fibre. **A** Myocytes are joined together through intercalated discs. **B** Within the myocytes, myofibrils are composed of longitudinal and transverse tubules extending from the sarcoplasmic reticulum. **C** The expanded section shows a schematic of an individual sarcomere with thick filaments composed of myosin and thin filaments composed primarily of actin. **D** Actin filaments are composed of troponin, tropomyosin and actin subunits. **E** The three stages of contraction, resulting in shortening of the sarcomere. (1) The actin-binding site is blocked by tropomyosin. (2) ATP-dependent release of calcium ions, which bind to troponin, displacing tropomyosin. The binding site is exposed. (3) Tilting of the angle of attachment of the myosin head, resulting in fibre shortening. (ADP = adenosine diphosphate; ATP = adenosine triphosphate)

These benefits are lost with progressive arterial stiffening, which occurs with ageing and kidney disease. Passing down the arterial tree, vascular smooth muscle cells play a progressively greater role until the resistance arterioles are encountered. Although all vessels contribute, the resistance vessels (diameter 50–200 µm) provide the greatest contribution to systemic vascular resistance, with small changes in radius having a marked influence on blood flow; resistance is inversely proportional to the fourth power of the radius (Poiseuille's Law). The tone of these resistance vessels is tightly regulated by humoral, neuronal and mechanical factors. Neurogenic constriction operates via α-adrenoceptors on vascular smooth muscle, and dilatation via muscarinic and β_2-adrenoceptors. In addition, systemic and locally released vasoactive substances influence tone; vasoconstrictors include noradrenaline (norepinephrine), angiotensin II and endothelin-1, whereas adenosine, bradykinin, prostaglandins and nitric oxide are vasodilators. Resistance to blood flow rises with viscosity and is mainly influenced by the haematocrit.

Coronary blood vessels receive sympathetic and parasympathetic innervation. While stimulation of α-adrenoceptors causes vasoconstriction and stimulation of β_2-adrenoceptors causes vasodilatation, the predominant effect of sympathetic stimulation in coronary arteries is vasodilatation. Parasympathetic stimulation also causes modest dilatation of healthy coronary arteries. Because of these homeostatic mechanisms that regulate vessel tone, narrowing or stenosis in a coronary artery does not limit flow, even during exercise, until the cross-sectional area of the vessel is reduced by at least 70%.

Endothelium

The endothelium plays a vital role in the control of vascular homeostasis. It synthesises and releases many vasoactive mediators that cause vasodilatation, including nitric oxide, prostacyclin and endothelium-derived hyperpolarising factor, and vasoconstriction, including angiotensin II and endothelin-1. A balance exists whereby the release of such factors contributes to the maintenance and regulation of vascular tone and BP. Damage to the endothelium may disrupt this balance and lead to vascular dysfunction, tissue ischaemia and hypertension.

The endothelium has a major influence on key regulatory steps in the recruitment of inflammatory cells and on the formation and dissolution of thrombus. Once activated, the endothelium expresses surface receptors such as E-selectin, intercellular adhesion molecule type 1 (ICAM-1) and platelet–endothelial cell adhesion molecule type 1 (PECAM-1), which mediate rolling, adhesion and migration of inflammatory leucocytes into the subintima. The endothelium also stores and releases the multimeric glycoprotein von Willebrand factor, which promotes thrombus formation by linking platelet adhesion to denuded surfaces, especially in the arterial vasculature. In contrast, once intravascular thrombus forms, tissue plasminogen activator is rapidly released from a dynamic storage pool within the endothelium to induce fibrinolysis and thrombus dissolution. These processes are critically involved in the development and progression of atherosclerosis, and endothelial dysfunction and injury are seen as central to the pathogenesis of many cardiovascular disease states.

Respiration

Cardiac output, BP and pulse rate change with respiration as the result of changes in blood flow to the right and left heart, as summarised in Box 16.1. During inspiration, the fall in intrathoracic pressure increases venous return into the chest and the right side of the heart, which increases cardiac output from the RV. However, blood is sequestered in the lungs due to the increased capacitance of the pulmonary vascular bed, leading to a reduction in blood flow to the LV and a slight fall in BP. With expiration the opposite sequence of events occurs: there is a fall in venous return to the right heart with a reduction in RV output, and a rise in the venous return to the left side of the heart with an increase in LV output. As the result of these changes, BP normally falls during inspiration but rises during expiration. These changes are exaggerated in patients with severe airways obstruction secondary to asthma or chronic obstructive pulmonary disease (COPD) leading to 'pulsus paradoxus', which describes an exaggerated fall in BP during inspiration. As well as being found in airways obstruction, pulsus paradoxus is also characteristic of cardiac tamponade. Here, cardiac filling is constrained by external pressure, and on inspiration, compression of the RV impedes the normal increase in flow during inspiration. The interventricular septum then moves to the left, impeding left ventricular filling and cardiac output. This produces an exaggerated fall in BP (> 10 mmHg fall during inspiration).

16.1 Haemodynamic effects of respiration

	Inspiration	Expiration
Jugular venous pressure	Falls	Rises
Blood pressure	Falls (up to 10 mmHg)	Rises
Heart rate	Accelerates	Slows
Second heart sound	Splits*	Fuses*

*Inspiration prolongs right ventricular ejection, delaying P_2, and shortens left ventricular ejection, bringing forward A_2; expiration produces the opposite effects.

Investigation of cardiovascular disease

Several investigations may be required in the diagnosis of cardiac disease and assessment of its severity. Basic tests, such as electrocardiography, chest X-ray and echocardiography, can be performed in an outpatient clinic or at the bedside, whereas more complex procedures such as cardiac catheterisation, radionuclide imaging, computed tomography (CT) and magnetic resonance imaging (MRI) require specialised facilities.

Electrocardiogram

The electrocardiogram (ECG) is used to assess cardiac rhythm and conduction as well as the diagnosis of myocardial ischaemia and infarction.

The ECG is recorded by electrodes on the body surface which detect the electrical depolarisation of myocardial tissue produced from a small dipole current. These signals are amplified and either printed or displayed on a monitor (Fig. 16.6). During sinus rhythm, the SA node triggers atrial depolarisation, producing a P wave. Depolarisation proceeds slowly through the AV node, which is too small to produce a depolarisation wave detectable from the body surface. The bundle of His, bundle branches and Purkinje system are then activated, initiating ventricular myocardial depolarisation, which produces the QRS complex. The muscle mass of

16.2 How to read a 12-lead electrocardiogram: examination sequence

Rhythm strip (lead II)	To determine heart rate and rhythm
Cardiac axis	Normal if QRS complexes +ve in leads I and II
P-wave shape	Tall P waves denote right atrial enlargement (P pulmonale) and notched P waves denote left atrial enlargement (P mitrale)
PR interval	Normal = 0.12–0.20 sec. Prolongation denotes impaired atrioventricular nodal conduction. A short PR interval occurs in Wolff–Parkinson–White syndrome
QRS duration	If > 0.12 sec, ventricular conduction is abnormal (left or right bundle branch block)
QRS amplitude	Large QRS complexes occur in slim young patients and in patients with left ventricular hypertrophy
Q waves	May signify previous myocardial infarction
ST segment	ST elevation may signify myocardial infarction, pericarditis or left ventricular aneurysm; ST depression may signify ischaemia or infarction
T waves	T-wave inversion has many causes, including myocardial ischaemia or infarction, and electrolyte disturbances
QT interval	Normal < 0.44 sec (male), 0.46 sec (female) corrected for heart rate. QT prolongation may occur with congenital long QT syndrome, low K$^+$, Mg^{2+} or Ca^{2+}, and some drugs (see Box 16.28)
ECG conventions	Depolarisation towards electrode: +ve deflection Depolarisation away from electrode: −ve deflection Sensitivity: 10 mm = 1 mV Paper speed: 25 mm per sec Each large (5 mm) square = 0.2 sec Each small (1 mm) square = 0.04 sec Heart rate = 1500/RR interval (mm) (i.e. 300 ÷ number of large squares between beats)

the ventricles is much larger than that of the atria, so the QRS complex is larger than the P wave. The interval between the onset of the P wave and the onset of the QRS complex is termed the ‘PR interval’ and largely reflects the duration of AV nodal conduction. Injury to the left or right bundle branch delays ventricular depolarisation, widening the QRS complex. Selective injury of one of the left fascicles (hemiblock) affects the electrical axis. Repolarisation is slower and spreads from the epicardium to the endocardium. Atrial repolarisation does not cause a detectable signal, but ventricular repolarisation produces the T wave. The QT interval represents the total duration of ventricular depolarisation and repolarisation.

The 12-lead ECG

The 12-lead ECG (Box 16.2) is generated from 10 electrodes that are attached to the skin. One electrode is attached to each limb and six electrodes are attached to the chest. In addition, the left arm, right arm and left leg electrodes are attached to a central terminal acting as an additional virtual electrode in the centre of the chest (the right leg electrode acts as an earthing electrode). The 12 ‘leads’ of the ECG refer to recordings made from pairs or sets of these electrodes. They comprise three groups: three dipole limb leads, three augmented voltage limb leads and six unipole chest leads.

Leads I, II and III are the dipole limb leads and refer to recordings obtained from pairs of limb electrodes. Lead I records the signal between the right (negative) and left (positive) arms. Lead II records the signal between the right arm (negative) and left leg (positive). Lead III records the signal between the left arm (negative) and left leg (positive). These three leads thus record electrical activity along three different axes in the frontal plane. Leads aVR, aVL and aVF are the augmented voltage limb leads. These record electrical activity between a limb electrode and a modified central terminal. For example, lead aVL records the signal between the left arm (positive) and a central (negative) terminal, formed by connecting the right arm and left leg electrodes (Fig. 16.7). Similarly augmented signals are obtained from the right arm (aVR) and left leg (aVF). These leads also record electrical activity in the frontal plane, with each lead 120° apart. Lead aVF thus examines activity along the axis +90°, and lead aVL along the axis −30°, and so on.

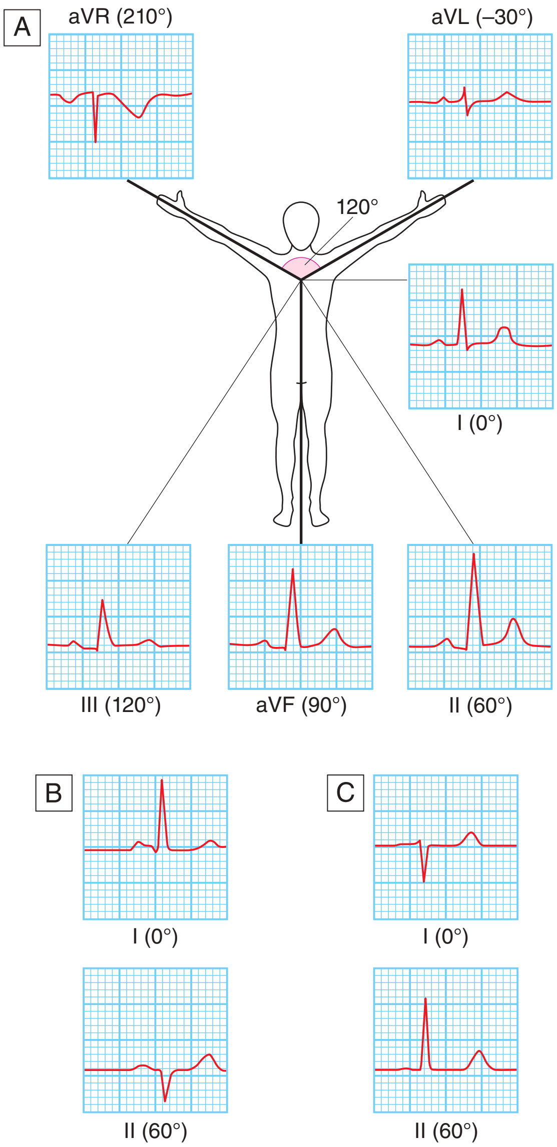

Fig. 16.7 **The appearance of the ECG from different leads in the frontal plane.** **A** Normal. **B** Left axis deviation, with negative deflection in lead II and positive in lead I. **C** Right axis deviation, with negative deflection in lead I and positive in lead II.

When depolarisation moves towards a positive electrode, it produces a positive deflection in the ECG; depolarisation in the opposite direction produces a negative deflection. The average vector of ventricular depolarisation is known as the frontal cardiac axis. When the vector is at right angles to a lead, the depolarisation in that lead is equally negative and positive (isoelectric). In Figure 16.7A, the QRS complex is isoelectric in aVL, negative in aVR and most strongly positive in lead II; the main vector or axis of depolarisation is therefore 60°. The normal cardiac axis lies between −30° and +90°. Examples of left and right axis deviation are shown in Figure 16.7B and C.

There are six chest leads, V$_1$–V$_6$, derived from electrodes placed on the anterior and lateral left side of the chest, over the heart. Each lead records the signal between the corresponding chest electrode (positive) and the central terminal (negative). Leads V$_1$ and V$_2$ lie approximately over the RV, V$_3$ and V$_4$ over the interventricular septum, and V$_5$ and V$_6$

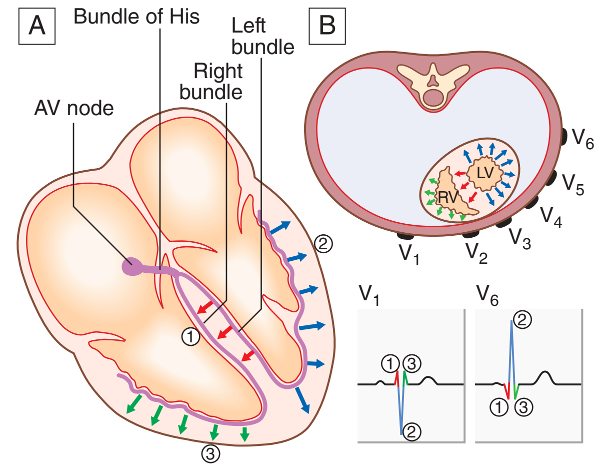

Fig. 16.8 **The sequence of activation of the ventricles.** **A** Activation of the septum occurs first (red arrows), followed by spreading of the impulse through the left ventricle (LV, blue arrows) and then the right ventricle (RV, green arrows). **B** Normal electrocardiographic complexes from leads V_1 and V_6. (AV = atrioventricular)

over the LV (Fig. 16.8). The LV has the greater muscle mass and contributes the major component of the QRS complex.

The shape of the QRS complex varies across the chest leads. Depolarisation of the interventricular septum occurs first and moves from left to right; this generates a small initial negative deflection in lead V_6 (Q wave) and an initial positive deflection in lead V_1 (R wave). The second phase of depolarisation is activation of the body of the LV, which creates a large positive deflection or R wave in V_6 (with reciprocal changes in V_1). The third and final phase involves the RV and produces a small negative deflection or S wave in V_6.

Exercise ECG

In exercise or stress electrocardiography, a 12-lead ECG is recorded during exercise on a treadmill or bicycle ergometer. It is similar to a resting ECG, except that the limb electrodes are placed on the shoulders and hips rather than the wrists and ankles. The Bruce Protocol is the most commonly used. During an exercise ECG, BP is recorded, and symptoms are assessed. Common indications for exercise testing are shown in Box 16.3. The test is considered positive if angina occurs, BP falls or fails to increase, or if there are ST segment shifts of more than 1 mm (see Fig. 16.56). Exercise testing is useful in objectively assessing the severity of symptoms and informing the potential diagnosis of angina due to coronary artery disease, and under these circumstances has reasonable sensitivity and excellent specificity (see Box 16.3). False-negative results can occur in patients with coronary artery disease, and not all patients with a positive test have coronary artery disease. This is especially true in low-risk individuals, such as asymptomatic young or middle-aged women, in whom an abnormal response is more likely to represent a false-positive than a true-positive test. Stress testing is contraindicated in the presence of acute coronary syndrome, decompensated heart failure and severe hypertension.

Ambulatory ECG

Ambulatory ECG recordings can be obtained using a portable digital recorder. These devices usually provide limb lead ECG recordings only, on a continuous basis for periods of between 1 and 7 days. The main indication for ambulatory ECG is in the investigation of patients with suspected arrhythmia, such as those with intermittent palpitation, dizziness or syncope. In this situation, a standard ECG provides only a snapshot of the cardiac rhythm and is unlikely to detect an intermittent arrhythmia, so a longer period of recording is required (see Fig. 16.30). Ambulatory ECG can also be used to assess rate control in patients with atrial fibrillation, and to detect transient myocardial ischaemia using ST segment analysis. If symptoms are infrequent, special recorders can be issued that can be activated by the patient when a symptom episode occurs and placed on the chest wall to record the cardiac rhythm at that point in time. With some devices, the recording can be transmitted to hospital electronically. If the symptoms are very infrequent but potentially serious, such as syncope, implantable 'loop recorders' resembling a leadless pacemaker can be used and implanted subcutaneously to record cardiac rhythm for prolonged periods of between 1 and 3 years (see Fig. 16.51).

i 16.3 Exercise testing

Indications

- To assess the symptoms and severity of exertional angina
- To assist in the diagnosis and risk stratification of stable angina
- To assess outcome after coronary revascularisation
- To diagnose and evaluate the treatment of exercise-induced arrhythmias

High-risk findings

- Low threshold for ischaemia (within stage 1 or 2 of the Bruce Protocol)
- Fall in BP on exercise
- Widespread, marked or prolonged ischaemic ECG changes
- Exercise-induced arrhythmia

(BP = blood pressure; ECG = electrocardiogram)

Cardiac biomarkers

Several biomarkers are available that can be measured in peripheral blood to assess myocardial dysfunction and ischaemia.

B-type natriuretic peptide

B-type natriuretic peptide (BNP) is a peptide hormone of 32 amino acids with diuretic properties. It is secreted by the LV as a 108-amino acid prohormone, which is cleaved to produce active BNP, and an inactive 76-amino acid N-terminal fragment (NT-proBNP). Serum concentrations are elevated in conditions associated with LV systolic dysfunction. Generally, NT-proBNP is measured in preference to BNP since it is more stable. Measurements of NT-proBNP are indicated for the diagnosis of LV dysfunction and to assess prognosis and response to therapy in patients with heart failure.

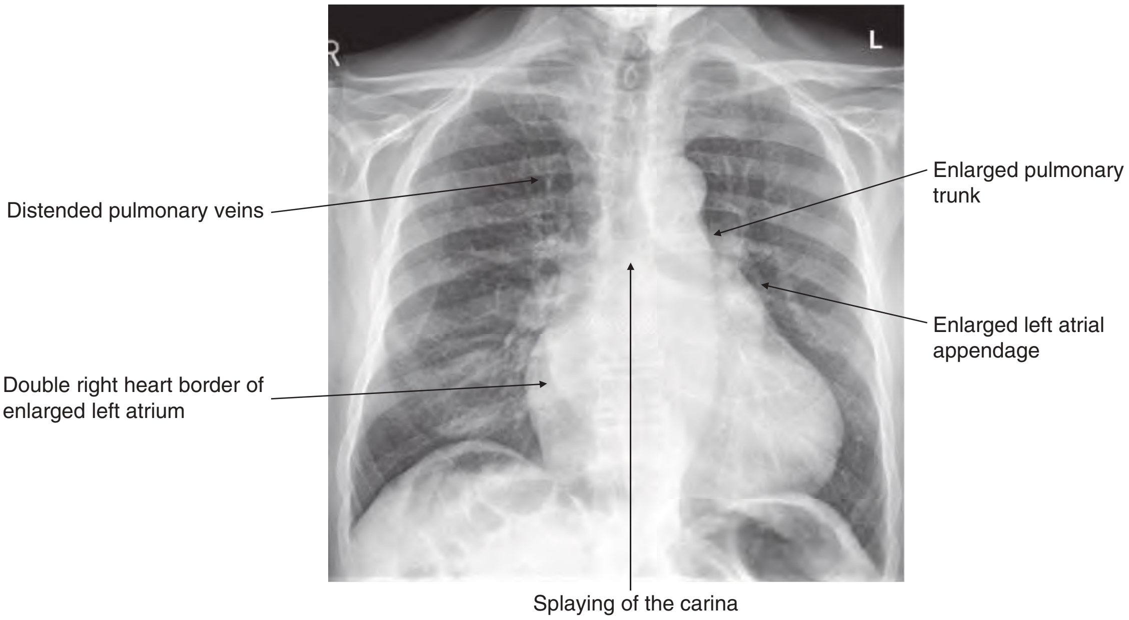
Cardiac troponins

Troponin I and troponin T are structural cardiac muscle proteins (see Fig. 16.5) that are released during myocyte necrosis, representing the cornerstone of the diagnosis of acute myocardial infarction (MI, see Box 16.47). Modern assays are extremely sensitive and can detect minor degrees of myocardial injury, such that elevated plasma troponin concentrations may be observed in conditions other than acute MI, such as pulmonary embolus, septic shock and pulmonary oedema. They may also be chronically elevated in conditions such as heart failure or left ventricular hypertrophy.

Chest X-ray

This is useful for determining the size and shape of the heart, and the state of the pulmonary blood vessels and lung fields. Most information is given by a postero-anterior (PA) projection taken in full inspiration. Anteroposterior (AP) projections can be performed when patient movement is restricted but result in magnification of the cardiac silhouette.

An estimate of overall heart size can be made by comparing the maximum width of the cardiac outline with the maximum internal transverse diameter of the thoracic cavity. The term cardiomegaly is used to describe an enlarged cardiac silhouette when the ratio of cardiac width to the width



R
L
Distended pulmonary veins
Enlarged pulmonary trunk

Splaying of the carina

Fig. 16.9 Chest X-ray of a patient with features of mitral stenosis and regurgitation including enlargement of the LA and prominence of the pulmonary artery trunk.

of the lung fields is greater than 0.5. Cardiomegaly can be caused by chamber dilatation, especially left ventricular dilatation, or by a pericardial effusion, but may also be due to a mediastinal mass or pectus excavatum. Cardiomegaly is not a sensitive indicator of left ventricular systolic dysfunction since the cardiothoracic ratio is normal in many patients with poor left ventricular function; also, it is not specific, since many patients with cardiomegaly on chest X-ray have normal echocardiograms.

Dilatation of individual cardiac chambers can be recognised by the characteristic alterations to the cardiac silhouette (Fig. 16.9):

- Left atrial dilatation results in prominence of the left atrial appendage, creating the appearance of a straight left heart border, a double cardiac shadow to the right of the sternum, and widening of the angle of the carina (bifurcation of the trachea) as the left main bronchus is pushed upwards.
- Right atrial enlargement projects from the right heart border towards the right lower lung field.
- Left ventricular dilatation causes prominence of the left heart border and enlargement of the cardiac silhouette. Left ventricular hypertrophy produces rounding of the left heart border (Fig. 16.10).
- Right ventricular dilatation increases heart size, displaces the apex upwards and straightens the left heart border.

Lateral or oblique projections may be useful for detecting pericardial calcification in patients with constrictive pericarditis or a calcified thoracic aortic aneurysm, as these abnormalities may be obscured by the spine on the PA view.

The lung fields on the chest X-ray may show congestion and oedema in patients with heart failure (see Fig. 16.25), and an increase in pulmonary blood flow ('pulmonary plethora') in those with left-to-right shunt. Pleural effusions may also occur in heart failure.

Echocardiography

Transthoracic echocardiography

Transthoracic echocardiography, commonly referred to as 'echo', is obtained by placing an ultrasound transducer on the chest wall to image the heart structures as a real-time two-dimensional 'slice'. This can be used for rapid evaluation of various aspects of cardiac structure and function (Box 16.4).

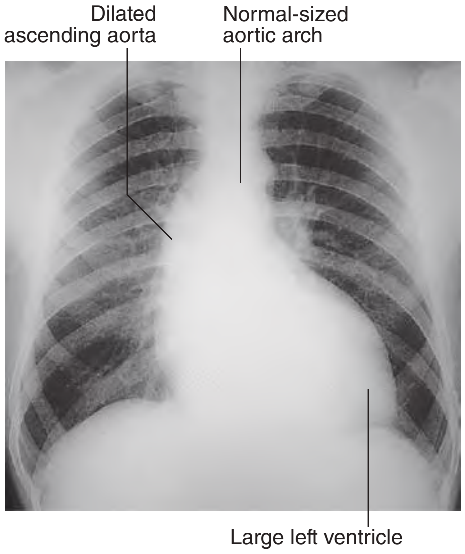

Fig. 16.10 Chest X-ray of a patient with aortic regurgitation, left ventricular enlargement and dilatation of the ascending aorta.

16.4 Common indications for echocardiography

- Assessment of left ventricular function
- Diagnosis and quantification of severity of valve disease
- Identification of structural heart disease in atrial fibrillation, hypertension, cardiomyopathies or congenital heart disease
- Detection of pericardial effusion
- Identification of vegetations in endocarditis

Doppler echocardiography

Doppler echocardiography provides information on blood flow within the heart and the great vessels. It is based on the Doppler principle that sound waves reflected from moving objects, such as red blood cells, undergo a frequency shift. Doppler echocardiography can therefore

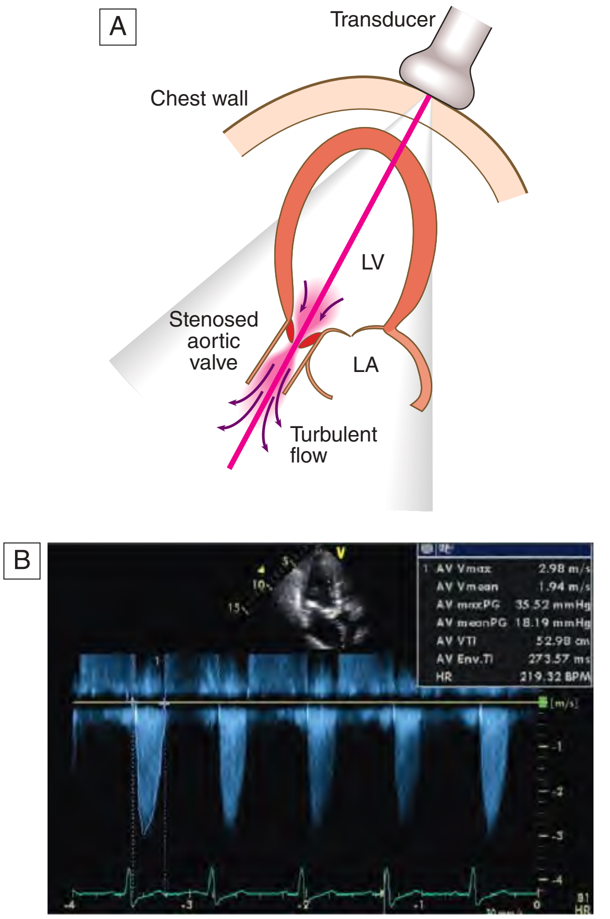

Fig. 16.11 **Doppler echocardiography in aortic stenosis.** **A** The aortic valve is imaged and a Doppler beam passed directly through the left ventricular outflow tract and the aorta into the turbulent flow beyond the stenosed valve. **B** The velocity of the blood cells is recorded to determine the maximum velocity and hence the pressure gradient across the valve. In this example, the peak velocity is approximately 450 cm/sec (4.5 m/sec), indicating severe aortic stenosis (peak gradient of 81 mmHg). (LA = left atrium; LV = left ventricle)

detect the speed and direction of blood flow in the heart chambers and great vessels. The information can be presented either as a plot of blood velocity against time for a particular point in the heart (Fig. 16.11) or as a colour overlay on a two-dimensional real-time echo picture (colour-flow Doppler, Fig. 16.12). Doppler echocardiography is useful in the detection of valvular regurgitation, where the direction of blood flow is reversed, and turbulence is seen. It is also used to detect pressure gradients across stenosed valves. For example, the normal resting systolic flow velocity across the aortic valve is approximately 1 m/sec; in the presence of aortic stenosis, this is increased as blood accelerates through the narrow orifice. In severe aortic stenosis, the peak aortic velocity may be increased to 5 m/sec (see Fig. 16.11). An estimate of the pressure gradient across a valve or lesion is given by the modified Bernoulli equation:

$$\text{Pressure gradient (mmHg)} = 4 \times (\text{peak velocity (m/sec)})^2$$

Advanced techniques include three-dimensional echocardiography, intravascular ultrasound (defines vessel wall abnormalities and guides coronary intervention), intracardiac ultrasound (provides high-resolution images), tissue Doppler imaging (quantifies myocardial contractility and diastolic function) and speckle tracking (assesses myocardial motion and strain).

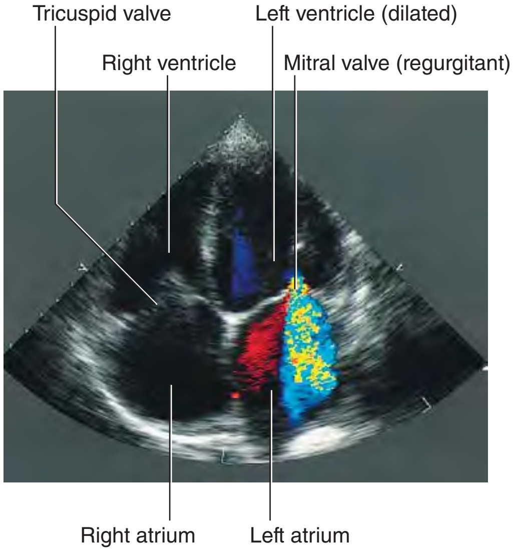

Fig. 16.12 **Echocardiographic illustration of the principal cardiac structures in the ‘four-chamber’ view.** Colour-flow Doppler has been used to demonstrate mitral regurgitation: a flame-shaped (yellow/blue) turbulent jet into the left atrium.

Transoesophageal echocardiography

Transoesophageal echocardiography (TOE) involves passing an endoscope-like ultrasound probe into the oesophagus and upper stomach under light sedation and positioning it behind the LA. It is particularly useful for imaging structures such as the left atrial appendage, pulmonary veins, thoracic aorta and interatrial septum, which may be poorly visualised by transthoracic echocardiography, especially if the patient is overweight or has obstructive airways disease. The high-resolution images that can be obtained make TOE particularly valuable for investigating patients with prosthetic (especially mitral) valve dysfunction, congenital abnormalities such as atrial septal defects, aortic dissection, infective endocarditis (vegetations that are too small to be detected by transthoracic echocardiography) and systemic embolism (intracardiac thrombus or masses).

Stress echocardiography

Stress echocardiography is used to investigate patients with suspected coronary artery disease who are unsuitable for exercise stress testing, such as those with mobility problems or pre-existing bundle branch block. A two-dimensional echo is performed before and during infusion of a moderate to high dose of an inotrope, such as dobutamine. Myocardial segments with poor perfusion become ischaemic and contract poorly under stress, manifesting as a wall motion abnormality on the scan. Stress echocardiography is sometimes used to examine myocardial viability in patients with impaired left ventricular function. Low-dose dobutamine can induce contraction in ‘hibernating’ myocardium; such patients may benefit from bypass surgery or percutaneous coronary intervention.

Computed tomography

Computed tomography (CT) is useful for imaging the cardiac chambers, great vessels, pericardium, and mediastinal structures and masses. Multidetector scanners can acquire up to 320 slices per rotation, allowing very high-resolution imaging in a single heartbeat. CT is often performed using a timed injection of X-ray contrast to produce clear images of blood vessels and associated pathologies. Contrast scans are very useful for imaging the aorta in suspected aortic dissection (see Fig. 16.73), and the pulmonary arteries and branches in suspected pulmonary embolism.

Some centres use cardiac CT scans for quantification of coronary artery calcification, which serves as a surrogate measure of coronary artery disease burden. However, modern multidetector scanning allows non-invasive coronary angiography (Fig. 16.13) with a spatial resolution approaching that of conventional coronary arteriography and at a lower radiation dose. CT coronary angiography is particularly useful in the initial assessment of patients with chest pain and a low or intermediate likelihood of disease, since it has a high negative predictive value in excluding coronary artery disease. Modern volume scanners are also able to assess myocardial perfusion, often at the same sitting.

Magnetic resonance imaging

Magnetic resonance imaging (MRI) can be used to generate cross-sectional images of the heart, lungs and mediastinal structures. It provides better differentiation of soft tissue structures than CT but is poor at demonstrating calcification. MRI scans need to be 'gated' to the ECG, allowing the scanner to produce moving images of the heart and mediastinal structures throughout the cardiac cycle. CT is the investigation of choice for imaging the aorta, including suspected dissection and can define the anatomy of the heart and great vessels in patients with congenital heart disease. It is also useful for detecting infiltrative conditions affecting the heart and for evaluation of the RV that is difficult to image by echocardiography.

Physiological data can be obtained from the signal returned from moving blood, which allows quantification of blood flow across regurgitant or stenotic valves. It is also possible to analyse regional wall motion in patients with suspected coronary disease or cardiomyopathy.

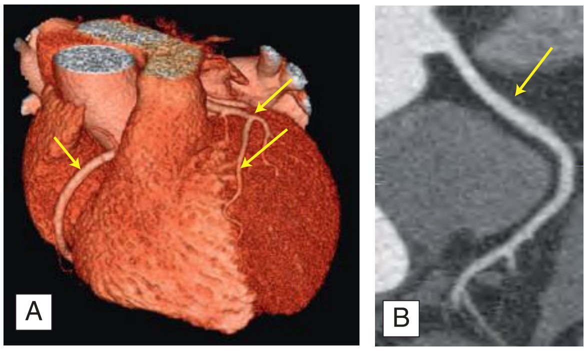

Fig. 16.13 Computed tomography coronary angiography, demonstrating normal coronary arteries (arrows). **A** Three-dimensional image. **B** Two-dimensional image.

Myocardial perfusion and viability can also be readily assessed by MRI. When enhanced by gadolinium-based contrast media, areas of myocardial hypoperfusion can be identified with better spatial resolution than nuclear medicine techniques. Later redistribution of this contrast, so-called delayed enhancement, can be used to identify myocardial scarring and fibrosis: this is a particular strength of cardiac MRI (Fig. 16.14). This can help in selecting patients for revascularisation procedures, or in identifying those with myocardial infiltration, such as that seen with sarcoid heart disease and arrhythmogenic right ventricular cardiomyopathy.

Cardiac catheterisation

This involves passing a specialised catheter through a peripheral vein or artery into the heart under X-ray guidance. Cardiac catheterisation allows BP and oxygen saturation to be measured in the cardiac chambers and great vessels as well as performing angiograms by injecting contrast media into a chamber or blood vessel.

Left heart catheterisation involves accessing the arterial circulation, usually through the radial artery, to allow catheterisation of the aorta, LV and coronary arteries. Coronary angiography is the most widely performed procedure, in which the left and right coronary arteries are selectively imaged, providing information about the extent and severity of coronary stenoses, thrombus and calcification (Fig. 16.15). Additional anatomical (intravascular ultrasound, optical coherence tomography) or functional (pressure wire) assessments are sometimes used to define plaque characteristics and severity more precisely. This permits planning of percutaneous coronary intervention and coronary artery bypass graft surgery. Left ventriculography can be performed during the procedure to determine the size and function of the LV (Fig. 16.16) and to demonstrate mitral regurgitation. Aortography defines the size of the aortic root and thoracic aorta and can help quantify aortic regurgitation. Left heart catheterisation is a day-case procedure and is relatively safe, with serious complications occurring in approximately 1 in 1000 cases.

Right heart catheterisation is used to assess right heart and pulmonary artery pressures and to detect intracardiac shunts by measuring oxygen saturations in different chambers. For example, a step up in oxygen saturation from 65% in the RA to 80% in the pulmonary artery is indicative of a large left-to-right shunt that might be due to a ventricular septal defect. Cardiac output can also be measured using thermodilution techniques. Left atrial pressure can be measured directly by puncturing the interatrial septum from the RA with a special catheter. For most purposes, a satisfactory approximation to left atrial pressure can be obtained by 'wedging' an end-hole or balloon catheter in a branch of the pulmonary artery. Swan–Ganz balloon catheters are often used to monitor pulmonary 'wedge' pressure as a guide to left heart filling pressure in critically ill patients (see Fig. 10.27 and Ch.10).

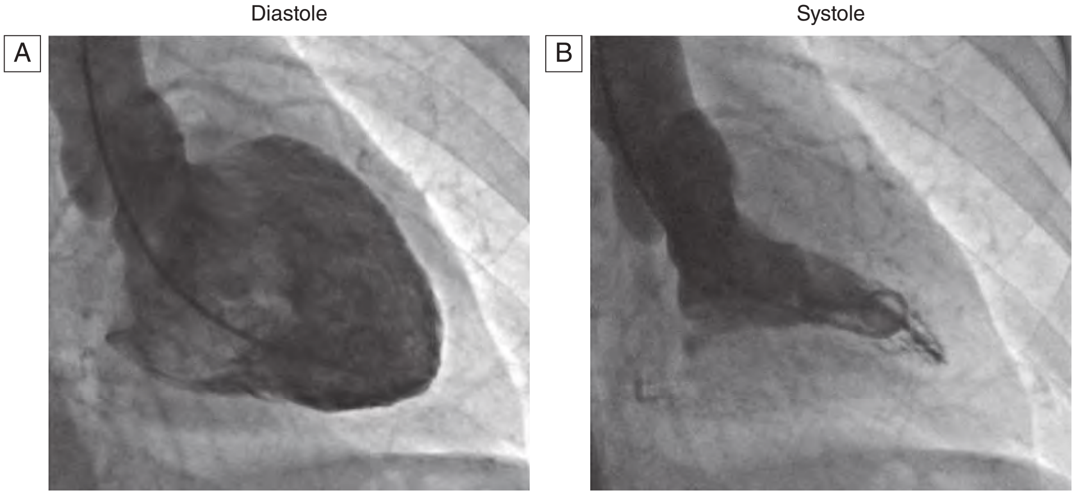

Fig. 16.16 **Left ventriculograms in diastole A and systole B in a patient with normal left ventricular contraction.**

Electrophysiology

Patients with known or suspected arrhythmia are investigated by percutaneous placement of electrode catheters into the heart via the femoral and neck veins. An electrophysiology study (EPS) is most commonly performed to evaluate patients for catheter ablation and is normally done at the same time as the ablation procedure. EPS is occasionally used for risk stratification of patients suspected of being at risk of ventricular arrhythmias.

Radionuclide imaging

Radionuclide imaging can be used to evaluate cardiac function but is declining in popularity due to the availability of alternative techniques, such as MRI and CT, that either do not involve exposure to radiation or provide superior quality data to radionuclide imaging.

Blood pool imaging

The patient is given an intravenous injection of radioisotope-labelled blood cells, and after 4–5 minutes, the distribution of isotope in the heart is evaluated by a gamma camera at different phases of the cardiac cycle, thereby permitting the calculation of ventricular ejection fraction. It can also assess the size and 'shape' of the cardiac chambers.

Myocardial perfusion scanning

The patient is given an intravenous injection of a radioactive isotope-labelled agent, such as [^{99m}Tc]technetium-tetrofosmin, that is rapidly taken up by the myocardium, and scintiscans of the myocardium are subsequently obtained by gamma camera at rest and during stress (see Fig. 16.57). Either exercise stress or pharmacological stress (using the inotrope dobutamine or the vasodilator dipyridamole) can be used. More sophisticated quantitative information can be obtained with positron emission tomography (PET), which can also be used to assess myocardial metabolism, but this is available in only a few centres.

Presenting problems in cardiovascular disease

Cardiovascular disease gives rise to several symptoms, which may overlap those caused by pathologies of other systems. Making the correct

i 16.5 New York Heart Association (NYHA) functional classification

Class I

- No limitation during ordinary activity

Class II

- Slight limitation during ordinary activity

Class III

- Marked limitation of normal activities without symptoms at rest

Class IV

- Unable to undertake physical activity without symptoms; symptoms may be present at rest

diagnosis depends on careful analysis of the factors that provoke symptoms, the subtle differences in how they are described by the patient, the clinical findings and the results of investigations. A close relationship between symptoms and exertion is usually suggestive of heart disease. The New York Heart Association (NYHA) functional classification is used to grade the degree of disability caused by cardiac symptoms (Box 16.5).

Chest discomfort on exertion

There are many non-cardiac causes of chest pain or discomfort, as discussed in Chapter 10. This section will focus on exertional chest discomfort, which is a typical presenting symptom of coronary artery disease.

Clinical assessment

Detailed history-taking is crucial in determining the likely cause of chest discomfort. Discomfort on exertion suggests angina pectoris (Fig. 16.17). The reproducibility, predictability and relationship to physical exertion (and occasionally emotion) of the symptom are the most important features. The duration of symptoms should be noted because patients with recent-onset angina are at greater risk than those with long-standing and unchanged symptoms. Physical examination is often normal but may reveal evidence of risk factors for cardiovascular disease, such as xanthoma or xanthelasma indicating hyperlipidaemia. Signs of anaemia or thyrotoxicosis may be identified, both of which can exacerbate angina. Cardiovascular examination may reveal evidence of left ventricular dysfunction or cardiac murmurs in patients with aortic valve disease and hypertrophic cardiomyopathy. Other manifestations of arterial disease, such as bruits and loss of peripheral pulses, may also be observed.

Investigations

A full blood count, fasting blood glucose, lipids, thyroid function tests and a 12-lead ECG are the most important baseline investigations. Stress testing, including exercise ECG, stress echocardiography and magnetic resonance perfusion imaging, can be helpful in confirming anginal symptoms and identifying high-risk patients who require further investigation and treatment but cannot reliably exclude the presence of coronary artery disease. CT coronary angiography is the investigation of choice to investigate suspected angina due to coronary artery disease. If a murmur is found, echocardiography should be performed to check for valve disease or hypertrophic cardiomyopathy.

Severe prolonged chest discomfort

Severe prolonged cardiac chest discomfort may be due to acute myocardial infarction or to unstable angina – known collectively as acute coronary syndrome.

Clinical assessment

Acute coronary syndrome is suggested by a previous history of stable angina but an episode of acute severe chest discomfort at rest can also be the first presentation of coronary artery disease. Making the correct diagnosis depends on analysing the character of the discomfort and its associated features. Physical examination may reveal signs of risk factors for coronary artery disease as described for exertional chest discomfort. There may also be pallor or sweating, which is indicative of autonomic disturbance and typical of acute coronary syndrome. Other features, such as arrhythmia, hypotension and heart failure, may occur. Although there is considerable overlap between the symptoms experienced by men and women, women are more likely to have discomfort between the shoulder blades, nausea or vomiting, and breathlessness, and are less likely to experience chest discomfort or sweating. Patients presenting with symptoms consistent with an acute coronary syndrome require immediate hospitalisation and urgent investigation, because there is a high risk of avoidable complications.

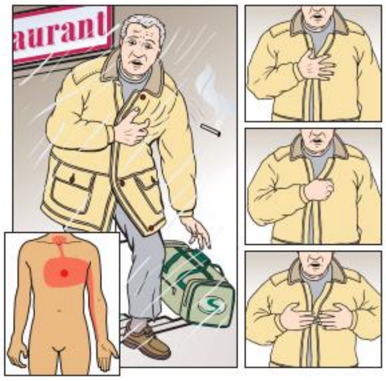

Fig. 16.17 Typical ischaemic cardiac pain. Characteristic hand gestures used to describe cardiac pain. Typical radiation of pain is shown in the schematic.

Investigations

A 12-lead ECG is mandatory and is the most useful method of initial triage, along with measurement of cardiac troponin I or T. While the ECG can be normal in an acute coronary syndrome, the diagnosis is supported by the presence of ST segment elevation or depression and an elevated level of troponin I or T, which indicates myocardial damage.

If the diagnosis remains unclear after initial investigation, repeat ECG recordings should be performed and are particularly useful if they can be obtained during an episode of pain. If the plasma troponin concentrations are normal at baseline, repeat measurements should be made 2–3 hours after the onset of symptoms or admission to hospital looking for evolving myocardial injury. New ECG changes or an elevated plasma troponin concentration usually confirm the diagnosis of an acute coronary syndrome. If the pain settles and does not recur, there are no new ECG changes and troponin concentrations remain normal, the patient can be discharged from hospital, but further investigations may be indicated to look for evidence of coronary artery disease, as discussed on page 460.

Management

The differential diagnosis and management of acute coronary syndrome are described in more detail later in this chapter.

Breathlessness

Cardiac causes of breathlessness include cardiac arrhythmias, acute and chronic heart failure, acute coronary syndrome, valvular disease, cardiomyopathy and constrictive pericarditis, all discussed later in this chapter. The differential diagnosis of breathlessness is wide, however, and has many other non-cardiac causes. These are discussed in more detail on pages 217 and 528.

Syncope

The term ‘syncope’ refers to loss of consciousness due to reduced cerebral perfusion. The differential diagnosis, investigation and management of syncope are discussed on page 220.

Palpitation

Palpitation is a common and sometimes frightening symptom that is usually due to a disorder of cardiac rhythm. Patients use the term to describe many sensations, including an unusually erratic, fast, slow or forceful heart beat, or even chest discomfort or breathlessness.

Clinical assessment

Initial evaluation should concentrate on determining the likely mechanism of palpitation and whether or not there is significant underlying heart disease. A detailed description of the sensation is essential, and patients should be asked to describe their symptoms clearly, or to demonstrate the sensation of rhythm by tapping with their hand. A provisional diagnosis can usually be made on the basis of the history (Box 16.6 and Fig. 16.18). Recurrent but short-lived bouts of an irregular heart rhythm are usually due to atrial or ventricular extrasystoles (ectopic beats). Some patients will describe the experience as a ‘flip’ or a ‘jump’ in the chest, while others report dropped or missed beats. Extrasystoles are often more frequent during periods of stress or debility; they can be triggered by alcohol or nicotine.

Episodes of a pounding, forceful and relatively fast (90–120/min) heart beat are a common manifestation of anxiety. These may also reflect a hyperdynamic circulation, such as anaemia, pregnancy and thyrotoxicosis, and can occur in some forms of valve disease such as aortic regurgitation. Discrete bouts of more rapid (over 120/min) and regular heart beats are more likely to be due to a paroxysmal supraventricular or ventricular tachycardia. In contrast, episodes of atrial fibrillation typically present with irregular and usually rapid palpitation.

Investigation

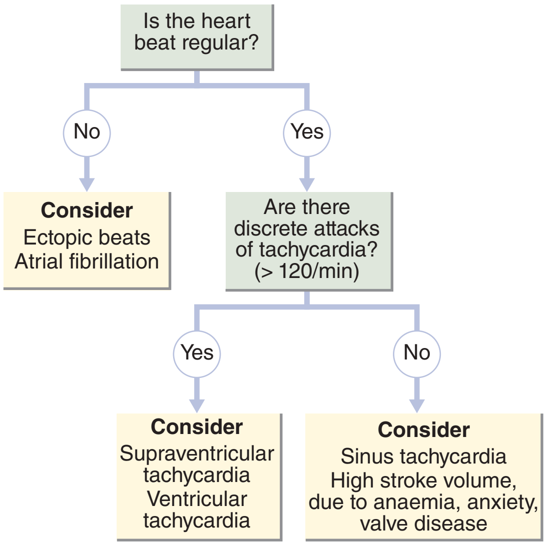
If initial assessment suggests that the palpitation is due to an arrhythmia, the diagnosis should be confirmed by recording an ECG during an episode. Ambulatory ECG monitors are useful if symptoms are frequent. Smartphone-based ECG recorders, smart watches and other wearable devices can be extremely helpful in capturing the ECG during episodes. Once an arrhythmia has been identified, additional investigations may be required, as discussed later in this chapter.

Management

Palpitation is usually benign and even if the patient’s symptoms are due to an arrhythmia, the outlook is good if there is no underlying structural heart disease. Most cases are due to an awareness of the normal heart beat, a sinus tachycardia or benign extrasystoles, in which case an explanation and reassurance may be all that is required. Palpitation associated with pre-syncope or syncope (p. 220) may reflect more serious structural or electrical disease and should be investigated without delay. Other arrhythmias may require treatment, such as drugs or ablation, and are discussed in more detail in the section on cardiac arrythmias.

16.6 How to evaluate palpitation

- Is the palpitation continuous or intermittent?
- Is the heart beat regular or irregular?
- What is the approximate heart rate?
- Do symptoms occur in discrete attacks?
  - Is the onset abrupt? How do attacks terminate?
- Are there any associated symptoms?
  - Chest pain, lightheadedness, polyuria (a feature of supraventricular tachycardia)
- Are there any precipitating factors, such as exercise or alcohol excess?
- Is there a history of structural heart disease, such as coronary artery disease or valvular heart disease?



Is the heart beat regular?
No
Yes
Consider
Ectopic beats
Atrial fibrillation
Are there discrete attacks of tachycardia? (> 120/min)
Yes
No
Consider
Supraventricular tachycardia
Ventricular tachycardia
Consider
Sinus tachycardia
High stroke volume, due to anaemia, anxiety, valve disease

Fig. 16.18 **A simple approach to the diagnosis of palpitation.**

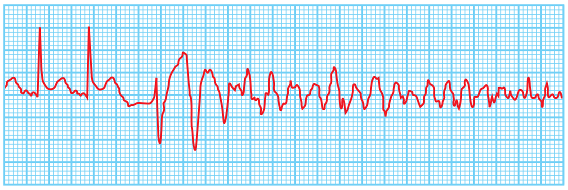


Fig. 16.19 **Ventricular fibrillation.** A bizarre chaotic rhythm, initiated in this case by two ventricular ectopic beats in rapid succession.

16.7 Causes of sudden arrhythmic death

Coronary artery disease (85%)

- Myocardial ischaemia
- Acute myocardial infarction
- Prior myocardial infarction with myocardial scarring

Structural heart disease (10%)

- Aortic stenosis
- Hypertrophic cardiomyopathy
- Dilated cardiomyopathy
- Arrhythmogenic right ventricular cardiomyopathy
- Congenital heart disease

No structural heart disease (5%)

- Long QT syndrome
- Brugada syndrome
- Wolff–Parkinson–White syndrome
- Adverse drug reactions (torsades de pointes)
- Severe electrolyte abnormalities

Cardiac arrest

Cardiac arrest describes the sudden and complete loss of cardiac output due to asystole, ventricular tachycardia or ventricular fibrillation (Fig. 16.19), or loss of mechanical cardiac contraction (pulseless electrical activity). The causes of sudden arrhythmic death are summarised in Box 16.7. The clinical diagnosis is based on the victim

16.8 Normal and abnormal heart sounds

Sound	Timing	Characteristics	Mechanisms	Variable features
First heart sound (S1)	Onset of systole	Usually single or narrowly split	Closure of mitral and tricuspid valves	Loud: hyperdynamic circulation (anaemia, pregnancy, thyrotoxicosis); mitral stenosis Soft: heart failure; mitral regurgitation
Second heart sound (S2)	End of systole	Split on inspiration Single on expiration	Closure of aortic and pulmonary valve	Fixed wide splitting with atrial septal defect
			A_2 first	Wide but variable splitting with delayed right heart emptying (right bundle branch block)
			P_2 second	Reversed splitting due to delayed left heart emptying (left bundle branch block)
Third heart sound (S3)	Early in diastole, just after S2	Low pitch, often heard as 'gallop'	From ventricular wall due to abrupt cessation of rapid filling	Physiological: young people, pregnancy Pathological: heart failure, mitral regurgitation
Fourth heart sound (S4)	End of diastole, just before S1	Low pitch	Ventricular origin (stiff ventricle and augmented atrial contraction) related to atrial filling	Absent in atrial fibrillation A feature of severe left ventricular hypertrophy
Systolic clicks	Early or mid-systole	Brief, high-intensity sound	Valvular aortic stenosis Valvular pulmonary stenosis Floppy mitral valve Prosthetic heart sounds from opening and closing of normally functioning mechanical valves	Click may be lost when stenotic valve becomes thickened or calcified Prosthetic clicks lost when valve obstructed by thrombus or vegetations
Opening snap (OS)	Early in diastole	High pitch, brief duration	Opening of stenosed leaflets of mitral valve Prosthetic heart sounds	Moves closer to S2 as mitral stenosis becomes more severe. May be absent in calcific mitral stenosis

being unconscious and pulseless; breathing may take some time to stop completely after cardiac arrest. Death is virtually inevitable, unless effective treatment is given promptly. Sudden cardiac death is usually caused by a catastrophic arrhythmia and accounts for 25%–30% of all deaths from cardiovascular disease, claiming an estimated 70 000 to 90 000 lives each year in the UK. Many of these deaths are potentially preventable. Management of cardiac arrest is further discussed in detail on page 240.

Abnormal heart sounds

The first indication of heart disease may be the discovery of an abnormal sound on auscultation (Box 16.8). This may be incidental – for example, during a routine examination – or may be prompted by symptoms of heart disease.

Clinical assessment

The aims of clinical assessment are, first, to determine if the abnormal sound is cardiac; second, to determine if it is pathological; and third, to try to determine its cause.

Is the sound cardiac?

Additional heart sounds and murmurs demonstrate a consistent relationship to the cardiac cycle, whereas extracardiac sounds, such as a pleural rub or venous hum, do not. Pericardial friction produces a characteristic scratching noise termed a pericardial rub, which may have two components corresponding to atrial and ventricular systole and may vary with posture and respiration.

Is the sound pathological?

Pathological sounds and murmurs are the product of turbulent blood flow or rapid ventricular filling due to abnormal loading conditions. Some added sounds are physiological but may also occur in pathological conditions; for example, a third sound is common in young people and in pregnancy but is also a feature of heart failure (see Box 16.8). Similarly, a systolic murmur due to turbulence across the right ventricular outflow tract may occur in hyperdynamic states such as anaemia or pregnancy but may also be due to pulmonary stenosis or an intracardiac shunt leading to volume overload of the RV, such as an atrial septal defect. Benign murmurs do not occur in diastole (Box 16.9), and systolic murmurs that radiate or are associated with a thrill are almost always pathological.

16.9 Features of a benign or innocent heart murmur

- Soft
- Mid-systolic
- Heard at left sternal border
- No radiation
- No other cardiac abnormalities

What is the origin of the sound?

Timing, intensity, location, radiation and quality are all useful clues to the origin and nature of an additional sound or murmur (Box 16.10). Radiation of a murmur is determined by the direction of turbulent blood flow and is detectable only when there is a high-velocity jet, such as in mitral regurgitation (radiation from apex to axilla) or aortic stenosis (radiation from base to neck). Similarly, the pitch and quality of the sound can help to distinguish the murmur, such as the 'blowing' murmur of mitral regurgitation or the 'rasping' murmur of aortic stenosis. The position of a murmur in relation to the cardiac cycle is crucial and should be assessed by timing it with the heart sounds, carotid pulse and apex beat (Figs. 16.20 and 16.21).

Systolic murmurs

Ejection systolic murmurs are associated with ventricular outflow tract obstruction and occur in mid-systole with a crescendo–decrescendo

16.10 How to assess a heart murmur

When does it occur?

- Time the murmur using heart sounds, carotid pulse and the apex beat. Is it systolic or diastolic?
- Does the murmur extend throughout systole or diastole or is it confined to a shorter part of the cardiac cycle?

How loud is it?

- Grade 1: very soft (audible only in ideal conditions)
- Grade 2: soft
- Grade 3: moderate
- Grade 4: loud with associated thrill
- Grade 5: very loud
- Grade 6: heard without stethoscope

Note: Diastolic murmurs are very rarely above grade 4

Where is it heard best?

- Listen over the apex and base of the heart, including the aortic and pulmonary areas

Where does it radiate?

- Listen at the neck, axilla or back

What does it sound like?

- Pitch is determined by flow (high pitch indicates high-velocity flow)
- Is the intensity constant or variable?

Fig. 16.21 The timing and pattern of cardiac murmurs.

pattern, reflecting the changing velocity of blood flow (Box 16.11). Pansystolic murmurs maintain a constant intensity and extend from the first heart sound throughout systole to the second heart sound, sometimes obscuring it. They occur when blood leaks from a ventricle into a low-pressure chamber at an even or constant velocity. Mitral regurgitation, tricuspid regurgitation and ventricular septal defect are the only causes of a pansystolic murmur. Late systolic murmurs are unusual but may occur in mitral valve prolapse, if the mitral regurgitation is confined to late systole, and hypertrophic obstructive cardiomyopathy, if dynamic obstruction occurs late in systole.

Diastolic murmurs

These are due to accelerated or turbulent flow across the mitral or tricuspid valves. They are low-pitched noises that are often difficult to hear and should be evaluated with the bell of the stethoscope. A mid-diastolic murmur may be due to mitral stenosis (located at the apex and axilla), tricuspid stenosis (located at the left sternal border), increased flow across the mitral valve (for example, the to-and-fro murmur of severe mitral regurgitation) or increased flow across the tricuspid valve (for example, a left-to-right shunt through a large atrial septal defect). Early diastolic murmurs have a soft, blowing quality with a decrescendo pattern and should be evaluated with the diaphragm of the stethoscope. They are due to regurgitation across the aortic or pulmonary valves and are best heard at the left sternal border, with the patient sitting forwards in held expiration.

Continuous murmurs

These result from a combination of systolic and diastolic flow, such as occurs with a persistent ductus arteriosus, and must be distinguished from extracardiac noises such as bruits from arterial shunts, venous hums (high rates of venous flow in children) and pericardial friction rubs.

Investigations

If clinical evaluation suggests that the additional sound is cardiac and likely to be pathological, then echocardiography is indicated to determine the underlying cause.

Management

Management of patients with additional heart sounds or murmurs depends on the underlying cause. More details are provided in the

16.11 Features of some common systolic murmurs

Condition	Timing and duration	Quality	Location and radiation	Associated features
Aortic stenosis	Mid-systolic	Loud, rasping	Base and left sternal border, radiating to suprasternal notch and carotids	Single second heart sound Ejection click (in young patients) Slow-rising pulse Left ventricular hypertrophy (pressure overload)
Mitral regurgitation	Pansystolic	Blowing	Apex, radiating to axilla	Soft first heart sound Third heart sound Left ventricular hypertrophy (volume overload)
Ventricular septal defect	Pansystolic	Harsh	Lower left sternal border, radiating to whole precordium	Thrill Biventricular hypertrophy
Benign	Mid-systolic	Soft	Left sternal border, no radiation	No other signs of heart disease

sections on specific valve defects and congenital anomalies later in this chapter.

Heart failure

Heart failure describes the clinical syndrome that develops when the heart cannot maintain adequate output or can do so only at the expense of elevated ventricular filling pressure. In mild to moderate forms of heart failure, symptoms occur only when the metabolic demand increases during exercise or some other form of stress. In severe heart failure, symptoms may be present at rest. In clinical practice, heart failure may be diagnosed when a patient with heart disease develops the signs or symptoms of a low cardiac output, pulmonary congestion or systemic venous congestion at rest or on exercise. Three types of heart failure are recognised.

Left heart failure

This is characterised by a reduction in left ventricular output and an increase in left atrial and pulmonary venous pressure. If left heart failure occurs suddenly – for example, as the result of an acute MI – the rapid increase in left atrial pressure causes pulmonary oedema. If the rise in atrial pressure is more gradual, as occurs with mitral stenosis, there is reflex pulmonary vasoconstriction, which protects the patient from pulmonary oedema. However, the resulting increase in pulmonary vascular resistance causes pulmonary hypertension, which in turn impairs right ventricular function.

Right heart failure

This is characterised by a reduction in right ventricular output and an increase in right atrial and systemic venous pressure. The most common causes are chronic lung disease, pulmonary embolism and pulmonary valvular stenosis. The term ‘cor pulmonale’ is used to describe right heart failure that is secondary to chronic lung disease.

Biventricular heart failure

In biventricular failure, both sides of the heart are affected. This may occur because the disease process, such as dilated cardiomyopathy or coronary heart disease, affects both ventricles or because disease of the left heart leads to chronic elevation of the left atrial pressure, pulmonary hypertension and right heart failure.

Epidemiology

Heart failure predominantly affects older people; the prevalence is 1.6% in the UK adult population but affects around 14% of those aged 80–89 years. In the UK, most patients admitted to hospital with heart failure are more than 70 years old; they typically remain hospitalised for a week or more and may be left with chronic disability. Although the outlook depends, to some extent, on the underlying cause of the problem, untreated heart failure generally carries a poor prognosis; approximately 50% of patients with severe heart failure due to left ventricular dysfunction will die within 2 years because of either pump failure or malignant ventricular arrhythmias. The most common causes are coronary artery disease and myocardial infarction but almost all forms of heart disease can lead to heart failure, as summarised in Box 16.12. An accurate diagnosis is important because treatment of the underlying cause may reverse heart failure or prevent its progression.

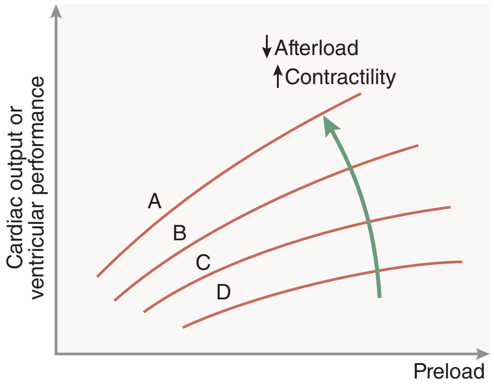

Fig. 16.22 Starling’s Law. Normal (A), mild (B), moderate (C) and severe (D) heart failure. Ventricular performance is related to the degree of myocardial stretching. An increase in preload (end-diastolic volume, end-diastolic pressure, filling pressure or atrial pressure) will therefore enhance function; however, overstretching causes marked deterioration. In heart failure, the curve moves to the right and becomes flatter. An increase in myocardial contractility or a reduction in afterload will shift the curve upwards and to the left (green arrow).

Pathogenesis

Heart failure occurs when cardiac output fails to meet the demands of the circulation. Cardiac output is determined by preload (the volume and pressure of blood in the ventricles at the end of diastole), afterload (the volume and pressure of blood in the ventricles during systole) and myocardial contractility, forming the basis of Starling’s Law (Fig. 16.22). The causes of heart failure are discussed below.

Ventricular dysfunction

Ventricular dysfunction is the most common cause of heart failure. This can occur because of impaired systolic contraction due to myocardial disease, or diastolic dysfunction where there is abnormal ventricular relaxation due to a stiff, non-compliant ventricle. This is most commonly found in patients with left ventricular hypertrophy. Systolic dysfunction

16.12 Mechanisms of heart failure

Cause	Examples	Features
Reduced ventricular contractility	Myocardial infarction (segmental dysfunction)	In coronary artery disease, 'akinetic' or 'dyskinetic' segments contract poorly and may impede the function of normal segments by distorting their contraction and relaxation patterns
	Myocarditis/cardiomyopathy (global dysfunction)	Progressive ventricular dilatation
Ventricular outflow obstruction (pressure overload)	Hypertension, aortic stenosis (left heart failure) Pulmonary hypertension, pulmonary valve stenosis (right heart failure)	Initially, concentric ventricular hypertrophy allows the ventricle to maintain a normal output by generating a high systolic pressure. Later, secondary changes in the myocardium and increasing obstruction lead to failure with ventricular dilatation and rapid clinical deterioration
Ventricular inflow obstruction	Mitral stenosis, tricuspid stenosis	Small, vigorous ventricle; dilated, hypertrophied atrium. Atrial fibrillation is common and often causes marked deterioration because ventricular filling depends heavily on atrial contraction
Ventricular volume overload	Left ventricular volume overload (mitral or aortic regurgitation) Ventricular septal defect Right ventricular volume overload (atrial septal defect) Increased metabolic demand (high output)	Dilatation and hypertrophy allow the ventricle to generate a high stroke volume and help to maintain a normal cardiac output. However, secondary changes in the myocardium lead to impaired contractility and worsening heart failure
Arrhythmia	Atrial fibrillation	Tachycardia does not allow for adequate filling of the heart, resulting in reduced cardiac output and back pressure
	Tachycardia	Prolonged tachycardia causes myocardial fatigue
	Complete heart block	Bradycardia limits cardiac output, even if stroke volume is normal
Diastolic dysfunction	Constrictive pericarditis	Marked fluid retention and peripheral oedema, ascites, pleural effusions and elevated jugular veins
	Restrictive cardiomyopathy	Bi-atrial enlargement (restrictive filling pattern and high atrial pressures). Atrial fibrillation may cause deterioration
	Left ventricular hypertrophy and fibrosis	Good systolic function but poor diastolic filling
	Cardiac tamponade	Hypotension, elevated jugular veins, pulsus paradoxus, poor urine output

and diastolic dysfunction often coexist, particularly in patients with coronary artery disease. Ventricular dysfunction reduces cardiac output, which, in turn, activates the sympathetic nervous system (SNS) and renin–angiotensin–aldosterone system (RAAS). Under normal circumstances, activation of the SNS and RAAS supports cardiac function but, in the setting of impaired ventricular function, the consequences are negative and lead to an increase in both afterload and preload (Fig. 16.23). A vicious circle may then be established because any additional fall in cardiac output causes further activation of the SNS and RAAS, and an additional increase in peripheral vascular resistance.

Activation of the RAAS causes vasoconstriction and sodium and water retention. This is primarily mediated by angiotensin II, a potent constrictor of arterioles, in both the kidney and the systemic circulation (see Fig. 16.23). Activation of the SNS also occurs and can initially sustain cardiac output through increased myocardial contractility and heart rate. Prolonged sympathetic stimulation has negative effects, however, causing cardiac myocyte apoptosis, cardiac hypertrophy and focal myocardial necrosis. Sympathetic stimulation also contributes to vasoconstriction and predisposes to arrhythmias. Sodium and water retention is further enhanced by the release of aldosterone, endothelin-1 (a potent vasoconstrictor peptide with marked effects on the renal vasculature) and, in severe heart failure, vasopressin (antidiuretic hormone, ADH). Natriuretic peptides are released from the atria in response to atrial dilatation and compensate to an extent for the sodium-conserving effect of aldosterone, but this mechanism is overwhelmed in heart failure. Pulmonary and peripheral oedema occur because of high left and right atrial pressures, and are compounded by sodium and water retention, caused by impairment of renal perfusion and by secondary hyperaldosteronism. If the underlying cause is a myocardial infarction, cardiac contractility is impaired and SNS and RAAS activation causes hypertrophy of non-infarcted segments, with thinning, dilatation and expansion of the

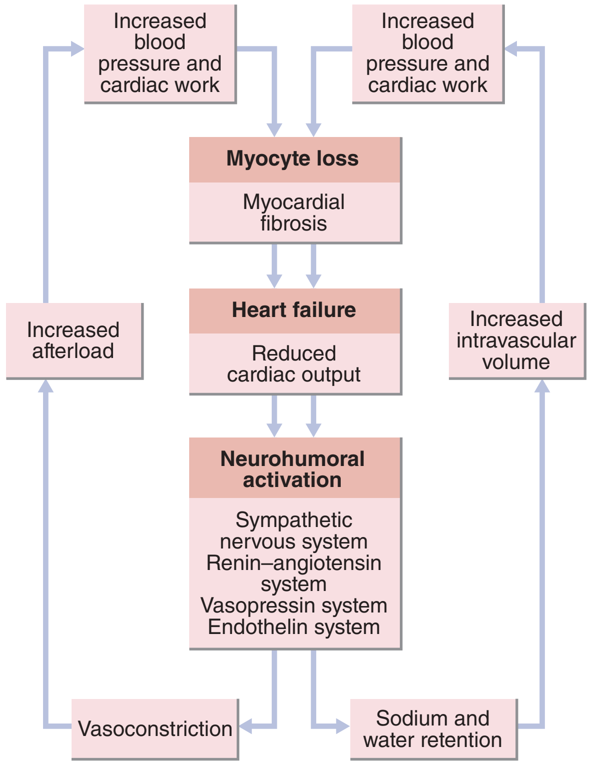

Fig. 16.23 Neurohumoral activation and compensatory mechanisms in heart failure. There is a vicious circle in progressive heart failure.

infarcted segment (see Fig. 16.63). This leads to further deterioration in ventricular function and worsening heart failure.

High-output failure

Sometimes cardiac failure can occur in patients without heart disease due to a large arteriovenous shunt, or where there is an excessively high cardiac output due to beri-beri, severe anaemia or thyrotoxicosis.

Valvular disease

Heart failure can also be caused by valvular disease in which there is impaired filling of the ventricles due to mitral or tricuspid stenosis; where there is obstruction to ventricular outflow, as occurs in aortic and pulmonary stenosis and hypertrophic cardiomyopathy; or as the result of ventricular overload secondary to valvular regurgitation.

Clinical assessment

Heart failure may develop suddenly, as in myocardial infarction (MI), or gradually, as in valvular heart disease. When there is gradual impairment of cardiac function, several compensatory changes take place. The term compensated heart failure is sometimes used to describe the condition of those with impaired cardiac function, in whom adaptive changes have prevented the development of overt heart failure. However, a minor event, such as an intercurrent infection or development of atrial fibrillation, may precipitate acute heart failure in these circumstances (Box 16.13). Similarly, acute heart failure sometimes supervenes as the result of a decompensating episode, on a background of chronic heart failure; this is called acute-on-chronic heart failure.

Acute left heart failure

Acute left heart failure presents with a sudden onset of dyspnoea at rest that rapidly progresses to acute respiratory distress, orthopnoea and ultimately respiratory failure. Often there is a clear precipitating factor, such as an acute MI, which may be apparent from the history. The patient appears agitated, pale and clammy. The peripheries are cool to the touch and the pulse is rapid, but in some cases, there may be an inappropriate bradycardia that aggravates the acute episode of heart failure. The BP is usually high because of SNS activation but may be normal or low if the patient is in cardiogenic shock.

The jugular venous pressure (JVP) is usually elevated, particularly with associated fluid overload or right heart failure. In acute heart failure, there has been no time for ventricular dilatation and the apex is not displaced. A ‘gallop’ rhythm, with a third heart sound, is heard quite early in the development of acute left-sided heart failure. A new systolic murmur may signify acute mitral regurgitation or ventricular septal rupture. Chest examination may reveal crepitations at the lung bases if there is pulmonary oedema, or crepitations throughout the lungs if this is severe. There may be expiratory wheeze. Patients with acute-on-chronic heart failure may have additional features of chronic heart failure (see below). Potential precipitants, such as an upper respiratory tract infection or inappropriate cessation of diuretic medication, may be identified on clinical examination or history-taking.

16.13 Factors that may precipitate or aggravate heart failure in pre-existing heart disease

- Myocardial ischaemia or infarction
- Intercurrent illness
- Arrhythmia (especially atrial fibrillation)
- Inappropriate reduction of therapy
- Administration of a drug with negative inotropic (β-blocker) or fluid-retaining properties (non-steroidal anti-inflammatory drugs, glucocorticoids)
- Pulmonary embolism
- Conditions associated with increased metabolic demand (pregnancy, thyrotoxicosis, anaemia)
- Intravenous fluid overload

Chronic heart failure

Patients with chronic heart failure commonly follow a relapsing and remitting course, with periods of stability and episodes of decompensation, leading to worsening symptoms that may necessitate hospitalisation. The clinical picture depends on the nature of the underlying heart disease, the type of heart failure that it has evoked, and the changes in the SNS and RAAS that have developed (see Box 16.12 and Fig. 16.24).

Low cardiac output causes fatigue and poor effort tolerance; the peripheries are cold, and the BP is low. To maintain perfusion of vital organs, blood flow is diverted away from skeletal muscle and this may contribute to fatigue, weakness and loss of muscle mass. Poor renal perfusion leads to oliguria and uraemia.

Pulmonary oedema due to left heart failure presents with dyspnoea and inspiratory crepitations over the lung bases. In contrast, right heart failure produces a high JVP with hepatic congestion and dependent peripheral oedema. In ambulant patients the oedema affects the lower legs, whereas in bed-bound patients it collects around the thighs and sacrum. Ascites or pleural effusion may occur (Fig. 16.24). Heart failure is not the only cause of oedema (Box 16.14).

Chronic heart failure is sometimes associated with marked weight loss (cardiac cachexia), caused by a combination of anorexia and impaired absorption due to gastrointestinal congestion, poor tissue perfusion due to a low cardiac output, and skeletal muscle atrophy due to immobility.

Complications of heart failure

Several complications may occur in advanced heart failure, as described below.

- *Renal impairment* is caused by poor renal perfusion due to low cardiac output and may be exacerbated by diuretic, angiotensin-converting enzyme (ACE) inhibitor and angiotensin receptor blocker (ARB) therapies.

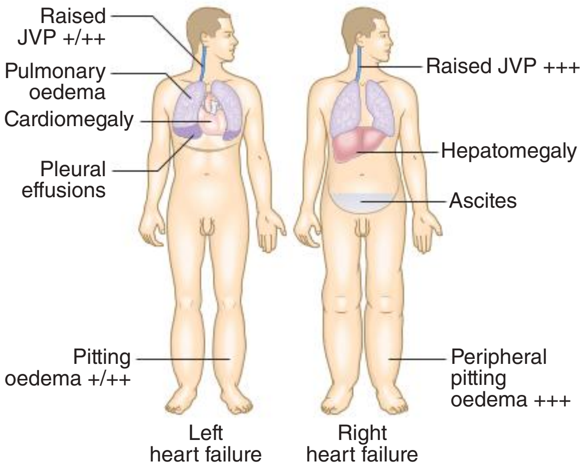

Fig. 16.24 Clinical features of left and right heart failure. (JVP = jugular venous pressure)

16.14 Differential diagnosis of peripheral oedema

- Cardiac failure: right or combined left and right heart failure, pericardial constriction, cardiomyopathy
- Chronic venous insufficiency: varicose veins
- Hypoalbuminaemia: nephrotic syndrome, liver disease, protein-losing enteropathy; often widespread, can affect arms and face
- Drugs:
  - Sodium retention: fludrocortisone, non-steroidal anti-inflammatory drugs
  - Increasing capillary permeability: nifedipine, amlodipine
- Idiopathic: women > men
- Chronic lymphatic obstruction

- *Hypokalaemia* may be caused by potassium-losing diuretics, and also by hyperaldosteronism due to activation of the renin–angiotensin system and impairment of aldosterone metabolism from hepatic congestion. Most of the body's potassium is intracellular and there may be substantial depletion of potassium stores, even when the plasma concentration is in the reference range.
- *Hyperkalaemia* may be due to the effects of drugs that promote renal resorption of potassium, in particular the combination of ACE inhibitors, ARBs and mineralocorticoid receptor antagonists. These effects are amplified if there is renal dysfunction due to low cardiac output or atherosclerotic renal vascular disease.
- *Hyponatraemia* is a feature of severe heart failure and is a poor prognostic sign. It may be caused by diuretic therapy, inappropriate water retention due to high vasopressin secretion, or failure of the cell membrane ion pump due to intracellular energy depletion.
- *Impaired liver function* is caused by hepatic venous congestion and poor arterial perfusion, which frequently cause mild jaundice and abnormal liver function tests; reduced synthesis of clotting factors can make anticoagulant control difficult.
- *Thromboembolism*. Deep vein thrombosis and pulmonary embolism may occur due to the effects of low cardiac output and enforced immobility. Systemic embolism, including stroke, occurs in patients with atrial fibrillation or flutter, or with intracardiac thrombus complicating mitral stenosis, MI or left ventricular aneurysm.
- *Atrial and ventricular arrhythmias* are very common and may be related to electrolyte changes such as hypokalaemia and hypomagnesaemia, myocardial fibrosis and the pro-arrhythmic effects of sympathetic activation. Atrial fibrillation occurs in approximately 20% of patients with heart failure and causes further impairment of cardiac function. Ventricular ectopic beats and non-sustained ventricular tachycardia are common findings in patients with heart failure and are associated with an adverse prognosis.
- *Sudden death* occurs in up to 50% of patients with heart failure and is most often due to ventricular fibrillation.

Investigations

An erect chest X-ray should be performed in all cases. This may show abnormal distension of the upper lobe pulmonary veins (Fig. 16.25). Vascularity of the lung fields becomes more prominent, and the pulmonary arteries dilate. Subsequently, interstitial oedema causes thickened interlobular septa and dilated lymphatics. These are evident as horizontal lines in the costophrenic angles (septal or 'Kerley B' lines). More advanced changes due to alveolar oedema cause a hazy opacification spreading from the hila, and pleural effusions. An ECG should be performed to assess for atrial fibrillation or atrial flutter. Echocardiography should be considered in all patients with heart failure in order to:

- determine the aetiology
- detect valvular heart disease, such as occult mitral or aortic stenosis, and other conditions that may be amenable to treatment
- identify patients who will benefit from long-term drug therapy and cardiac device implantation.

Serum urea, creatinine and electrolytes, haemoglobin and thyroid function may help to establish the nature and severity of the underlying heart disease and detect any complications. BNP is elevated in heart failure and is a prognostic marker, as well as being useful in differentiating heart failure from other causes of breathlessness or peripheral oedema.

Management of acute heart failure

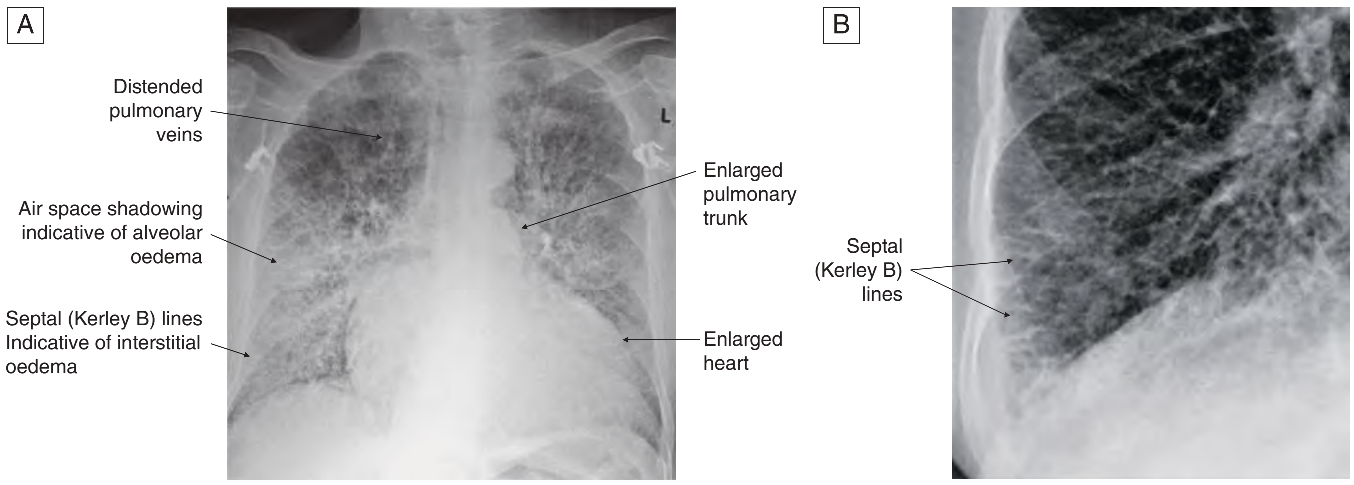
Acute heart failure with pulmonary oedema is a medical emergency that should be treated urgently. The patient should initially be kept rested upright, with continuous monitoring of cardiac rhythm, BP and pulse oximetry. Intravenous opiates can be of value in distressed patients but must be used sparingly, as they may cause respiratory depression and exacerbation of hypoxaemia and hypercapnia. The key elements of management are summarised in Box 16.15.

If these measures prove ineffective, inotropic agents such as dobutamine (2.5–10 μg/kg/min) may be required to augment cardiac

16.15 Management of acute pulmonary oedema

Action	Effect
Sit the patient up	Reduces preload
Give high-flow oxygen	Corrects hypoxia
Consider continuous positive airway pressure (CPAP) of 5–10 mmHg by tight-fitting mask	Reduces preload and pulmonary capillary hydraulic gradient
Administer nitrates*: IV glyceryl trinitrate (10–200 μg/min)	Reduces preload and afterload
Administer a loop diuretic: Furosemide (50–100 mg IV)	Combats fluid overload

*The dose of nitrate should be titrated upwards every 10 minutes until there is an improvement or systolic blood pressure is < 110 mmHg.
(IV = intravenous)



A

16.16 General measures for the management of heart failure

Education

- Explanation of nature of disease, treatment and self-help strategies

Diet

- Good general nutrition and weight reduction for the obese
- Avoidance of high-salt foods and added salt, especially for patients with severe congestive heart failure

Alcohol

- Minimise or eliminate alcohol consumption; alcohol-induced cardiomyopathy requires abstinence

Smoking

- Cessation

Exercise

- Regular moderate aerobic exercise within limits of symptoms

Vaccination

- Consideration of influenza, COVID-19 and pneumococcal vaccination

16.17 Congestive cardiac failure in old age

- **Incidence**: rises with age and affects 5%–10% of those in their eighties
- **Common causes**: coronary artery disease, hypertension and calcific degenerative valvular disease
- **Diastolic dysfunction**: often prominent, particularly in those with a history of hypertension
- **ACE inhibitors and ARBs**: improve symptoms and mortality but are more frequently associated with postural hypotension and renal impairment than in younger patients
- **SGLT2 inhibitors:** effective in reducing hospitalisation due to heart failure
- **Loop diuretics**: usually required but may be poorly tolerated in those with urinary incontinence and men with prostate enlargement

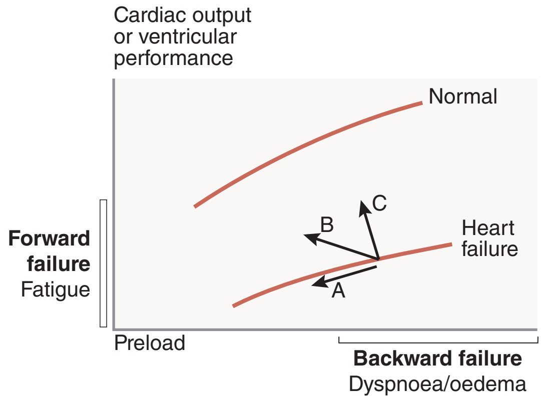

Fig. 16.26 The effect of treatment on ventricular performance curves in heart failure. Diuretics and venodilators (A), angiotensin-converting enzyme (ACE) inhibitors and mixed vasodilators (B), and positive inotropic agents (C).

output, particularly in hypotensive patients. An intra-aortic balloon pump may be beneficial in patients with acute cardiogenic pulmonary oedema and shock. Following management of the acute episode, additional measures must be used to control heart failure in the longer term, as discussed below.

Management of chronic heart failure

The aims of treatment in chronic heart failure are to improve cardiac function by increasing contractility and coordination of the myocardium, by optimising preload or decreasing afterload, and controlling cardiac rate and rhythm (see Fig. 16.23). This can be achieved by using drug treatments, implantable device therapy, coronary revascularisation, and in resistant cases, mechanical assist devices or cardiac transplantation.

Education

Education of patients and their relatives about the causes and treatment of heart failure can improve adherence to a management plan (Box 16.16). Some patients may need to weigh themselves daily, as a measure of fluid load, and adjust their diuretic therapy accordingly.

Drug treatment

Many drug treatments are now available for heart failure. Drugs that reduce preload are appropriate in patients with evidence of pulmonary or systemic venous congestion, whereas those that reduce afterload or increase myocardial contractility are more useful in patients with signs and symptoms of a low cardiac output. Some considerations specific to management of older patients are given in Box 16.17.

Diuretics Diuretics promote urinary sodium and water excretion, leading to a reduction in blood plasma volume, which in turn reduces preload and improves pulmonary and systemic venous congestion. They may also reduce afterload and ventricular volume, leading to a fall in ventricular wall tension and increased cardiac efficiency. Although a fall in preload (ventricular filling pressure) normally reduces cardiac output, patients with heart failure are beyond the apex of the Starling curve, so there may be a substantial and beneficial fall in filling pressure with either no change or an improvement in cardiac output (see Figs. 16.22 and 16.26). Over-diuresis can cause excessive volume depletion, resulting in a fall in cardiac output with hypotension, lethargy and renal failure. This is especially likely in patients with a marked diastolic component to their heart failure.

Oedema may persist, despite oral loop diuretic therapy, in some patients with severe chronic heart failure, particularly if there is renal impairment. Under these circumstances an intravenous infusion of a loop diuretic, such as furosemide (5–10 mg/hr), may initiate a diuresis. Combining this with a thiazide diuretic, such as bendroflumethiazide (5 mg daily), may augment the diuresis but care must be taken to avoid an excessive fluid loss, hyponatraemia and hypokalaemia.

Mineralocorticoid receptor antagonists, such as spironolactone and eplerenone, are potassium-sparing diuretics that are of particular benefit in patients with heart failure with severe left ventricular systolic dysfunction. They improve long-term clinical outcome in individuals with severe heart failure or heart failure following acute MI but may cause hyperkalaemia, particularly when used with an ACE inhibitor.

Originally developed as a treatment for type 2 diabetes mellitus, sodium-glucose co-transporter 2 (SGLT2) inhibitors block the resorption of glucose in the nephron of the kidney to cause an osmotic diuresis. Their use is associated with reduced hospitalisations for heart failure and lower mortality in patients with heart failure irrespective of the presence of diabetes. However, they are associated with an increased risk of genitourinary tract infections and diabetic ketoacidosis.

Angiotensin-converting enzyme inhibitors Angiotensin-converting enzyme (ACE) inhibitors play a central role in the management of heart failure since they interrupt the vicious circle of neurohumoral activation that is characteristic of the disease by preventing the conversion of angiotensin I to angiotensin II. This, in turn, reduces peripheral vasoconstriction, activation of the sympathetic nervous system (Fig. 16.27), and salt and water retention due to aldosterone release, as well as preventing the activation of the RAAS caused by diuretic therapy.

In moderate and severe heart failure, ACE inhibitors can produce a substantial improvement in effort tolerance and in mortality. They can also improve outcome and prevent the onset of overt heart failure in patients with poor residual left ventricular function following MI.

Vasoconstriction
Enhanced sympathetic activity
Arrhythmogenesis
β-blockers
Mineralocorticoid receptor antagonists
Salt and water retention
Diuretics

Fig. 16.27 Neurohumoral activation of the renin–angiotensin and sympathetic nervous systems has adverse (red) effects on the cardiovascular system which are counterbalanced by beneficial effects of endogenous natriuretic and vasoactive peptide systems (yellow). Heart failure treatments are targeted at inhibiting the detrimental pathways and enhancing the beneficial compensatory systems.

Adverse effects of ACE inhibitors include hypotension and renal impairment, especially in patients with bilateral renal artery stenosis or those with pre-existing renal disease. An increase in serum potassium concentration may also occur, which can be beneficial in offsetting the hypokalaemia associated with loop diuretic therapy. In stable patients without hypotension (systolic BP over 100 mmHg), ACE inhibitors can usually be safely started in the community. In other patients, however, it is usually advisable to withhold diuretics for 24 hours before starting treatment with a small dose of a long-acting agent, preferably given at night (Box 16.18). Renal function and serum potassium must be monitored and should be checked 1–2 weeks after starting therapy.

Angiotensin receptor blockers Angiotensin receptor blockers (ARBs) act by blocking the action of angiotensin II on the heart, peripheral vasculature and kidneys. In heart failure they produce beneficial haemodynamic changes similar to those of ACE inhibitors (see Fig. 16.27) but are generally better tolerated. They have comparable effects on mortality and are a useful alternative for patients who cannot tolerate ACE inhibitors. They should be started at a low dose and titrated upwards, depending on response (see Box 16.18). Unfortunately, they share all the more serious adverse effects of ACE inhibitors, including renal dysfunction and hyperkalaemia.

Neprilysin inhibitors The only drug currently in this class is sacubitril, a small-molecule inhibitor of neutral endopeptidase, or neprilysin, which is responsible for the breakdown of the endogenous diuretics, ANP and BNP, as well as vasoactive peptides such as bradykinin and substance P (see Fig. 16.27). If used in combination with the ARB valsartan, in an initial oral dose of 24 mg sacubitril and 26 mg valsartan daily, it produces additional symptomatic and mortality benefit over ACE inhibition and is increasingly being used in preference to ACE inhibitors in patients with chronic heart failure.

Vasodilators These drugs are valuable in chronic heart failure, when ACE inhibitors or ARBs are contraindicated. Venodilators, such as nitrates, reduce preload. Arterial dilators, such as hydralazine, reduce afterload (see Fig. 16.26). Their use is limited by pharmacological tolerance and hypotension.

16.18 Dosages of ACE inhibitors, angiotensin receptor blockers, β-blockers and neprilysin inhibitors in heart failure

	Starting dose	Target dose
ACE inhibitors		
Enalapril	2.5 mg twice daily	10 mg twice daily
Lisinopril	2.5 mg daily	20 mg daily
Ramipril	1.25 mg daily	10 mg daily
Angiotensin receptor blockers		
Losartan	25 mg daily	100 mg daily
Candesartan	4 mg daily	32 mg daily
Valsartan	40 mg daily	160 mg daily
β-blockers		
Bisoprolol	1.25 mg daily	10 mg daily
Metoprolol	25 mg twice daily	100 mg twice daily
Carvedilol	3.125 mg twice daily	25 mg twice daily
Neprilysin inhibitor-ARB		
Sacubitril–valsartan	24/26 mg twice daily	97/103 mg twice daily

Beta-adrenoceptor antagonists (β-blockers) Beta-blockade helps to counteract the deleterious effects of enhanced sympathetic stimulation and reduces the risk of arrhythmias and sudden death. When initiated in standard doses, β-blockers may precipitate acute-on-chronic heart failure, but when given in small incremental doses they can increase ejection fraction, improve symptoms, reduce the frequency of hospitalisation, and reduce mortality in patients with chronic heart failure. Beta-blockers also reduce incidence of atrial fibrillation and ventricular arrhythmia. A typical regimen is bisoprolol, starting at 1.25 mg daily and increased gradually over 12 weeks to a target maintenance dose of 10 mg daily. Beta-blockers are more effective at reducing mortality than ACE inhibitors, with a relative risk reduction of 33% versus 20%, respectively.

Ivabradine Ivabradine acts on the I_f inward current in the SA node, resulting in reduction of heart rate. Typical dosages are 2.5–5 mg twice daily, increasing to 7.5 mg twice daily if necessary. It reduces hospital admission and mortality rates in patients with heart failure due to moderate or severe left ventricular systolic impairment. In trials, its effects were most marked in patients with a relatively high heart rate (over 77/min), so ivabradine is best suited to patients who cannot take β-blockers or whose heart rate remains high despite β-blockade. It is ineffective in patients with atrial fibrillation.

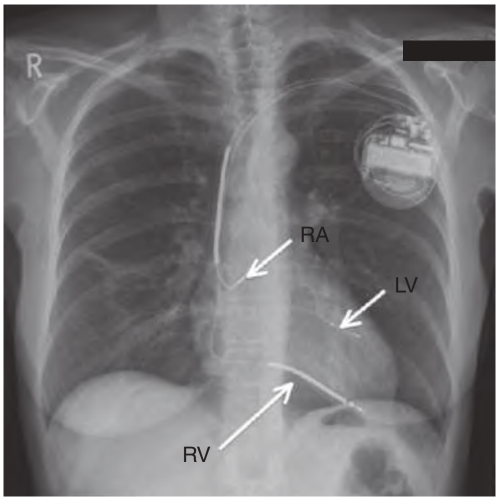
Digoxin Digoxin in maintenance doses of 0.0625–0.25 mg daily can be used to provide rate control in patients with heart failure and atrial fibrillation. In patients with severe heart failure (NYHA class III–IV, see Box 16.5), digoxin reduces the likelihood of hospitalisation for heart failure, although it has no effect on long-term survival.

Amiodarone This is a potent anti-arrhythmic drug that has little negative inotropic effect and may be valuable in patients with poor left ventricular function. It is effective only in the treatment of symptomatic arrhythmias and should not be used as a preventative agent in asymptomatic patients. Amiodarone is used for prevention of symptomatic atrial arrhythmias and of ventricular arrhythmias when other pharmacological options have been exhausted.

Non-pharmacological treatments

Implantable cardiac defibrillators These devices are indicated in patients with heart failure who have had, or who are at high risk of, life-threatening ventricular arrhythmias, since they reduce the risk of sudden death.

Cardiac resynchronisation therapy devices In patients with marked conduction system disease, especially left bundle branch block, there is uncoordinated left ventricular contraction which exacerbates heart failure. Cardiac resynchronisation therapy (CRT) overcomes dyssynchronous contraction by pacing the LV and RV simultaneously (Fig. 16.28). This improves cardiac output and is associated with improved symptoms and reduced mortality.



[redacted]

Fig. 16.28 Chest X-ray of a biventricular pacemaker and defibrillator (cardiac resynchronisation therapy). The right ventricular lead (RV) is in position in the ventricular apex and is used for both pacing and defibrillation. The left ventricular lead (LV) is placed via the coronary sinus, and the right atrial lead (RA) is placed in the right atrial appendage; both are used for pacing only.

Coronary revascularisation Coronary artery bypass surgery or percutaneous coronary intervention may improve function in areas of the myocardium that are 'hibernating' because of inadequate blood supply and can be used to treat carefully selected patients with heart failure and coronary artery disease. If necessary, 'hibernating' myocardium can be identified by stress echocardiography and specialised nuclear or magnetic resonance imaging.

Cardiac transplantation Cardiac transplantation is an established and successful treatment for patients with intractable heart failure. Coronary artery disease and dilated cardiomyopathy are the most common indications. The use of transplantation is limited by the efficacy of modern drug and device therapies, as well as the availability of donor hearts, so it is generally reserved for young patients with severe symptoms despite optimal therapy.

Conventional heart transplantation is contraindicated in patients with pulmonary vascular disease due to long-standing left heart failure, complex congenital heart disease such as Eisenmenger syndrome, or primary pulmonary hypertension because the RV of the donor heart may fail in the face of high pulmonary vascular resistance. However, heart–lung transplantation can be successful in patients with Eisenmenger syndrome, and lung transplantation has been used for primary pulmonary hypertension.

Although cardiac transplantation usually produces a dramatic improvement in the recipient's quality of life, serious complications may occur:

- *Rejection*. In spite of routine therapy with tacrolimus, mycophenolate mofetil and corticosteroids, episodes of rejection are common and may present with heart failure, arrhythmias or subtle ECG changes. Cardiac biopsy is often used to confirm the diagnosis before starting treatment with high-dose corticosteroids.
- *Accelerated atherosclerosis*. Recurrent heart failure is often due to progressive atherosclerosis in the coronary arteries of the donor heart. This is not confined to patients who underwent transplantation for coronary artery disease and is probably a manifestation of chronic rejection. Angina is rare because the heart has been denervated.
- *Infection*. Opportunistic infection with organisms such as cytomegalovirus or *Aspergillus* remains a major cause of death in transplant recipients.

Ventricular assist devices Because of the limited supply of donor organs, ventricular assist devices (VADs) may be employed as a bridge to cardiac transplantation and as short-term restoration therapy following a potentially reversible insult such as viral myocarditis. In some patients, VADs may be used as a long-term therapy if no other options exist.

These devices assist cardiac output by using a roller, centrifugal or pulsatile pump that, in some cases, is implantable and portable. They withdraw blood through cannulae inserted in the atria or ventricular apex and pump it into the pulmonary artery or aorta. They are designed not only to unload the ventricles but also to provide support to the pulmonary and systemic circulations. Their more widespread application is limited by high complication rates (haemorrhage, systemic embolism, infection, neurological and renal sequelae), although some improvements in survival and quality of life have been demonstrated in patients with severe heart failure.

Cardiac arrhythmias

A cardiac arrhythmia is defined as a disturbance of the electrical rhythm of the heart. Arrhythmias are often a manifestation of structural heart disease but may also occur because of abnormal conduction or depolarisation in an otherwise healthy heart. By convention a heart rate of more than 100/min is a tachycardia, and a heart rate of less than 60/min is a bradycardia.

Pathogenesis

Under normal circumstances, the cardiac cycle is initiated by spontaneous depolarisation in the SA node. The atria and ventricles then activate sequentially as the depolarisation wave passes through specialised conducting tissues (see Fig. 16.4). The SA node acts as a pacemaker and its intrinsic rate is regulated by the autonomic nervous system; parasympathetic (vagal) activity decreases the heart rate and sympathetic activity increases it via cardiac sympathetic nerves and circulating catecholamines.

Abnormal heart rhythms, called arrhythmias, usually occur as the result of pathology affecting the conduction system of the heart. There are three main mechanisms of tachycardia:

- *Increased automaticity*. The tachycardia is produced by spontaneous depolarisation of an ectopic focus in the atria, atrioventricular junction or ventricles, often in response to catecholamines. Single depolarisations lead to atrial, junctional or ventricular premature (ectopic) beats. Repeated depolarisation leads to atrial, junctional or ventricular tachycardia.
- *Re-entry*. The tachycardia is initiated by an ectopic beat and sustained by a re-entry circuit (Fig. 16.29). Most tachyarrhythmias are caused by re-entry.
- *Triggered activity*. This can cause ventricular arrhythmias in patients with coronary artery disease. It is a form of secondary depolarisation arising from an incompletely repolarised cell membrane. Arrhythmias may be supraventricular (sinus, atrial or junctional) or ventricular in origin.

Supraventricular rhythms usually produce narrow QRS complexes because the ventricles are depolarised in their normal sequence via the AV node, the bundle of His, bundle branches and Purkinje fibres. In contrast, ventricular arrhythmias usually produce broad QRS complexes because ventricular activation occurs slowly via myocardial cells rather than the rapidly conducting Purkinje fibres. Occasionally, supraventricular tachycardia can mimic ventricular tachycardia and present as a broad-complex tachycardia due to coexisting bundle branch block or the presence of an additional atrioventricular connection (accessory pathway, see below).

Bradycardia is caused by impaired impulse generation by the SA node, or impaired propagation through the AV node or His–Purkinje conduction system. If the sinus rate becomes unduly slow, another, more distal part of the conducting system may assume the role of pacemaker. This is known as an escape rhythm and may arise in the AV node or His bundle (junctional rhythm) or in the ventricles (idioventricular rhythm).

Clinical features

Many arrhythmias are asymptomatic but sustained tachycardias typically present with rapid palpitation, dizziness, chest discomfort or breathlessness. Extreme tachycardias can also cause syncope because the heart is unable to fill properly at extreme rates. Bradycardias tend to cause symptoms of low cardiac output, including fatigue, lightheadedness and syncope. Extreme bradycardias or tachycardias can precipitate sudden death or cardiac arrest.

Investigations

A 12-lead ECG, if taken during symptoms, is usually diagnostic. If arrhythmias are intermittent and the resting ECG is normal, an attempt should be made to capture the abnormal rhythm using an ambulatory ECG or a patient-activated ECG. Many smart watches have single lead ECG recording capability and are a useful adjunct in clinical practice.

Management

Features of individual arrhythmias are discussed below. Management depends on the nature of the arrhythmia and the general principles of medical management are discussed later in this chapter.

Sinus arrhythmia

This is defined as a cyclical alteration of the heart rate during respiration, with an increase during inspiration and a decrease during expiration. Sinus arrhythmia is a normal phenomenon and can be quite pronounced in children. Absence of heart rate variation with breathing or with changes in posture may be a feature of diabetic neuropathy, autonomic neuropathy or increased sympathetic drive. Sinus arrhythmia does not require treatment.

Sinus bradycardia

This may occur in healthy people at rest and is a common finding in athletes. Some pathological causes are listed in Box 16.19. If sinus bradycardia is asymptomatic, then no treatment is required. Symptomatic sinus bradycardia may occur acutely during an MI and can be treated with intravenous atropine (0.6–1.2 mg). Patients with recurrent or persistent symptomatic sinus bradycardia should be considered for permanent pacemaker implantation.

Sinus tachycardia

Sinus tachycardia is usually due to an increase in sympathetic activity associated with exercise or emotion. Healthy young adults can produce a rapid sinus rate, up to 200/min, during intense exercise. Sinus tachycardia usually does not require treatment but sometimes may reflect an underlying disease, as summarised in Box 16.19.

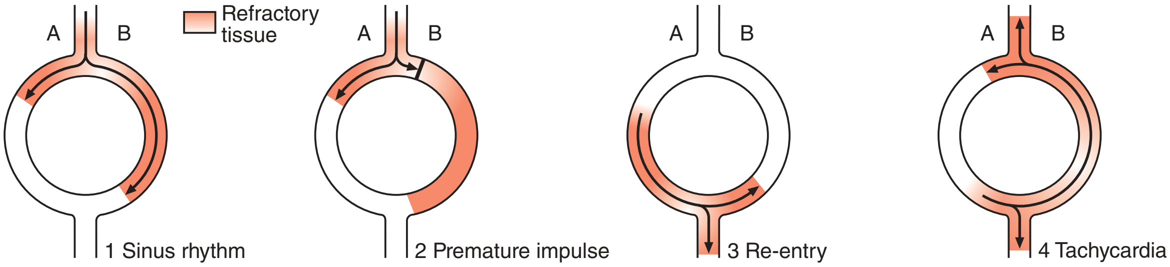


Fig. 16.29 The mechanism of re-entry. Re-entry can occur when there are two alternative pathways with different conducting properties, such as the atrioventricular node and an accessory pathway, or an area of normal and an area of ischaemic tissue. Here, pathway A conducts slowly and recovers quickly, while pathway B conducts rapidly and recovers slowly. (1) In sinus rhythm, each impulse passes down both pathways before entering a common distal pathway. (2) As the pathways recover at different rates, a premature impulse may find pathway A open and B closed. (3) Pathway B may recover while the premature impulse is travelling selectively down pathway A. The impulse can then travel retrogradely up pathway B, setting up a closed loop or re-entry circuit. (4) This may initiate a tachycardia that continues until the circuit is interrupted by a change in conduction rates or electrical depolarisation.

Sinoatrial disease

Sinoatrial disease or 'sick sinus syndrome' can occur at any age but is commonest in older people. It is caused by degenerative changes in the SA node and is characterised by a variety of arrhythmias (Box 16.20). The typical presentation is with palpitation, dizzy spells or syncope, due to intermittent tachycardia, bradycardia, or pauses in sinus rhythm with no atrial or ventricular activity (Fig. 16.30). It is not uncommon for patients with sinus bradycardia to have coexistent paroxysmal atrial fibrillation (AF) which can cause irregular tachycardia if AV nodal conduction remains brisk. This is called 'tachy-brady syndrome'. If these patients are not suitable for catheter ablation for AF due to frailty or other comorbidities, a pacemaker is usually required along with anti-arrhythmic or rate control medication.

In sinoatrial disease, a permanent pacemaker improves symptoms but not prognosis so is not indicated in asymptomatic patients. A dual-chamber pacemaker is normally used (see p. 458). The right atrial lead is used to assist the SA node, and the right ventricular lead is a backup in case AV nodal block occurs later on.

16.19 Some pathological causes of sinus bradycardia and tachycardia

Sinus bradycardia

- Myocardial infarction
- Sinus node disease (sick sinus syndrome)
- Hypothermia
- Hypothyroidism
- Cholestatic jaundice
- Raised intracranial pressure
- Drugs (β-blockers, digoxin, verapamil)

Sinus tachycardia

- Anxiety
- Fever
- Anaemia
- Heart failure
- Thyrotoxicosis
- Phaeochromocytoma
- Drugs (β-agonists)

16.20 Common features of sinoatrial disease

- Sinus bradycardia
- Sinoatrial block (sinus arrest)
- Paroxysmal atrial fibrillation
- Paroxysmal atrial tachycardia
- Atrioventricular block

Atrioventricular block

This usually occurs as the result of disease affecting the AV node. AV block can be intermittent, however, and may become evident only when the conducting tissue is stressed by a rapid atrial rate. Reflecting this fact, atrial tachyarrhythmias are often associated with AV block. Episodes of ventricular asystole may also complicate complete heart block or Mobitz type II second-degree AV block. Several types of AV block are recognised.

First-degree atrioventricular block

In this condition, AV conduction is delayed and so the PR interval is prolonged (> 0.20 sec; Fig. 16.31). It rarely causes symptoms and does not usually require treatment.

Second-degree atrioventricular block

Here, dropped beats occur because some impulses from the atria fail to conduct to the ventricles. Two subtypes are recognised. In Mobitz type I second-degree AV block (Fig. 16.32), there is progressive lengthening of successive PR intervals, culminating in a dropped beat. The cycle then repeats itself. Mobitz I is also known as the Wenckebach phenomenon and is usually due to impaired conduction in the AV node itself. The phenomenon may be physiological and is sometimes observed at rest or during sleep in athletic young adults with high vagal tone.

In Mobitz type II second-degree AV block (Fig. 16.33), the PR interval of the conducted impulses remains constant, but some P waves are intermittently not conducted. This is usually caused by disease of the His–Purkinje system and carries a risk of asystole.

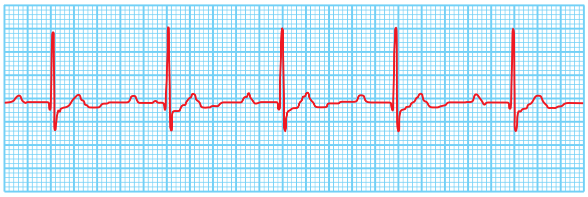

Fig. 16.31 First-degree atrioventricular block. The PR interval is prolonged and measures 0.32 sec.

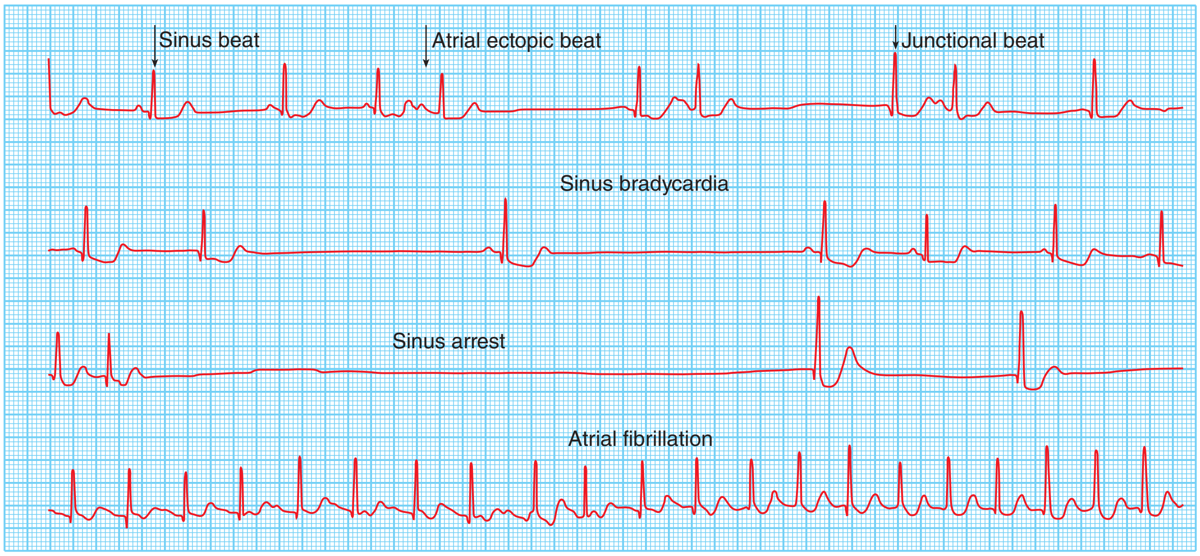

Fig. 16.30 Sinoatrial disease (sick sinus syndrome). A continuous rhythm strip from a 24-hour ECG tape recording illustrating periods of sinus rhythm, atrial ectopics, junctional beats, sinus bradycardia, sinus arrest and paroxysmal atrial fibrillation.

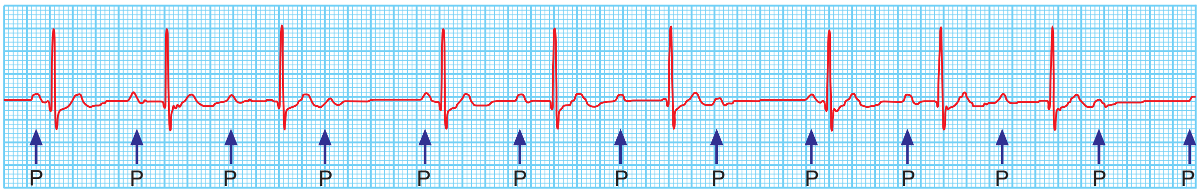

Fig. 16.32 **Second-degree atrioventricular block (Mobitz type I – the Wenckebach phenomenon).** The PR interval progressively increases until a P wave is not conducted. The cycle then repeats itself. In this example, conduction is at a ratio of 4:3, leading to groupings of three ventricular complexes in a row.

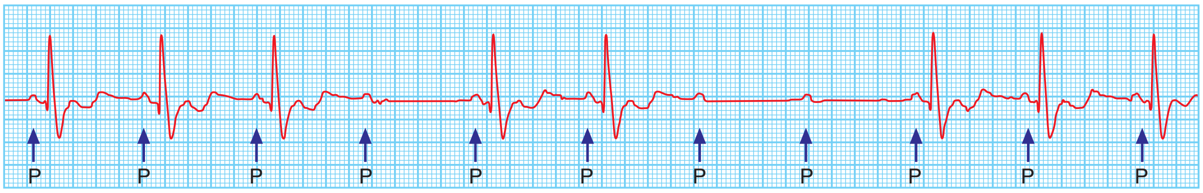

Fig. 16.33 **Second-degree atrioventricular block (Mobitz type II).** The PR interval of conducted beats is normal but some P waves are not conducted. The constant PR interval distinguishes this from the Wenckebach phenomenon.

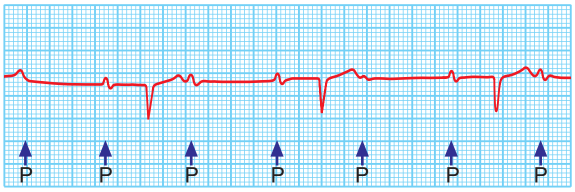

Fig. 16.34 **Second-degree atrioventricular block with fixed 2:1 block.** Alternate P waves are not conducted. This may be due to Mobitz type I or II block.

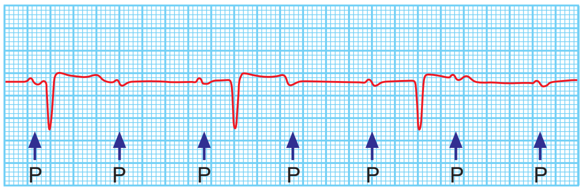

Fig. 16.35 **Complete (third-degree) atrioventricular block.** There is complete dissociation of atrial and ventricular complexes. The atrial rate is 80/min and the ventricular rate is 38/min.

i 16.21 Causes of complete atrioventricular block

Congenital

Acquired

- Idiopathic fibrosis
- Myocardial infarction/ischaemia
- Inflammation:
  - Infective endocarditis
  - Sarcoidosis
  - Chagas disease
- Trauma
- Drugs:
  - Digoxin
  - β-blockers
  - Calcium antagonists

In 2:1 AV block (Fig. 16.34), alternate P waves are not conducted, so it is not usually possible to distinguish between Mobitz type I and type II block.

Third-degree atrioventricular block

In third-degree AV block, conduction fails completely, and the atria and ventricles beat independently. This is known as AV dissociation, as shown in Figure 16.35. Ventricular activity is maintained by an escape rhythm arising in the AV node or bundle of His (narrow QRS complexes) or the distal Purkinje tissues or myocardium (broad QRS complexes). Distal escape rhythms tend to be slower and less reliable. Complete AV block (Box 16.21) produces a slow (25–50/min), regular pulse that does not vary with exercise, except in the case of congenital complete AV block. There is usually a compensatory increase in stroke volume, producing a large-volume pulse. Cannon waves may be visible in the neck and the intensity of the first heart sound varies due to the loss of AV synchrony.

Clinical features

The typical presentation is with recurrent syncope or 'Stokes–Adams' attacks. These episodes are characterised by sudden loss of consciousness that occurs without warning and results in collapse. A brief anoxic seizure (due to cerebral ischaemia) may occur if there is prolonged asystole. There is pallor and a death-like appearance during the attack, but when the heart starts beating again there is a characteristic flush. In distinction to epilepsy, recovery is rapid. Sinoatrial disease and neurocardiogenic syncope (p. 220) may cause similar symptoms.

Management

This depends on the clinical circumstances. Inferior MI is sometimes complicated by transient AV block because the right coronary artery (RCA) supplies the AV node. There is usually a reliable escape rhythm and, if the patient remains well, no treatment is required. Symptomatic second- or third-degree AV block may respond to atropine (0.6 mg IV, repeated as necessary) or, if this fails, a temporary pacemaker. In most cases, the AV block will resolve within 7–10 days.

Second- or third-degree AV heart block complicating acute anterior MI indicates extensive ventricular damage involving both bundle branches and carries a poor prognosis. If the patient presents with asystole, intravenous atropine (3 mg) or intravenous isoprenaline (2 mg in 500 mL 5% dextrose, infused at 10–60 mL/hr) may help to maintain the circulation until a temporary pacing electrode can be inserted. Temporary pacing can provide effective rhythm support in the short term.

Patients with symptomatic bradyarrhythmias associated with AV block should be treated with a permanent pacemaker. Asymptomatic first-degree or Mobitz type I second-degree AV block (Wenckebach phenomenon) does not require treatment but may be an indication of underlying

16.22 Common causes of bundle branch block

Right bundle branch block

- Normal variant
- Right ventricular hypertrophy or strain, e.g. pulmonary embolism
- Congenital heart disease, e.g. atrial septal defect
- Coronary artery disease

Left bundle branch block

- Coronary artery disease
- Hypertension
- Aortic valve disease
- Cardiomyopathy

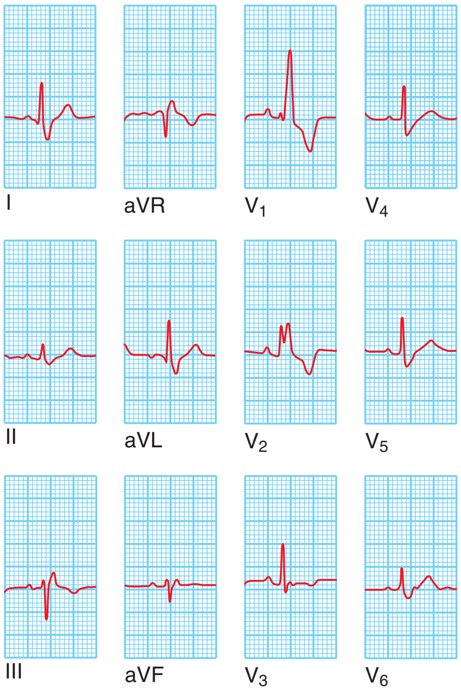

Fig. 16.36 Right bundle branch block. Note the wide QRS complexes with 'M'-shaped configuration in leads V_1 and V_2 and a wide S wave in lead I.

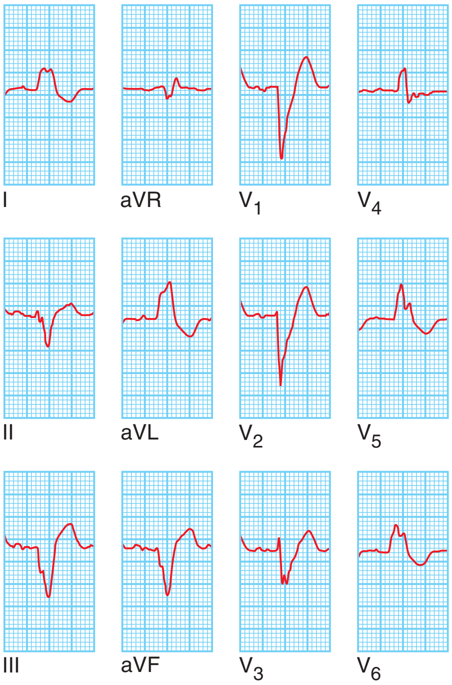

Fig. 16.37 Left bundle branch block. Note the wide QRS complexes with loss of the Q wave or septal vector in lead I and 'M'-shaped QRS complexes in V_5 and V_6.

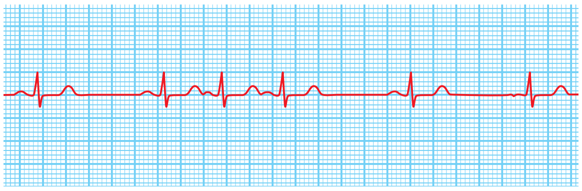

Fig. 16.38 Atrial ectopic beats. The first, second and fifth complexes are normal sinus beats. The third, fourth and sixth complexes are atrial ectopic beats with identical QRS complexes and abnormal (sometimes barely visible) P waves.

heart disease. A permanent pacemaker is usually indicated in patients with asymptomatic Mobitz type II second-degree AV block or third-degree AV heart block because of the risk of asystole and sudden death. Pacing improves prognosis.

Bundle branch block

Damage to the right or left bundle branch of the conducting system can occur because of many pathologies, including ischaemic heart disease, hypertensive heart disease and cardiomyopathy. However, right bundle branch block (RBBB) can occur as a normal variant in healthy individuals (Box 16.22). In left bundle branch block (LBBB) and RBBB, depolarisation proceeds through a slow myocardial route in the affected ventricle rather than through the rapidly conducting Purkinje tissues that constitute the bundle branches. This causes delayed conduction into the LV or RV, broadens the QRS complex ($\geq$0.12 sec) and produces characteristic alterations in QRS morphology (Figs. 16.36 and 16.37). Damage to the left bundle can also occur after it divides into anterior and posterior fascicles, when it is called hemiblock. In this case, the QRS complex remains narrow but the direction of ventricular depolarisation is changed, causing left axis deviation in left anterior hemiblock and right axis deviation in left posterior hemiblock (see Fig. 16.7). The combination of RBBB and left anterior or posterior hemiblock is known as bifascicular block. LBBB often signifies underlying heart disease and causes ventricular incoordination, which may aggravate symptoms in patients with heart failure. This can be treated in selected patients by cardiac resynchronisation therapy pacemakers.

Atrial ectopic beats

Atrial ectopic beats usually cause no symptoms but can give the sensation of a missed beat or an abnormally strong beat. The ECG (Fig. 16.38) shows a premature but otherwise normal QRS complex; if visible, the preceding P wave has a different morphology because the atria activate from an abnormal site. In most cases these are of no consequence, although very frequent atrial ectopic beats may herald the onset of atrial fibrillation. Treatment is rarely necessary, but β-blockers can be used if symptoms are intrusive.

Atrial tachycardia

Atrial tachycardia may be a manifestation of increased atrial automaticity, sinoatrial disease or digoxin toxicity. It produces a narrow-complex tachycardia with abnormal P-wave morphology, sometimes associated with AV block if the atrial rate is rapid. It may respond to β-blockers, which reduce automaticity, or class I or III anti-arrhythmic drugs (see Box 16.30). The ventricular response in rapid atrial tachycardias may be

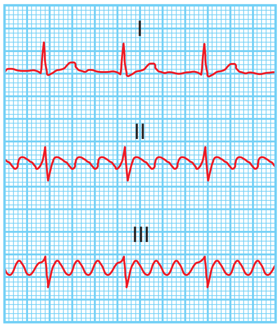

Fig. 16.39 **Atrial flutter.** Simultaneous recording showing atrial flutter with 4:1 atrioventricular block. Flutter waves are visible only in leads II and III.

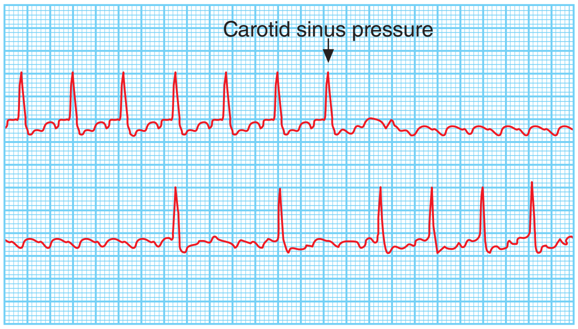

Fig. 16.40 **Carotid sinus pressure in atrial flutter: continuous trace.** The diagnosis of atrial flutter with 2:1 block was established when carotid sinus pressure produced temporary atrioventricular block, revealing the flutter waves.

controlled by AV node-blocking drugs. Catheter ablation (p. 460) can be used to target the ectopic focus and should be offered as an alternative to anti-arrhythmic drugs in patients with recurrent atrial tachycardia.

Atrial flutter

Atrial flutter is characterised by a large (macro) re-entry circuit, usually within the right atrium encircling the tricuspid annulus. The atrial rate is approximately 300/min, and is usually associated with 2:1, 3:1 or 4:1 AV block (with corresponding heart rates of 150, 100 or 75/min). Rarely, in young patients, every flutter wave is conducted, producing a rate of 300/min and, potentially, haemodynamic compromise. The ECG shows sawtooth flutter waves (Fig. 16.39). When there is regular 2:1 AV block, it may be difficult to identify flutter waves that are buried in QRS complexes and T waves. Atrial flutter should be suspected when there is a narrow-complex tachycardia of 150/min. Carotid sinus pressure or intravenous adenosine may help to establish the diagnosis by temporarily increasing the degree of AV block and revealing flutter waves (Fig. 16.40).

Management

Atrial flutter can be managed by either 'rate control' or 'rhythm control'. Rate control uses AV node-blocking drugs, such as β-blockers, verapamil or digoxin at the dosages shown in Box 16.30, to control the ventricular rate. In most cases rhythm control is preferable. This can be achieved by either direct current (DC) cardioversion, or catheter ablation. DC cardioversion is associated with a high recurrence rate even when drugs, such as β-blockers or amiodarone, are used afterwards. Class Ic anti-arrhythmic drugs, such as flecainide, are contraindicated because they can produce a paradoxical extreme tachycardia and haemodynamic compromise. Catheter ablation offers a greater than 90% chance of permanent cure and is the treatment of choice for patients with persistent symptoms. Anticoagulant management in patients with atrial flutter, including management around cardioversion, is identical to that of patients with atrial fibrillation.

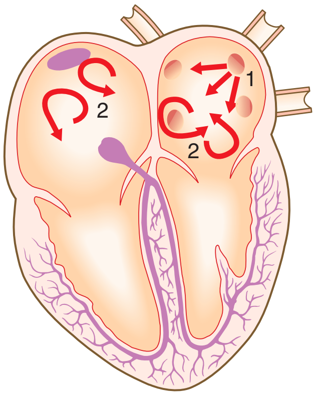

Fig. 16.41 **Mechanisms initiating atrial fibrillation.** (1) Ectopic beats, often arising from the pulmonary veins, trigger atrial fibrillation. (2) Re-entry within the atria maintains atrial fibrillation, with multiple interacting re-entry circuits operating simultaneously.

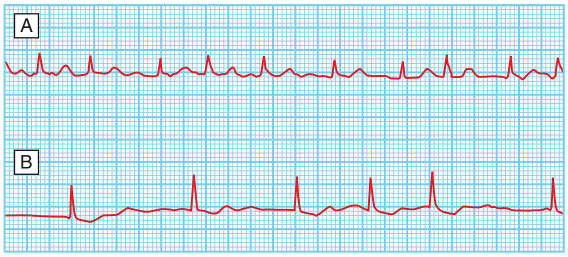

Fig. 16.42 **Two examples of atrial fibrillation.** The QRS complexes are irregular and there are no P waves. **A** There is usually a fast ventricular rate, between 120 and 160/min, at the onset of atrial fibrillation. **B** In chronic atrial fibrillation, the ventricular rate may be much slower, because of medication and AV nodal fatigue.

Atrial fibrillation

Atrial fibrillation (AF) is the most common sustained cardiac arrhythmia, with an overall prevalence of 0.5% in the adult population of the UK. The prevalence rises with age, affecting 1% of those aged 60–64 years, increasing to 9% of those aged over 80 years. It is associated with significant morbidity and increased mortality. This is mainly because of its association with underlying heart disease but also because of its association with systemic embolism and stroke.

Pathogenesis

AF is a complex arrhythmia characterised by both abnormal automatic firing and the presence of multiple interacting re-entry circuits within the atria. Episodes of AF are initiated by rapid bursts of ectopic beats arising from the pulmonary veins or from diseased atrial tissue. It becomes sustained because of re-entrant conduction within the atria or sometimes because of continuous ectopic firing (Fig. 16.41). During episodes of AF, the atria beat rapidly but in an uncoordinated and ineffective manner. The ventricles are activated irregularly at a rate determined by conduction through the AV node. This produces the characteristic 'irregularly irregular' pulse. The ECG (Fig. 16.42) shows normal but irregular QRS complexes; there are no P waves, but the baseline may show irregular fibrillation waves. Commonly, AF is classified as paroxysmal (intermittent episodes that self-terminate within 7 days), persistent (prolonged episodes that can be terminated by electrical or pharmacological cardioversion) or permanent. It can be difficult to identify what type of AF patients have at first presentation, but this usually becomes clearer as time progresses. Unfortunately for many patients, paroxysmal AF becomes

16.23 Common causes of atrial fibrillation

- Coronary artery disease (including acute MI)
- Valvular heart disease, especially rheumatic mitral valve disease
- Hypertension
- Sinoatrial disease
- Hyperthyroidism
- Alcohol
- Cardiomyopathy
- Congenital heart disease
- Chest infection
- Pulmonary embolism
- Pericardial disease
- Idiopathic (lone atrial fibrillation)
- Obesity

16.24 Atrial fibrillation in old age

- **Prevalence**: rises with age, reaching 9% in those over 80 years.
- **Symptoms**: sometimes asymptomatic but often accompanied by diastolic heart failure.
- **Hyperthyroidism**: atrial fibrillation may emerge as the dominant feature of otherwise silent or occult hyperthyroidism.
- **Cardioversion**: followed by high rates (~70% at 1 year) of recurrent atrial fibrillation.
- **Stroke**: atrial fibrillation is an important cause of cerebral embolism, found in 15% of all stroke patients and 2%–8% of those with transient ischaemic attacks (TIAs).
- **Anticoagulation**: although the risk of thromboembolism rises, the hazards of anticoagulation also become greater with age because of increased comorbidity, particularly cognitive impairment and falls.
- **Direct oral anticoagulants**: alternatives to warfarin. No blood monitoring is required, there are fewer drug interactions, and fixed dosing may aid adherence. Renal impairment affects dosing; for example, apixaban dose is reduced from 5 mg twice daily to 2.5 mg twice daily if two or more of the following apply: estimated GFR < 30 mL/min/1.73m^2, age 80 years or greater, weight 60 kg or less.
- **Warfarin**: in those over 75 years, care should be taken to maintain an INR (International Normalised Ratio) below 3.0 because of the increased risk of intracranial haemorrhage.

persistent as the underlying disease process progresses. When AF persists for a period of months, structural remodelling occurs, leading to atrial fibrosis and dilatation that predispose to chronicity of the AF. Early treatment of AF can sometimes prevent the arrhythmia from becoming persistent.

Many forms of heart disease can present with AF (Box 16.23), particularly those that are associated with enlargement or dilatation of the atria. Alcohol excess, obesity, hypertension, coronary artery disease, hyperthyroidism and chronic lung disease are also common causes of AF, although multiple predisposing factors may coexist. About 50% of all patients with paroxysmal AF and 20% of patients with persistent or permanent AF have structurally normal hearts; this is known as 'lone atrial fibrillation'. Aspects of atrial fibrillation that pertain particularly to old age are listed in Box 16.24.

Clinical features

The typical presentation is with palpitation, breathlessness and fatigue. In patients with poor ventricular function or valve disease, AF may precipitate or aggravate cardiac failure because of loss of atrial function and heart rate control. A fall in BP may cause lightheadedness, and chest pain may occur with underlying coronary artery disease, sometimes accompanied by ST segment and T-wave abnormalities on the ECG, and troponin elevation. In older patients, AF may not be associated with a rapid ventricular rate and may be asymptomatic, only to be discovered coincidentally during routine clinical examination or with an ECG. Asymptomatic AF may also present with systemic embolism and is a major cause of stroke in older people.

Investigations

Assessment of patients with newly diagnosed AF should include a full history, physical examination, a 12-lead ECG, echocardiogram and thyroid function tests to exclude thyrotoxicosis. The echocardiogram is used to identify any structural heart disease, particularly mitral valve disease.

Management

Management depends on whether the AF is transient or persistent and whether there is a clear precipitating factor. Modifying risk factors improves patients' chances of maintaining sinus rhythm. Strong evidence exists supporting losing weight if obese, reducing/abstaining from alcohol, and treating hypertension, heart failure and sleep apnoea. When AF complicates an acute illness such as a chest infection or pulmonary embolism, treatment of the underlying disorder will often restore sinus rhythm. When AF does not resolve, the choice lies between rate control or rhythm control. Stroke risk stratification and prevention are the most important issues in managing atrial fibrillation. Management of paroxysmal and persistent AF is discussed below.

Paroxysmal atrial fibrillation

Occasional attacks of AF that are well tolerated do not require treatment. Beta-blockers are normally used as first-line therapy, since they reduce the ectopic firing that normally initiates the arrhythmia and they also help to control the ventricular rate. They are particularly useful for treating coexistent coronary artery disease, hypertension and cardiac failure. Class Ic drugs (see Box 16.30), such as propafenone or flecainide, are also effective at preventing episodes but should not be given to patients with coronary artery disease or left ventricular dysfunction. Flecainide is seldom used alone, since it can precipitate atrial flutter and is usually prescribed with a rate-limiting β-blocker. Class III drugs can also be used; amiodarone is the most effective agent for preventing AF, but side-effects restrict its use to when other measures fail. Dronedarone is an effective alternative but is contraindicated in patients with heart failure or significant left ventricular impairment. Calcium channel blockers, such as diltiazem (200–400 mg daily), are sometimes used to prevent AF but they are not as effective.

Catheter ablation can be considered as an alternative to anti-arrhythmic drug therapy. Ablation targets the left atrial to pulmonary venous connections, preventing ectopic triggering of AF. Ablation prevents AF in approximately 75% of patients, although a repeat procedure is sometimes required. Catheter ablation for AF improves prognosis in some patients with coexisting heart failure with reduced ejection fraction. Ablation is not risk-free, and serious complications include cardiac tamponade, stroke, phrenic nerve injury, and pulmonary vein stenosis. Atrio-oesophageal fistula is an exceptionally rare, but often fatal, complication of left atrial ablation.

Catheter ablation for AF usually involves delivering thermal injury to tissues. Radiofrequency (RF) energy delivers heat to injure tissues and create fibrosis. Oppositely, cryoablation creates tissue fibrosis by freezing to around −40 to −50 degrees Celsius. Novel, non-thermal, ablation techniques are emerging in the form of electroporation (also known as pulsed field ablation) where short bursts of DC energy cause disruption of atrial myocardial cell membranes and fibrosis. As there is no thermal energy involved this reduces the risk of atrio-oesophageal fistula.

Persistent atrial fibrillation

There are two options for treating persistent AF – rate control or rhythm control. With both options prophylaxis against thromboembolism is required on either a short-term or long-term basis.

Rhythm control Restoration of sinus rhythm is appropriate if the arrhythmia causes troublesome symptoms and if there is a treatable underlying cause. Electrical DC cardioversion or pharmacological cardioversion may be used. Cardioversion is initially successful in most patients, but relapse is frequent (25%–50% at 1 month and 70%–90% at 1 year). Attempts to restore and maintain sinus rhythm are most successful if AF has been present for less than 3 months, the patient is young and there is no important structural heart disease.

Immediate cardioversion can be considered if AF has been present for less than 24 hours. In stable patients with no history of structural heart disease, intravenous flecainide (2 mg/kg over 30 mins, maximum dose 150 mg) can be used and will restore sinus rhythm in 75% of patients within 8 hours. In patients with structural or ischaemic heart disease, intravenous amiodarone can be given through a central venous catheter. DC cardioversion may also be used but requires deep sedation or general anaesthesia. If AF has been present for 24 hours or longer, or if there is doubt about its duration, cardioversion should be deferred until the patient has been established on effective oral anticoagulation for a minimum of 3 weeks and any underlying problems, such as hypertension or alcohol excess, have been corrected. Prophylactic treatment with amiodarone can reduce the risk of recurrence. Catheter ablation can help maintain sinus rhythm in persistent AF but is a less successful treatment than for paroxysmal AF.

Rate control If sinus rhythm cannot be restored, treatment should be directed at controlling the heart rate. Beta-blockers, rate-limiting calcium antagonists, such as verapamil or diltiazem (see Box 16.29 and Fig. 16.49), and digoxin all reduce the ventricular rate by slowing AV conduction. This alone may produce a striking improvement in cardiac function, particularly in patients with mitral stenosis. Beta-blockers and rate-limiting calcium antagonists are more effective than digoxin at controlling the heart rate during exercise and have additional benefits in patients with hypertension or structural heart disease. Combination therapy with digoxin and a β-blocker can help with rate control but calcium channel antagonists should not be used with β-blockers because of the risk of bradycardia.

In exceptional cases, poorly controlled and symptomatic AF can be treated by implanting a permanent pacemaker and then deliberately inducing complete AV nodal block with catheter ablation. This is known as the 'pace and ablate' strategy.

Anticoagulation for prevention of thromboembolism and stroke Loss of atrial contraction and left atrial dilatation cause stasis of blood in the LA and may lead to thrombus formation in the left atrial appendage. This predisposes patients to stroke and systemic embolism. Patients undergoing cardioversion for AF of greater than 24 hours' duration require temporary anticoagulation to reduce these risks. Direct oral anticoagulants or warfarin may be used. Anticoagulation should be started for at least 3 weeks before cardioversion and should be maintained for at least 4 weeks following successful cardioversion. Long-term anticoagulation should be considered (depending on CHA$_2$DS$_2$-VA score, Box 16.25) irrespective of whether cardioversion has been successful.

When considering anticoagulation, the risk of stroke is balanced against the risk of bleeding with anticoagulation. Patients with AF secondary to mitral stenosis should always be anticoagulated (with a vitamin K antagonist) because the thrombotic risk is so high. In other patients, clinical scoring systems can be used to assess the risk of stroke and bleeding.

Stroke risk is usually assessed by the CHA$_2$DS$_2$-VA score (Box 16.25), and the HAS-BLED score can be used to identify patients at higher bleeding risk (Box 16.26). Patients at higher bleeding risk should have any risk factors optimised and require more careful monitoring if anticoagulated. In patients with paroxysmal AF, stroke risk is similar to that in patients with persistent AF when adjusted for CHA$_2$DS$_2$-VA score. The risk of embolism is only weakly related to the frequency and duration of AF episodes, so stroke prevention guidelines do not distinguish between those with paroxysmal, persistent and permanent AF.

16.25 CHA$_2$DS$_2$-VA stroke risk scoring system for non-valvular atrial fibrillation

	Parameter	Score
C	Congestive heart failure	1 point
H	Hypertension history	1 point
A$_2$	Age ≥ 75 years	2 points
D	Diabetes mellitus	1 point
S$_2$	Previous stroke or transient ischaemic attack (TIA)	2 points
V	Vascular disease	1 point
A	Age 65–74 years	1 point
	Maximum total score	8 points

Annual stroke risk
0 points = 0% (no prophylaxis required)
1 point = 1.3% (consider oral anticoagulant)
2+ points = > 2.2% (oral anticoagulant recommended)

From Van Gelder IC, Rienstra M, Bunting KV, et al. 2024 ESC Guidelines for the management of atrial fibrillation developed in collaboration with the European Association for Cardio-Thoracic Surgery (EACTS). Eur Heart J 2024;45(36):3314–3414.

16.26 HAS-BLED bleeding risk scoring system for patients receiving oral anticoagulation

	Parameter	Score
H	Hypertension; current systolic blood pressure > 160 mmHg	1 point
A	Abnormal liver function (cirrhosis OR bilirubin > twice upper limit of reference range or transaminases > three times upper limit of reference range)	1 point
	Abnormal renal function (creatinine > 200 µmol/L (2.26 mg/dL))	1 point
S	Stroke history	1 point
B	Bleeding: prior major event	1 point
L	Labile INR on warfarin	1 point
E	Elderly: age ≥ 65 years	1 point
D	Drugs:	
	Use of antiplatelet drug	1 point
	High alcohol consumption	1 point
Maximum total score		9 points

HAS-BLED score of ≥ 3 points requires close patient monitoring.

Several agents can be used to reduce stroke risk in AF. The factor Xa inhibitors rivaroxaban, apixaban and edoxaban, and the direct thrombin inhibitor dabigatran (collectively referred to as direct-acting oral anticoagulants, or DOACs) have largely replaced warfarin for stroke prevention in AF. These drugs are described in more detail in Chapter 24. They are at least as effective at preventing thrombotic stroke and are generally associated with a lower risk of major bleeding. Other advantages include the lack of requirement for monitoring and the fact that they have fewer drug and food interactions. Anticoagulation should be considered in patients with AF and CHA$_2$DS$_2$-VA score of 1, and is recommended in patients with a risk score of 2 or more. Stroke risk is reduced with anticoagulation by around two-thirds, with an annual major bleeding risk of around 1%. Prothrombin complex concentrates and other reversal agents can be used if patients of DOACs have a life-threatening bleed. These include idarucizumab, which binds to dabigatran, and andexanet alfa, which binds to apixaban and rivaroxaban.

Warfarin can be used, adjusted to a target INR (International Normalised Ratio) of 2.0–3.0. If bleeding does occur in warfarin-treated patients, anticoagulation can be reversed by administering vitamin K or clotting factors. Aspirin should not be used since it has little or no effect on embolic stroke and is associated with significant bleeding risk.

Supraventricular tachycardia

The term supraventricular tachycardia (SVT) describes a group of regular tachycardias that have a similar appearance on ECG. These are usually narrow-complex tachycardias and are characterised by a re-entry circuit or automatic focus involving the atria. The three principal types are atrioventricular nodal re-entrant tachycardia (AVNRT), atrioventricular re-entrant tachycardia (AVRT) and atrial tachycardia. The term SVT is not strictly accurate as, in many cases, the ventricles also form part of the re-entry circuit.

Atrioventricular nodal re-entrant tachycardia

Atrioventricular nodal re-entrant tachycardia (AVNRT) is a type of SVT caused by re-entry in a circuit involving the AV node and its two right atrial input pathways: a superior 'fast' pathway and an inferior 'slow' pathway (see Fig. 16.44A). This produces a regular tachycardia with a rate of 120–240/min. It tends to occur in the absence of structural heart disease and episodes may last from a few seconds to many hours. The patient is usually aware of a rapid, very forceful, regular heart beat and may experience chest discomfort, lightheadedness or breathlessness. Polyuria, mainly due to the release of ANP, is sometimes a feature. The ECG (Fig. 16.43) usually shows a tachycardia with normal QRS complexes, or a notch in the terminal portion of the QRS in lead V1 (a pseudo R′) but occasionally there may be rate-dependent bundle branch block.

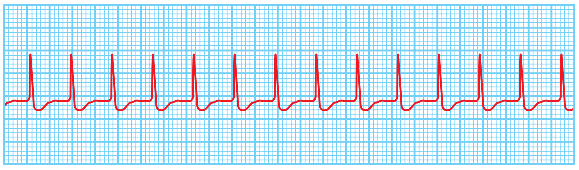

Fig. 16.43 Supraventricular tachycardia. The rate is 180/min and the QRS complexes are normal.

Management

Treatment is not always necessary. However, an acute episode may be terminated by carotid sinus pressure or by the Valsalva manoeuvre. Adenosine (3–12 mg rapidly IV in incremental doses until tachycardia stops) or verapamil (5 mg IV over 1 min) will restore sinus rhythm in most cases. Intravenous β-blocker or flecainide can also be used. In rare cases, when there is severe haemodynamic compromise, the tachycardia should be terminated by DC cardioversion.

In patients with recurrent SVT, catheter ablation is the most effective therapy and will permanently prevent SVT in around 95% of cases, with a very small risk of complication. Alternatively, prophylaxis with oral β-blocker, verapamil or flecainide may be used but commits predominantly young patients to long-term drug therapy and can create difficulty in female patients, as these drugs should be avoided during pregnancy where possible.

Atrioventricular re-entrant tachycardia

In this condition there is an abnormal band of conducting tissue that connects the atria and ventricles. This so-called accessory pathway comprises rapidly conducting fibres that resemble Purkinje tissue, in that they conduct very rapidly and are rich in sodium channels. In about 50% of cases, this pathway conducts only in the retrograde direction (from ventricles to atria) and thus does not alter the appearance of the ECG in sinus rhythm. This is known as a 'concealed' accessory pathway. In the rest, the pathway also conducts in an antegrade direction (from atria to ventricles), so AV conduction in sinus rhythm is mediated via both the AV node and the accessory pathway, distorting the QRS complex. Premature ventricular activation via the pathway shortens the PR interval and produces a 'slurred' initial deflection of the QRS complex, called a delta wave (Fig. 16.44B). This is known as a 'manifest' accessory pathway. As the

Fig. 16.44 Atrioventricular nodal re-entrant tachycardia (AVNRT) and Wolff–Parkinson–White (WPW) syndrome. **A** Atrioventricular (AV) nodal re-entrant tachycardia. The mechanism of AVNRT occurs via two right atrial AV nodal input pathways: the slow (S) and fast (F) pathways. Antegrade conduction occurs via the slow pathway; the wavefront enters the AV node and passes into the ventricles, at the same time re-entering the atria via the fast pathway. In WPW syndrome, there is a strip of accessory conducting tissue that allows electricity to bypass the AV node and spread from the atria to the ventricles rapidly and without delay. When the ventricles are depolarised through the AV node the ECG is normal, but when the ventricles are depolarised through the accessory conducting tissue the ECG shows a very short PR interval and a broad QRS complex. **B** Sinus rhythm. In sinus rhythm, the ventricles are depolarised through (1) the AV node and (2) the accessory pathway, producing an ECG with a short PR interval and broadened QRS complexes; the characteristic slurring of the upstroke of the QRS complex is known as a delta wave. The degree of pre-excitation (the proportion of activation passing down the accessory pathway) and therefore the ECG appearances may vary a lot, and at times the ECG can look normal. **C** Orthodromic tachycardia. This is the most common form of tachycardia in WPW syndrome. The re-entry circuit passes antegradely through the AV node and retrogradely through the accessory pathway. The ventricles are therefore depolarised in the normal way, producing a narrow-complex tachycardia that is indistinguishable from other forms of supraventricular tachycardia. **D** Atrial fibrillation. In this rhythm, the ventricles are largely depolarised through the accessory pathway, producing an irregular broad-complex tachycardia that is often more rapid than the example shown.

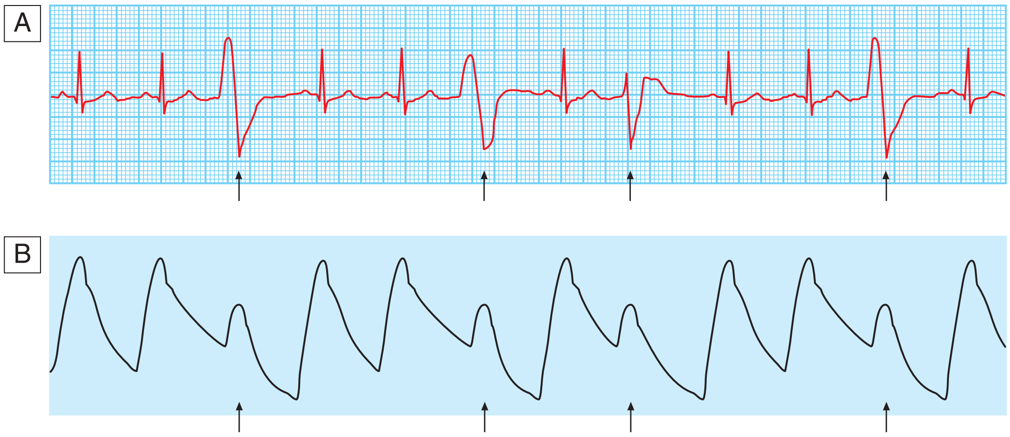

Fig. 16.45 **Ventricular ectopic beats.** **A** There are broad, bizarre QRS complexes (arrows) with no preceding P wave in between normal sinus beats. Their configuration varies, so these are multifocal ectopics. **B** A simultaneous arterial pressure trace is shown. The ectopic beats result in a weaker pulse (arrows), which may be perceived as a 'dropped beat'.

AV node and accessory pathway have different conduction speeds and refractory periods, a re-entry circuit can develop, causing tachycardia (Fig. 16.44C); when associated with symptoms, the condition is known as Wolff–Parkinson–White (WPW) syndrome. The ECG during this tachycardia can be indistinguishable from that of AVNRT (Fig. 16.44A).

Management

Carotid sinus pressure or intravenous adenosine can terminate the tachycardia. If AF occurs, it can produce a dangerously rapid ventricular rate if the patient has an accessory pathway capable of rapid antegrade conduction. This is because the accessory pathway lacks the rate-limiting properties of the AV node (Fig. 16.44D). This is known as pre-excited atrial fibrillation and may cause collapse, syncope and even death. It should be treated as an emergency, usually with DC cardioversion.

Catheter ablation is first-line treatment in symptomatic patients and is nearly always curative. Alternatively, prophylactic anti-arrhythmic drugs, such as flecainide or propafenone (see Box 16.30) can be used to slow conduction in, and prolong the refractory period of, the accessory pathway. Long-term drug therapy is not the preferred treatment for most patients and amiodarone should not be used due to its side-effect profile; ablation is safer and more effective. Digoxin and verapamil shorten the refractory period of the accessory pathway and should not be used.

Ventricular premature beats

Ventricular premature beats (VPBs) are frequently found in healthy people and their prevalence increases with age. Ectopic beats in patients with otherwise normal hearts are more prominent at rest and disappear with exercise. Sometimes VPBs are a manifestation of subclinical coronary artery disease or cardiomyopathy but also may occur in patients with established heart disease following an MI. Most patients with VPBs are asymptomatic but some present with an irregular heart beat, missed beats or abnormally strong beats, due to increased cardiac output of the post-ectopic sinus beat. Patients can also present with fatigue and light-headedness. On examination the pulse is irregular, with weak or missed beats because the stroke volume is low when left ventricular contraction occurs before filling is complete (Fig. 16.45). The ECG shows broad and bizarre QRS complexes because the ventricles are activated sequentially rather than simultaneously. The complexes may be unifocal (identical beats arising from a single ectopic focus) or multifocal (varying morphology with multiple foci, see Fig. 16.46). 'Couplet' and 'triplet' are the terms used to describe two or three successive ectopic beats. A run of alternating sinus and ventricular ectopic beats is known as ventricular 'bigeminy'. The significance depends on the presence or absence of underlying heart disease.

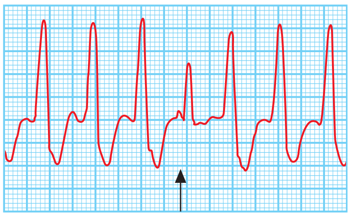

Fig. 16.46 **Ventricular tachycardia: fusion beat.** In ventricular tachycardia, there is independent atrial and ventricular activity. Occasionally, a P wave is conducted to the ventricles through the AV node, producing a normal sinus beat in the middle of the tachycardia (a capture beat); more commonly, however, the conducted impulse fuses with an impulse from the tachycardia (a fusion beat, arrow). This can occur only when there is atrioventricular dissociation and is therefore diagnostic of ventricular tachycardia.

Management

Treatment may not be necessary, unless the patient is highly symptomatic, in which case β-blockers or, in some situations, catheter ablation can be used. There is no evidence that anti-arrhythmic therapy improves prognosis but the discovery of very frequent VPBs in a patient not known to have heart disease should prompt further investigations to screen for structural heart disease and ischaemic heart disease. It is common for VPBs to occur during an acute MI. Persistent, frequent VPBs (over 10/hr) in patients who have survived the acute phase of MI indicate a poorer long-term outcome. In this situation, anti-arrhythmic drugs do not improve and may even worsen prognosis. The exception is β-blockers, which should be prescribed for other reasons following MI. Similarly, heart failure of any cause is associated with VPBs. While they indicate an adverse prognosis, this is not improved by anti-arrhythmic drugs. Effective treatment of the heart failure may suppress the ectopic beats.

Ventricular tachycardia

Ventricular tachycardia (VT) occurs most commonly in the settings of acute MI, chronic coronary artery disease and cardiomyopathy. It is associated with extensive ventricular disease, impaired left ventricular function and ventricular aneurysm. In these settings, VT may cause haemodynamic compromise or degenerate into ventricular fibrillation (see Fig. 16.19). VT is most often caused by re-entry within scarred ventricular tissue, and less often by abnormal automaticity or triggered activity in ischaemic tissue. Patients may experience palpitation, dyspnoea, lightheadedness and syncope. The ECG shows tachycardia and broad, abnormal QRS complexes with a rate of more than 120/min (Fig. 16.46).

It may be difficult to distinguish VT from SVT with bundle branch block or pre-excitation (WPW syndrome) on ECG but features in favour of VT are listed in Box 16.27. A 12-lead ECG (Fig. 16.47) or electrophysiology study may help establish the diagnosis. When there is doubt, it is safer to manage the problem as VT.

Patients recovering from MI sometimes have periods of idioventricular rhythm ('slow' VT) at a rate only slightly above the preceding sinus rate and below 120/min. These episodes often reflect reperfusion of the infarct territory and may be a good sign. They are usually self-limiting and asymptomatic, and do not require treatment. Other forms of sustained VT require treatment, often as an emergency.

Occasionally, VT occurs in patients with otherwise healthy hearts ('normal heart VT'), usually because of abnormal automaticity in the right ventricular outflow tract or one of the fascicles of the left bundle branch.

16.27 Features more in keeping with ventricular tachycardia

- History of myocardial infarction
- Atrioventricular dissociation (pathognomonic)
- Capture/fusion beats (pathognomonic; see Fig. 16.46)
- Extreme left or right axis deviation
- Very broad QRS complexes (> 140 msecs)
- No response to carotid sinus massage or intravenous adenosine

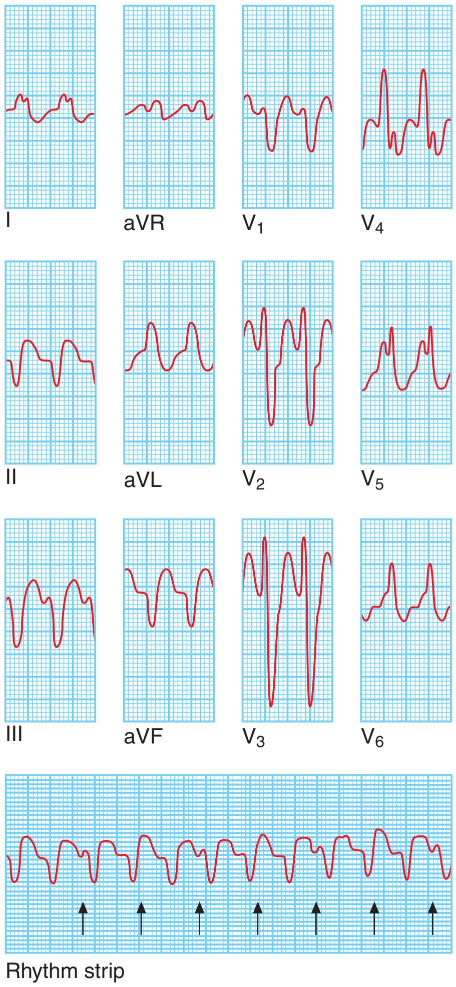

Fig. 16.47 Ventricular tachycardia: 12-lead ECG. There are typically very broad QRS complexes and marked left axis deviation. There is also atrioventricular dissociation; some P waves are visible, and others are buried in the QRS complexes (arrows).

Management

Prompt action to restore sinus rhythm is required and should usually be followed by prophylactic therapy. Synchronised DC cardioversion is the treatment of choice if systolic BP is less than 90 mmHg or if the arrhythmia is poorly tolerated. If the arrhythmia is well tolerated, intravenous amiodarone may be given as a bolus, followed by a continuous infusion (see Box 16.30). Intravenous lidocaine can also be used but may depress left ventricular function, causing hypotension or acute heart failure. Hypokalaemia, hypomagnesaemia, acidosis and hypoxia should be corrected if present.

Beta-blockers are effective at preventing VT by reducing ventricular automaticity. Amiodarone can be added if additional control is needed. Class Ic anti-arrhythmic drugs should not be used for prevention of VT in patients with coronary artery disease or heart failure because they depress myocardial function and can increase the likelihood of a dangerous arrhythmia. In patients with poor left ventricular function or where VT is associated with haemodynamic compromise, the use of an implantable cardiac defibrillator is recommended. In resistant cases of focal or scar-mediated VT, catheter ablation can be used to interrupt the arrhythmia focus or circuit. The treatment of choice for VT occurring in a normal heart is catheter ablation, which often can be curative.

Torsades de pointes

This form of polymorphic VT is a complication of prolonged ventricular repolarisation (prolonged QT interval). The ECG shows rapid irregular complexes that seem to twist around the baseline as the mean QRS axis changes (Fig. 16.48). The arrhythmia is usually non-sustained and repetitive but may degenerate into ventricular fibrillation. During periods of sinus rhythm, the ECG will usually show a prolonged QT interval (> 0.44 sec in men, > 0.46 sec in women when corrected to a heart rate of 60/min).

Some of the common causes are listed in Box 16.28. The arrhythmia is more common in women and is often triggered by a combination of factors, such as administration of QT-prolonging medications and hypokalaemia. The congenital long QT syndromes are a family of genetic disorders that are characterised by mutations in genes that code for cardiac potassium or sodium channels. Long QT syndrome subtypes have different triggers, which are important when counselling patients. Adrenergic stimulation through vigorous exercise is a common trigger in long QT type 1, and a sudden noise may trigger arrhythmias in long QT type 2. Arrhythmias are more common during sleep in type 3.

Management

Intravenous magnesium (8 mmol over 15 mins, then 72 mmol over 24 hrs) should be given in all cases. If this is ineffective, atrial pacing should be tried. This often suppresses the arrhythmia through rate-dependent shortening of the QT interval. Intravenous isoprenaline is a reasonable alternative to pacing but should be avoided in patients with the congenital long QT syndromes. Once initial control has been achieved, efforts should be made to identify and treat the underlying cause or stop medications that predispose to the arrhythmia. If the underlying cause cannot be corrected or the arrhythmia is the result of an inherited syndrome, then long-term pharmacological therapy may be necessary. Beta-blockers are effective at preventing syncope in patients with congenital long QT syndrome. Some patients, particularly those with extreme QT interval prolongation (> 500 msecs), history of syncope, or certain high-risk genotypes, should be considered for an implantable defibrillator. Left stellate ganglion block may be of value in patients with resistant arrhythmias.

Brugada syndrome is a related genetic disorder that may present with polymorphic VT or sudden death. Mutations are often found in the *SCN5A* gene which encodes a sodium channel expressed in cardiac myocytes. It is characterised by an abnormal ECG (right bundle branch block and ST elevation in V_1 and V_2 but not usually prolongation of the QT interval). An implantable defibrillator can be considered in patients with

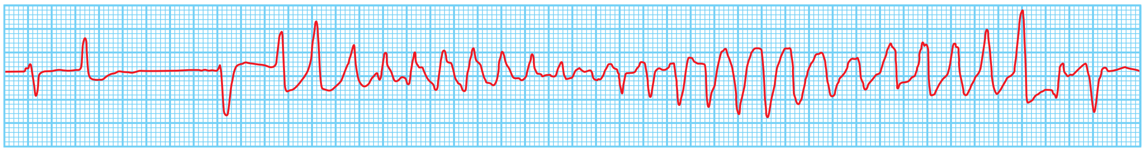

Fig. 16.48 **Torsades de pointes.** A bradycardia with a long QT interval is followed by polymorphic ventricular tachycardia that is triggered by an R on T ectopic.

16.28 Causes of long QT interval and torsades de pointes

Bradycardia

- Bradycardia potentiates other factors that cause torsades de pointes

Electrolyte disturbance

- Hypokalaemia
- Hypomagnesaemia
- Hypocalcaemia

Drugs*

- Disopyramide, flecainide and other class Ia, Ic anti-arrhythmic drugs (Box 16.29 and Fig. 16.49)
- Sotalol, amiodarone and other class III anti-arrhythmic drugs
- Amitriptyline and other tricyclic antidepressants
- Chlorpromazine and other phenothiazines
- Erythromycin and other macrolides
- Hydroxychloroquine and chloroquine

Congenital syndromes

- Long QT1: gene affected *KCNQ1*: K^+ channel, 30%–35%
- Long QT2: gene affected *HERG*: K^+ channel, 25%–30%
- Long QT3: gene affected *SCN5A*: Na^+ channel, 5%–10%
- Long QT4–12: rare; various genes implicated

*Many other drugs that are not shown can be associated with prolongation of the QT interval. See www.crediblemeds.org for a complete list.

a typical type I ECG pattern and a history of syncope or documented ventricular arrhythmia.

Principles of management of cardiac arrhythmias

Cardiac arrhythmias can be managed with anti-arrhythmic drug therapy, cardiac implantable electronic devices (CIEDs), or catheter ablation.

Anti-arrhythmic drugs

Traditionally, the Vaughan Williams system has been used to categorise anti-arrhythmic drugs based on their effects on the action potential. Increased understanding of the mechanisms of action has allowed further subclassification, based on the cardiac ion channels and receptors on which they act see (Box 16.29 and Fig. 16.49). The individual agents, dosages and most common side-effects are summarised in Box 16.30 and the general principles of use are summarised in Box 16.31.

Class I drugs

Class I drugs act principally by suppressing excitability and slowing conduction in atrial or ventricular muscle. They block sodium channels, of which there are several types in cardiac tissue. These drugs should generally be avoided in patients with heart failure because they depress myocardial function, and class Ia and Ic drugs are often pro-arrhythmic.

16.29 Classification of anti-arrhythmic drugs by effect on the intracellular action potential*

Class I: membrane-stabilising agents (sodium channel blockers)

(a) Block Na^+ channel and prolong action potential
- Quinidine, disopyramide

(b) Block Na^+ channel and shorten action potential
- Lidocaine, mexiletine

(c) Block Na^+ channel with no effect on action potential
- Flecainide, propafenone

Class II: β-adrenoceptor antagonists (β-blockers)

- Atenolol, bisoprolol, metoprolol

Class III: drugs whose main effect is to prolong the action potential

- Amiodarone, dronedarone, sotalol

Class IV: slow calcium channel blockers

- Verapamil, diltiazem

*Some drugs, such as digoxin, ivabradine and adenosine, have no place in this classification, while others, such as amiodarone, have properties in more than one class.

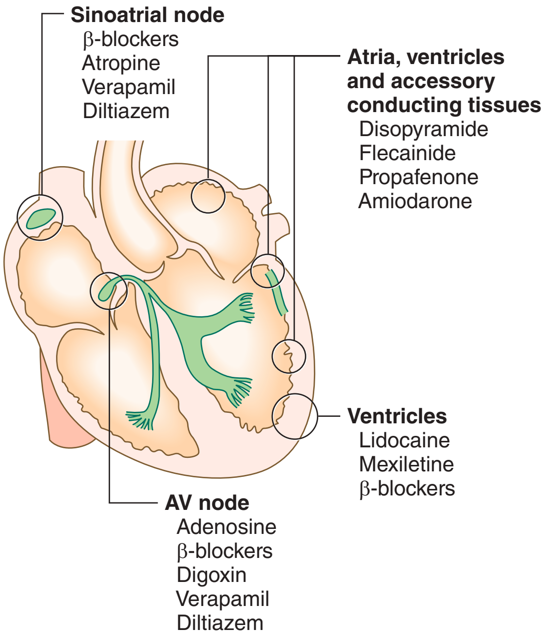

Fig. 16.49 **Classification of anti-arrhythmic drugs by site of action.** (AV = atrioventricular)

Class Ia drugs

These prolong cardiac action potential duration and increase the tissue refractory period. They are used to prevent both atrial and ventricular arrhythmias.

16.30 Uses, dosage and side-effects of anti-arrhythmic drugs

Drug	Main uses	Route	Dosage (adult)	Important side-effects
Class I				
Disopyramide	Prevention and treatment of atrial and ventricular tachyarrhythmias	IV	2 mg/kg at 30 mg/min, then 0.4 mg/kg/hr (max 800 mg/day)	Myocardial depression, hypotension, dry mouth, urinary retention
Lidocaine	Treatment and short-term prevention of VT and VF	IV	Bolus 50–100 mg, 4 mg/min for 30 mins, then 2 mg/min for 2 hrs, then 1 mg/min for 24 hrs	Myocardial depression, delirium, convulsions
Mexiletine	Prevention and treatment of ventricular tachyarrhythmias	IV	Loading dose: 100–250 mg at 25 mg/min, then 250 mg in 1 hr, then 250 mg in 2 hrs Maintenance therapy: 0.5 mg/min	Myocardial depression, gastrointestinal irritation, delirium, dizziness, tremor, nystagmus, ataxia
		Oral	167–500 mg daily	
Flecainide	Prevention and treatment of atrial and ventricular tachyarrhythmias	IV	2 mg/kg over 10 mins, then if required 1.5 mg/kg/hr for 1 hr, then 0.1 mg/kg/hr	Myocardial depression, dizziness
		Oral	50–150 mg twice daily	
Propafenone	Prevention and treatment of atrial and ventricular tachyarrhythmias	Oral	150 mg 3 times daily for 1 week, then 300 mg twice daily	Myocardial depression, dizziness
Class II				
Atenolol	Treatment and prevention of SVT and AF, prevention of VEs and exercise-induced VF	IV	2.5 mg at 1 mg/min, repeated at 5-min intervals (max 10 mg)	Myocardial depression, bradycardia, bronchospasm, fatigue, depression, nightmares, cold peripheries
		Oral	25–100 mg daily	
Bisoprolol		Oral	2.5–10 mg daily	
Metoprolol		IV	5 mg over 2 mins to a maximum of 15 mg	
Class III				
Amiodarone	Serious or resistant atrial and ventricular tachyarrhythmias	IV	5 mg/kg over 20–120 mins, then up to 15 mg/kg/24 hrs	Photosensitivity skin discoloration, corneal deposits, thyroid dysfunction, alveolitis, nausea and vomiting, hepatotoxicity, peripheral neuropathy, torsades de pointes; potentiates digoxin and warfarin
		Oral	Initially 600–1200 mg/day, then 100–400 mg daily	
Dronedarone	Paroxysmal atrial fibrillation	Oral	400 mg twice daily	Renal and hepatic dysfunction requiring regular blood monitoring
Sotalol*	AF, rarely ventricular tachyarrhythmias	IV	10–20 mg slowly	Can cause torsades de pointes
		Oral	40–160 mg twice daily	
Class IV				
Verapamil	Treatment of SVT, control of AF	IV	5–10 mg over 30 secs	Myocardial depression, hypotension, bradycardia, constipation
		Oral	40–120 mg 3 times daily or 240 mg SR daily	
Other				
Atropine	Treatment of bradycardia and/or hypotension due to vagal over-activity (see Box 16.32)	IV	0.6–3 mg	Dry mouth, thirst, blurred vision, atrial and ventricular extrasystoles
Adenosine	Treatment of SVT, aid to diagnosis in unidentified tachycardia	IV	3 mg over 2 secs, followed if necessary by 6 mg, then 12 mg at intervals of 1–2 mins	Flushing, dyspnoea, chest pain Avoid in asthma
Digoxin	Rate control of AF	IV	Loading dose: 0.5–1 mg (total), 0.5 mg over 30 mins, then 0.25–0.5 mg after 4–6 hrs	Gastrointestinal disturbance, xanthopsia, arrhythmias
		Oral	0.5 mg repeated after 6 hrs, then 0.0625–0.25 mg daily	

*Sotalol also has class II activity as a β-blocker.
(AF = atrial fibrillation; IV = intravenous; SR = sustained-release formulation; SVT = supraventricular tachycardia; VE = ventricular ectopic; VF = ventricular fibrillation; VT = ventricular tachycardia)

Disopyramide

This is an effective drug but causes anticholinergic side-effects, such as urinary retention, and can precipitate glaucoma. It can depress myocardial function and should be avoided in cardiac failure.

Quinidine

This drug is effective at preventing AF and is occasionally used in Brugada syndrome. It is strongly pro-arrhythmic and can cause gastro-intestinal upset.

Class Ib drugs

These shorten the action potential and tissue refractory period. They act on channels found predominantly in ventricular myocardium and so are used to treat or prevent VT and VF.

Lidocaine

This must be given intravenously and has a very short plasma half-life.

Mexiletine

This can be given intravenously or orally but has many side-effects.

i

16.31 Anti-arrhythmic drugs: principles of use

Anti-arrhythmic drugs are potentially toxic and should be used carefully according to the following principles:

- Many arrhythmias are benign and do not require specific treatment
- Precipitating or causal factors should be corrected if possible:
  - Alcohol excess
  - Myocardial ischaemia
  - Hyperthyroidism
  - Acidosis
  - Hypokalaemia
  - Hypomagnesaemia
- If drug therapy is required, it is best to use as few drugs as possible
- In difficult cases, programmed electrical stimulation (electrophysiological study) may help to identify the optimum therapy
- When managing life-threatening arrhythmias, it is essential to ensure that prophylactic treatment is effective. Ambulatory monitoring and exercise testing may be of value
- Patients on long-term anti-arrhythmic drugs should be reviewed regularly and attempts made to withdraw therapy if the factors that precipitated the arrhythmias are no longer operative
- For patients with recurrent supraventricular tachycardia or atrial flutter, radiofrequency ablation is the treatment of choice

Class Ic drugs

These affect the slope of the action potential without altering its duration or refractory period. They are used mainly for prophylaxis of AF but are effective in prophylaxis and treatment of supraventricular or ventricular arrhythmias. They are useful for WPW syndrome because they block conduction in accessory pathways. They should not be used in patients with previous MI because they increase the risk of arrhythmia in this setting.

Flecainide

This is effective for prevention of AF, and an intravenous infusion may be used for pharmacological cardioversion of AF of less than 24 hours' duration. Since flecainide can cause slow atrial flutter with a paradoxically rapid ventricular rate, it should be prescribed along with an AV node-blocking drug such as a β-blocker to control the ventricular rate.

Propafenone

This also has some β-blocker (class II) properties. Important interactions with digoxin, warfarin and cimetidine have been described.

Class II drugs

This group comprises the β-adrenoceptor antagonists (β-blockers). These agents reduce the rate of SA node depolarisation and cause relative block in the AV node, making them useful for rate control in atrial flutter and AF. They can be used to prevent VT and SVT. They reduce myocardial excitability and the risk of arrhythmic death in patients with coronary artery disease and heart failure.

Non-selective β-blockers

These act on both β_1 and β_2 receptors. Beta$_2$-blockade causes side-effects, such as bronchospasm and peripheral vasoconstriction. Propranolol is non-selective and is subject to extensive first-pass metabolism in the liver. The effective oral dose is therefore unpredictable and must be titrated after treatment is started with a small dose. Other non-selective drugs include nadolol and carvedilol.

Cardioselective β-blockers

These act mainly on myocardial β_1 receptors and are relatively well tolerated. Bisoprolol and metoprolol are examples of cardioselective β-blockers.

Sotalol

This is a racemic mixture of two isomers with non-selective β-blocker (mainly l-sotalol) and class III (mainly d-sotalol) activity. It may cause torsades de pointes.

Class III drugs

Class III drugs act by prolonging the plateau phase of the action potential, thus lengthening the refractory period. These drugs are very effective at preventing atrial and ventricular tachyarrhythmias. They cause QT interval prolongation and can predispose to torsades de pointes and VT, especially in patients with other predisposing risk factors (see Box 16.28). Disopyramide and sotalol have some class III activity but the main drug in this class is amiodarone, as discussed below.

Amiodarone

While amiodarone is primarily considered a class III drug, it also has class I, II and IV activity. It is probably the most effective drug currently available for controlling paroxysmal AF. It is also used to prevent episodes of recurrent VT, particularly in patients with poor left ventricular function or those with implantable defibrillators (to prevent unnecessary DC shocks). Amiodarone has a very long tissue half-life (25–110 days). An intravenous or oral loading regime is often used to achieve therapeutic tissue concentrations. The drug's effects may last for weeks or months after treatment has been stopped. Side-effects are common (up to one-third of patients), numerous and potentially serious. Drug interactions are also common (see Box 16.30).

Dronedarone

Dronedarone is related to amiodarone but has a short tissue half-life and fewer side-effects. It has recently been shown to be effective at preventing episodes of atrial flutter and AF. It is contraindicated in patients with permanent AF, or if there is heart failure or left ventricular impairment, because it increases mortality. Regular liver and renal function test monitoring is required.

Class IV drugs

These block the 'slow calcium channel', which is important for impulse generation and conduction in atrial and nodal tissue, although it is also present in ventricular muscle. Their main indications are prevention of SVT (by blocking the AV node) and rate control in patients with AF. They depress cardiac contractility and should be avoided in left ventricular systolic dysfunction.

Verapamil

This is the most widely used drug in this class. Intravenous verapamil may cause profound bradycardia or hypotension and should not be used in conjunction with β-blockers.

Diltiazem

This has similar properties to verapamil.

Other anti-arrhythmic drugs

Atropine sulphate

Atropine is a muscarinic receptor antagonist that increases the sinus rate and SA and AV conduction. It is the treatment of choice for severe bradycardia or hypotension due to vagal over-activity. It is used for initial management of symptomatic bradyarrhythmias complicating inferior MI, and in cardiac arrest due to asystole. The usual dose is 0.6 mg IV, repeated if necessary to a maximum of 3 mg. Repeat dosing may be necessary because the drug disappears rapidly from the circulation after parenteral administration. Side-effects are listed in Box 16.30.

16.32 Response to intravenous adenosine

Arrhythmia	Response
Supraventricular tachycardia	Termination
Atrial fibrillation, atrial flutter, atrial tachycardia	Transient atrioventricular block
Ventricular tachycardia	No effect

16.33 Digoxin toxicity

Extracardiac manifestations

- Anorexia, nausea, vomiting
- Diarrhoea
- Altered colour vision (xanthopsia)

Cardiac manifestations

- Bradycardia
- Multiple ventricular ectopics
- Ventricular bigeminy (alternate ventricular ectopics)
- Atrial tachycardia (with variable block)
- Ventricular tachycardia
- Ventricular fibrillation

Adenosine

This works by binding to A1 receptors in conducting tissue, producing a transient AV block lasting a few seconds. It is used to terminate SVTs when the AV node is part of the re-entry circuit, or to help establish the diagnosis in difficult arrhythmias, such as atrial flutter with 2:1 AV block (see Fig. 16.40) or broad-complex tachycardia (see Boxes 16.30 and 16.32). Adenosine is given as an intravenous bolus, initially 3 mg over 2 seconds (see Box 16.30) but escalating doses may be required if no response. Patients should be warned to expect short-lived and sometimes distressing flushing, breathlessness and chest pain. Adenosine can cause bronchospasm and should be avoided in patients with asthma; its effects are greatly potentiated by dipyridamole and inhibited by theophylline and other xanthines.

Digoxin

Digoxin is a glycoside purified from the European foxglove, *Digitalis lanata*, which slows conduction and prolongs the refractory period in the AV node. This effect helps to control the ventricular rate in AF. Digoxin shortens refractory periods and enhances excitability and conduction in other parts of the heart, including accessory pathways. It may therefore increase atrial and ventricular ectopic activity and can lead to more complex atrial and ventricular tachyarrhythmias. Digoxin is largely excreted by the kidneys, and the maintenance dose (see Box 16.30) should be reduced in children, older people and those with renal impairment. It is widely distributed and has a long tissue half-life (36 hours), so that effects may persist for several days. Measurement of plasma digoxin concentration can help identify digoxin toxicity or under-treatment (Box 16.33).

Non-pharmacological treatments

Electrical cardioversion and defibrillation

Electrical cardioversion, also known as direct current (DC) cardioversion, is useful for terminating arrhythmias. The shock depolarises the myocardium, interrupts the arrhythmia and produces a brief period of asystole, followed by the resumption of sinus rhythm. Cardioversion is usually carried out as an elective procedure under general anaesthesia. The shock is delivered immediately after the R wave because, if it is applied during ventricular repolarisation (on the T wave), it may provoke VF. A 100–150 Joule shock is normally used.

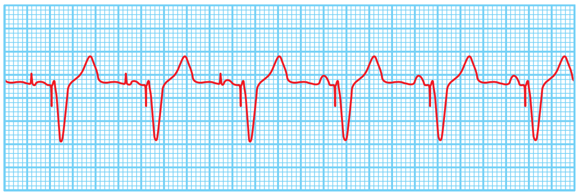

Fig. 16.50 Dual-chamber pacing. The first three beats show atrial and ventricular pacing with narrow pacing spikes in front of each P wave and QRS complex. The last four beats show spontaneous P waves with a different morphology and no pacing spike; the pacemaker senses or tracks these P waves and maintains atrioventricular synchrony by pacing the ventricle after an appropriate interval.

Defibrillators are primarily used in the management of cardiac arrest due to VF and deliver a high-energy unsynchronised shock, since the precise timing of the discharge is not important in this situation. A biphasic shock is used during which the shock polarity is reversed mid-shock. This reduces the total shock energy required to depolarise the heart. In VF and other emergencies, the energy of the first and second shocks should be 150 Joules and thereafter up to 200 Joules; there is no need for an anaesthetic, as the patient is unconscious.

Temporary pacemakers

Temporary pacing involves delivery of an electrical impulse into the heart to initiate tissue depolarisation and to trigger cardiac contraction. This is achieved by inserting a bipolar pacing electrode through the internal jugular, subclavian or femoral vein and positioning it usually at the apex of the RV, using fluoroscopic imaging. The electrode is connected to an external pacemaker with an adjustable energy output and pacing rate. The ECG of right ventricular pacing is characterised by regular broad QRS complexes with a left bundle branch block pattern. Each complex is immediately preceded by a ‘pacing spike’ (Fig. 16.50). The pacemaker will operate only if the heart rate falls below a preset level. Occasionally, temporary atrial or dual-chamber pacing (see below) is used.

Temporary pacing is indicated for transient AV block and other arrhythmias complicating acute MI or cardiac surgery, to maintain the rhythm in other situations of reversible bradycardia (such as metabolic disturbance or drug overdose), or as a bridge to permanent pacing. Complications include pneumothorax, cardiac tamponade, brachial plexus or subclavian artery injury, local infection or sepsis (usually with *Staphylococcus aureus*), and pericarditis. Failure of the system may be due to lead displacement or a progressive increase in the threshold (exit block) caused by tissue oedema. Complication rates increase with time and so a temporary pacing system should ideally not be used for more than 7 days.

Transcutaneous pacing is administered by delivering an electrical stimulus through two large adhesive gel pad electrodes placed over the apex and upper right sternal border, or over the anterior and posterior chest. It is easy and quick to set up but causes discomfort because it induces forceful pectoral and intercostal muscle contraction. Modern external defibrillators often incorporate a transcutaneous pacing system that can be used until transvenous pacing is established.

Permanent pacemakers

Permanent pacemakers are small, flat, metal devices that are implanted under the skin, usually in the pectoral area (Fig. 16.51). They contain a battery, a pulse generator, and programmable electronics that allow adjustment of pacing and memory functions. Pacing electrodes (leads) can be placed via the subclavian or cephalic veins into the right ventricle or the right atrial appendage or, to maintain AV synchrony, both.

Permanent pacemakers are controlled using an external programmer through a wireless telemetry system, allowing rate, output, timing and other parameters to be adjusted. This allows the device settings to be tailored to the patient’s needs. Aside from their therapeutic role,

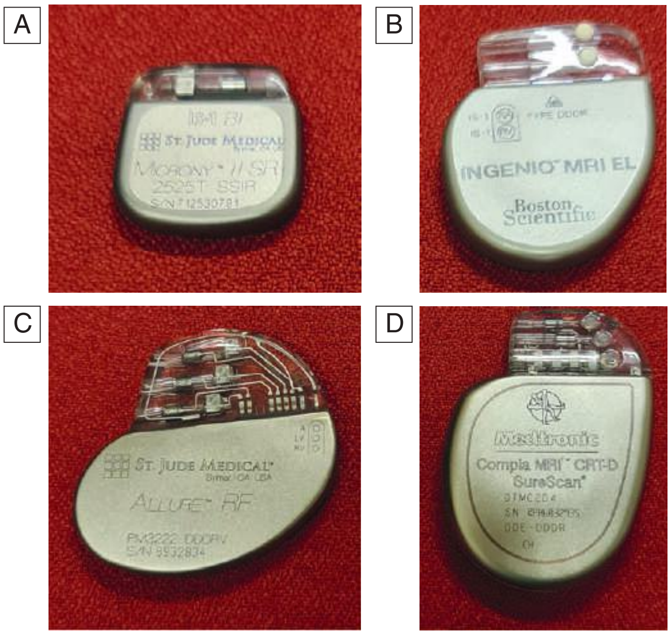

Fig. 16.51 **Cardiac implantable electronic devices.** **A** Single-chamber pacemaker. **B** Dual-chamber pacemaker. **C** Cardiac resynchronisation therapy pacemaker (CRT-P). **D** Cardiac resynchronisation therapy defibrillator (CRT-D).

i 16.34 International generic pacemaker code

Chamber paced	Chamber sensed	Response to sensing
0 = none	0 = none	0 = none
A = atrium	A = atrium	T = triggered
V = ventricle	V = ventricle	I = inhibited
D = both	D = both	D = both

pacemakers store useful diagnostic data about the patient's heart rate trends and the occurrence of tachyarrhythmias, such as AF or VT.

Single-chamber atrial pacing is indicated in patients with SA disease without AV block and ventricular pacing in patients with continuous AF and bradycardia. Dual-chamber pacing is most often used in patients with second- or third-degree AV block. Here, the atrial electrode is used to detect spontaneous atrial activity and trigger ventricular pacing (see Fig. 16.50), thereby preserving AV synchrony and allowing the ventricular rate to increase, together with the sinus node rate, during exercise and other forms of stress. Dual-chamber pacing has many advantages over single-chamber ventricular pacing, including superior haemodynamics and better effort tolerance; a lower prevalence of atrial arrhythmias in patients with SA disease; and avoidance of 'pacemaker syndrome', in which a fall in BP and dizziness occur due to loss of AV synchrony in patients with a single ventricular pacemaker who remain in sinus rhythm.

A code is used to signify the pacing mode (Box 16.34). For example, a system that paces the atrium, senses the atrium and is inhibited if it senses spontaneous activity, is designated AAI. Most dual-chamber pacemakers are programmed to a mode termed DDD; in this case, ventricular pacing is triggered by a sensed sinus P wave and inhibited by a sensed spontaneous QRS complex. A fourth letter, 'R', is added if the pacemaker has a rate response function. For example, the letters AAIR indicate an atrial demand pacemaker with a rate response function. Rate-responsive pacemakers are used in patients with chronotropic incompetence, who are unable to increase their heart rate during exercise. These devices have a sensor that triggers an increase in heart rate in response to movement or increased respiratory rate. The sensitivity of the sensor is programmable, as is the maximum paced heart rate.

i 16.35 Key indications for implantable cardiac defibrillator therapy

Primary prevention

- After myocardial infarction, if the left ventricular ejection fraction is < 30%
- Mild to moderate symptomatic heart failure on optimal drug therapy, with left ventricular ejection fraction < 35%
- Some patients with inherited cardiac conditions (long QT syndrome, cardiomyopathy)

Secondary prevention

- Survivors of ventricular fibrillation or ventricular tachycardia cardiac arrest not having a transient or reversible cause
- Ventricular tachycardia with haemodynamic compromise or significant left ventricular impairment (left ventricular ejection fraction < 35%)

Early complications of permanent pacing include pneumothorax, cardiac tamponade, infection and lead displacement. Late complications include infection (which usually necessitates extraction of the pacing system), erosion of the generator or lead, chronic pain related to the implant site, and lead fracture due to mechanical fatigue.

Implantable cardiac defibrillators

In addition to the functions of a permanent pacemaker, implantable cardiac defibrillators (ICDs) can also detect and terminate life-threatening ventricular tachyarrhythmias. ICDs are larger than pacemakers mainly because of the need for a large battery and capacitor to enable cardioversion or defibrillation. ICD leads are usually slightly broader than pacing leads as they have one or two shock coils along the length of the lead used for delivering defibrillation in addition to usual functions of a pacemaker lead. ICDs can terminate ventricular tachyarrhythmias using overdrive pacing, cardioversion or defibrillation. They are implanted in a similar manner to pacemakers and carry a similar risk of complications. In addition, patients can be prone to psychological problems and anxiety, particularly if they have experienced repeated shocks from their device.

The evidence-based indications for ICD implantation are shown in Box 16.35. These can be divided into secondary prevention indications, when patients have already had a potentially life-threatening ventricular arrhythmia, and primary prevention indications, when patients are at significant future risk of arrhythmic death. A common primary prevention indication is in patients with ischaemic cardiomyopathy, inherited conditions associated with a high risk of sudden cardiac death such as long QT syndrome, hypertrophic cardiomyopathy and arrhythmogenic right ventricular cardiomyopathy. ICDs are expensive and so the indications for which the devices are routinely implanted depend on the health-care resources available.

Cardiac resynchronisation therapy

Cardiac resynchronisation therapy (CRT) is a useful treatment for selected patients with heart failure, in whom cardiac function is impaired by the presence of left bundle branch block. This conduction defect is associated with poorly coordinated left ventricular contraction that can aggravate heart failure in susceptible patients. Pacing systems used to deliver CRT comprise a right atrial lead, a right ventricular lead and a third lead that is placed via the coronary sinus into one of the veins on the epicardial surface of the LV (see Fig. 16.28). Simultaneous septal and left ventricular epicardial pacing resynchronises left ventricular contraction.

CRT improves symptoms and quality of life and reduces mortality in patients with moderate to severe (NYHA class III–IV) heart failure who are in sinus rhythm, with left bundle branch block and left ventricular ejection fraction of 35% or less. Bi-ventricular CRT also prevents heart failure progression in similar patients with mild (NYHA class I–II) heart failure symptoms. These devices are more effective in patients in sinus rhythm than in those with AF. These devices can be combined with a defibrillator (CRT-D) because many patients with heart failure are predisposed to ventricular arrhythmias. Emerging evidence suggests that left bundle branch area pacing (LBBAP) is at least as good at delivering cardiac resynchronisation pacing as bi-ventricular CRT pacing, and this technique is now entering clinical practice. In LBBAP, the ventricular lead of a dual chamber pacemaker is advanced deep into the interventricular septum and activates the His–Purkinje conduction system, rather than local myocardium, resulting in a narrow or near-normal QRS.

Other implantable cardiac devices

Leadless pacemakers are very small devices that are implanted into the trabeculated right ventricular septum. They are considerably less likely to become infected. These devices only provide ventricular pacing.

Non-transvenous ICDs are available with the defibrillation leads placed either above or underneath the sternum with the generator on the outside the sternum. These devices have no intravascular components so are less likely to become infected and result in bacteraemia.

Catheter ablation therapy

Catheter ablation therapy is the treatment of choice for patients with SVT or atrial flutter and is a useful treatment for some patients with AF or ventricular arrhythmias (Fig. 16.52). It involves inserting a series of catheter electrodes into the heart through the venous system. These are used to record the activation sequence of the heart in sinus rhythm, during tachycardia and after pacing manoeuvres. Once the arrhythmia focus or circuit, such as an accessory pathway in WPW syndrome, has been identified, a catheter is used to ablate the culprit tissue. This can be done either by using heat, which is termed radiofrequency ablation, or by freezing, which is termed cryoablation. The procedure takes approximately 1–4 hours and does not require a general anaesthetic, although the patient may experience some discomfort during the ablation procedure. Serious complications are rare (< 1%) but include complete heart block requiring pacemaker implantation, and cardiac tamponade. For many arrhythmias, radiofrequency ablation is very attractive because it offers the prospect of a lifetime cure, thereby eliminating the need for long-term drug therapy.

The technique has revolutionised the management of many arrhythmias and is now the treatment of choice for AVNRT and AV re-entrant (accessory pathway) tachycardias, where it is curative in around 95% of cases. Focal atrial tachycardias and atrial flutter can also be treated by radiofrequency ablation, although some patients subsequently experience episodes of AF.

AF ablation involves electrically isolating the pulmonary veins, which are usually the trigger for this arrhythmia. This is effective at reducing episodes of AF in around 70%–80% of younger patients with structurally normal hearts.

In patients with permanent AF and poor rate control, in whom drugs are ineffective or are not tolerated, rate control can be achieved by implantation of a permanent pacemaker, followed by ablation of the AV node to induce complete AV block, thus allowing the pacemaker to assume heart rate control. Ablation is often effective in patients with VT occurring in a structurally normal heart and can be life-saving in patients with refractory VT due to ventricular scar or structural disease.

Coronary artery disease

Coronary artery disease (CAD) is the commonest cause of angina and acute coronary syndrome and the leading cause of death worldwide. It also has a devastating effect on quality of life. Disability-adjusted life years, a measure of healthy years of life lost, can be used to indicate the burden of disease rather than the resulting deaths. It has been estimated that CAD is responsible for 10% of disability-adjusted life years in low-income countries and 18% in high-income ones. In the UK, 1 in 3 men and 1 in 4 women die from CAD, an estimated 188 000 people have a myocardial infarct each year, and approximately 2.3 million people are living with CAD. The death rates from CAD in the UK are among the highest in Western Europe (more than 70 000 people) but are falling, particularly in younger age groups; over the last 50 years, CAD mortality has more than halved. In Eastern Europe and much of Asia, the rates of CAD are rapidly rising. Occult CAD is common in those who present with other forms of atherosclerotic vascular disease, such as intermittent claudication or stroke, and is an important cause of morbidity and mortality in these patients.

Pathogenesis

In most patients, CAD is caused by atherosclerosis (Box 16.36) but rarely it can occur as the result of aortitis, vasculitis and autoimmune connective tissue diseases. Atherosclerosis is a progressive inflammatory disorder of the arterial wall that is characterised by focal lipid-rich deposits of atheroma that remain clinically silent until they become large enough to impair tissue perfusion, or until ulceration and disruption of the lesion occurs resulting in thrombotic occlusion or distal embolisation of the vessel. Atherosclerosis begins early in life with deposits of lipids in the vessel wall, which tend to occur at sites of altered arterial shear stress, such as bifurcations, and are associated with abnormalities of endothelial function. Impaired arterial function has been detected among high-risk children and adolescents, such as cigarette smokers and those with familial hyperlipidaemia or hypertension. Early lesions have been found in the arteries of victims of accidental death in the second and third decades

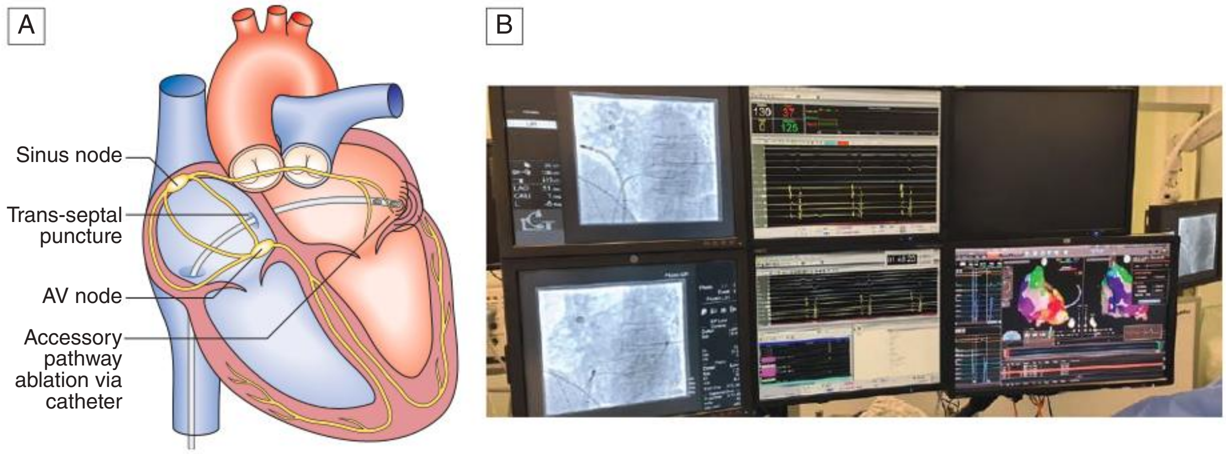

Fig. 16.52 Radiofrequency ablation. **A** Schematic of an ablation of the accessory conducting pathway in Wolff–Parkinson–White syndrome (see text for details). **B** Fluoroscopy and mapping for an ablation procedure. (AV = atrioventricular)

16.36 Coronary artery disease: clinical manifestations and pathology

Clinical problem	Pathology
Stable angina	Ischaemia due to fixed atheromatous stenosis of one or more coronary arteries
Unstable angina	Ischaemia caused by dynamic complete or partial obstruction of a coronary artery due to plaque rupture or erosion with superimposed thrombosis
Myocardial infarction (type 1)	Myocardial necrosis caused by acute occlusion of a coronary artery due to plaque rupture or erosion with superimposed thrombosis
Myocardial infarction (type 2)	Supply–demand imbalance where blood flow cannot meet the needs of the myocardium. This may be caused by fixed atheromatous obstruction with high myocardial demand for blood
Heart failure	Myocardial dysfunction due to infarction or ischaemia
Arrhythmia	Altered conduction due to ischaemia or infarction
Sudden death	Ventricular arrhythmia, asystole or massive myocardial infarction

of life, but clinical manifestations often do not appear until the sixth, seventh or eighth decade. During evolution of an atherosclerotic plaque, monocytes and other inflammatory cells bind to receptors expressed by endothelial cells. Subsequently, they migrate into the intima, and phagocytose oxidised low-density lipoprotein (LDL) particles to become lipid-laden macrophages or foam cells. Extracellular lipid pools appear in the intimal space when foam cells die and release their contents (Fig. 16.53). In response to cytokines and growth factors produced by activated macrophages, smooth muscle cells migrate from the media of the arterial wall into the intima, and change from a contractile to a fibroblastic phenotype, which can stabilise the atherosclerotic lesion. If this is successful, the lipid core will be covered by smooth muscle cells and matrix, producing a stable atherosclerotic plaque that will remain asymptomatic until it becomes large enough to obstruct arterial flow.

In an established atherosclerotic plaque, macrophages mediate inflammation and smooth muscle cells promote repair. If inflammation predominates, the plaque becomes active or unstable and may be complicated by ulceration and thrombosis. Cytokines, such as interleukin-1, tumour necrosis factor-alpha, interferon-gamma, platelet-derived growth factors and matrix metalloproteinases, are released by activated macrophages. They cause the intimal smooth muscle cells overlying the plaque to become senescent and the collagen cross-links within the plaque to degrade. This results in thinning of the protective fibrous cap, making the lesion vulnerable to mechanical stress that ultimately causes erosion, fissuring or rupture of the plaque surface (see Fig. 16.53). Any breach in the integrity of the plaque will expose its contents to blood and will trigger platelet aggregation and thrombosis that extend into the atheromatous plaque and the arterial lumen. This may cause partial or complete obstruction at the site of the lesion or distal embolisation, resulting in infarction or ischaemia of the affected organ. This common mechanism underlies acute coronary syndromes, as well as other manifestations of atherosclerotic disease such as lower limb ischaemia and stroke (Ch. 27).

The number and complexity of arterial plaques increase with age and risk factors (see below) but the rate of progression of individual plaques is variable. There is a complex and dynamic interaction between mechanical wall stress and atherosclerotic lesions. Vulnerable plaques are characterised by a lipid-rich core, a thin fibrocellular cap, speckled calcification and an increase in inflammatory cells that release specific enzymes to degrade matrix proteins. In contrast, stable plaques are typified by a small lipid pool, a thick fibrous cap, heavy calcification and plentiful collagenous cross-links. Fissuring or rupture tends to occur at sites of maximal mechanical stress, particularly the margins of an eccentric plaque, and may be triggered by a surge in BP, such as during exercise or emotional stress. Surprisingly, most plaque events are subclinical and heal spontaneously, although this may allow thrombus to be incorporated into the lesion, producing plaque growth and further obstruction to flow.

Atherosclerosis may induce complex changes in the media that lead to arterial remodelling. Some arterial segments may slowly constrict (negative remodelling), while others may gradually enlarge (positive remodelling). These changes are important because they may amplify or minimise the degree to which atheroma encroaches into the arterial lumen.

Many risk factors have been identified for atherosclerosis, but the causes are incompletely understood since unknown factors account for up to 40% of the variation in risk from one person to the next.

Age and sex

Age is the most powerful independent risk factor for atherosclerosis and sex also plays a role. Pre-menopausal women have lower rates of disease than men, although the sex difference disappears after the menopause: women develop the same degree of coronary artery disease 10 years later than men. Hormone replacement therapy (HRT) is not effective in the prevention of CAD, and HRT in post-menopausal women is associated with an increased risk of cardiovascular events.

Genetics

Atherosclerotic CAD often runs in families and a positive family history is common in patients with early-onset disease (age <50 in men and <55 in women). Twin studies have shown that a monozygotic twin of an affected individual has an eightfold increased risk and a dizygotic twin a fourfold increased risk of dying from CAD compared to the general population due to a combination of shared genetic, environmental and lifestyle factors. The commonest risk factors, such as hypertension, hyperlipidaemia and diabetes mellitus, are inherited in a polygenic manner.

Smoking

There is a strong relationship between cigarette smoking and CAD, especially in younger (<70 years) individuals, and this is the most important modifiable risk factor.

Hypertension

The incidence of atherosclerosis increases as BP rises, and this is related to systolic and diastolic BP, as well as pulse pressure. Antihypertensive therapy reduces cardiovascular mortality, stroke and heart failure.

Hypercholesterolaemia

The risk of atherosclerosis rises with serum cholesterol concentrations and lowering serum total and LDL cholesterol concentrations reduces the risk of cardiovascular events.

Diabetes mellitus

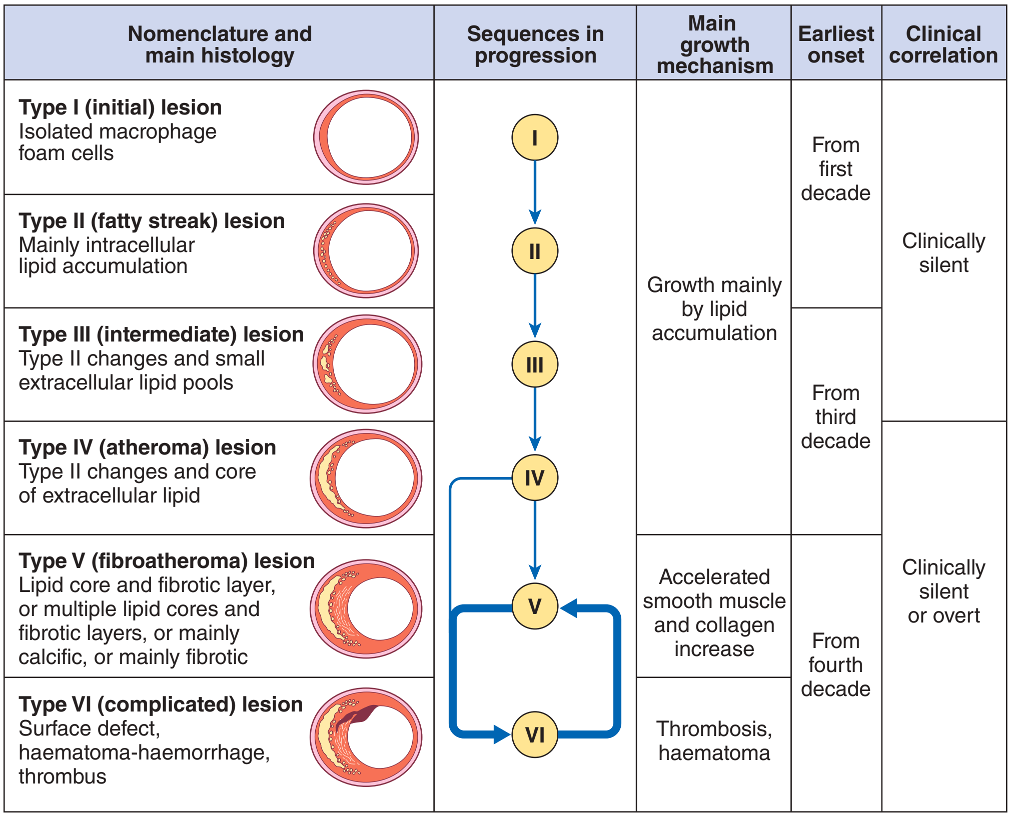
This is a potent risk factor for all forms of atherosclerosis, especially type 2 diabetes mellitus. It is often associated with diffuse disease that is difficult to treat. Insulin resistance (normal glucose homeostasis with high levels of insulin) is associated with obesity, physical inactivity and is a risk factor for CAD. Glucose intolerance makes a major contribution to the high incidence of CAD in people from South Asia and some other ethnic groups.

Haemostatic factors

Platelet activation and high plasma fibrinogen concentrations are associated with an increased risk of coronary thrombosis, whereas antiphospholipid antibodies are associated with recurrent arterial thromboses.

Physical activity

Regular exercise (brisk walking, cycling or swimming for 20 minutes two or three times a week) has a protective effect, whereas inactivity roughly doubles the risk of CAD and is a major risk factor for stroke.



Nomenclature and main histology	Sequences in progression	Main growth mechanism	Earliest onset	Clinical correlation
Type I (initial) lesion Isolated macrophage foam cells	I	Growth mainly by lipid accumulation	From first decade	Clinically silent
Type II (fatty streak) lesion Mainly intracellular lipid accumulation	II			
Type III (intermediate) lesion Type II changes and small extracellular lipid pools	III		From third decade	
Type IV (atheroma) lesion Type II changes and core of extracellular lipid	IV			Clinically silent or overt
Type V (fibroatheroma) lesion Lipid core and fibrotic layer, or multiple lipid cores and fibrotic layers, or mainly calcific, or mainly fibrotic	V	Accelerated smooth muscle and collagen increase	From fourth decade	
Type VI (complicated) lesion Surface defect, haematoma-haemorrhage, thrombus	VI	Thrombosis, haematoma

A definition of advanced types of atherosclerotic lesions and a histological classification of atherosclerosis. Circulation 1995;92:1355–1374. © 1995 American Heart Association.*

Obesity

Obesity, particularly if central or truncal, is an independent risk factor, although it is often associated with other adverse factors such as hypertension, diabetes mellitus and physical inactivity.

Alcohol

Excess alcohol consumption is associated with hypertension and cerebrovascular disease.

Diet

Diets deficient in fresh fruit, vegetables and polyunsaturated fatty acids are associated with an increased risk of cardiovascular disease. The introduction of a Mediterranean-style diet reduces cardiovascular events. However, dietary supplements, such as vitamins C and E, beta-carotene, folate and fish oils, do not reduce cardiovascular events and, in some cases, have been associated with harm.

Personality

While certain personality traits are associated with an increased risk, there is little evidence to support the popular belief that stress is a direct cause of CAD.

Social deprivation

Social deprivation is strongly associated with cardiovascular disease. This may be partly due to associations with lifestyle risk factors, such as smoking and alcohol excess, which are more common in socially deprived individuals. Current guidelines recommend that treatment thresholds should be lowered for patients from socially deprived areas.

The effect of risk factors can be multiplicative rather than additive. People with a combination of risk factors are at greatest risk and so assessment should take account of all identifiable risk factors. It is important to distinguish between relative risk (the proportional increase in risk) and absolute risk (the actual chance of an event). For example, a man of 35 years with a plasma cholesterol of 7 mmol/L (approximately 170 mg/dL), who smokes 40 cigarettes a day, is much more likely to die from CAD within the next decade than a non-smoking man of the same age with a normal cholesterol, but the absolute likelihood of his dying during this time is small (high relative risk, low absolute risk).

i **16.37 Population-based strategies to prevent coronary disease**

- Do not smoke
- Take regular exercise (minimum of 20 mins, three times per week)
- Maintain an ‘ideal’ body weight
- Eat a mixed diet rich in fresh fruit and vegetables
- Aim to get no more than 10% of energy intake from saturated fat

Management

Two approaches can be employed. Primary prevention aims to introduce lifestyle changes or therapeutic interventions to prevent CAD and other forms of atherosclerosis in the whole population or in healthy individuals with an elevated risk of disease. Secondary prevention involves initiating treatment in patients who already have had an event, with the aim of reducing the risk of subsequent events. The distinction between primary and secondary prevention is increasingly seen as arbitrary since many people will have CAD despite having no symptoms or having not experienced any clinical events.

Primary prevention

The population-based strategy aims to modify the risk factors of the whole population through diet and lifestyle advice, on the basis that even a small reduction in smoking or average cholesterol, or modification of exercise and diet, will produce worthwhile benefits (Box 16.37). Some risk factors, such as obesity and smoking, are also associated with a higher risk of other diseases and should be actively discouraged through public health measures. The effectiveness of this approach has been demonstrated by introduction of legislation to restrict smoking in public places, which has been associated with reductions in rates of MI.

The targeted strategy aims to identify and to treat high-risk individuals who have a combination of risk factors that can be quantified by composite scoring systems. It is important to consider the absolute risk of atheromatous cardiovascular disease that an individual is facing before initiating treatment since this will help to determine whether the potential benefits of intervention are likely to outweigh the expense, inconvenience and possible side-effects of treatment. For example, a 65-year-old man with an average BP of 150/90 mmHg, who smokes and has diabetes mellitus with a total:high-density lipoprotein (HDL) cholesterol ratio of 8, has a 10-year risk of MI or stroke of 56%. Conversely, a 55-year-old woman who has an identical BP, is a non-smoker, does not have diabetes mellitus, and has a total:HDL cholesterol ratio of 6 has a much better outlook, with a 10-year coronary MI or stroke risk of 5.7%. Lowering cholesterol will reduce the risk in both of these individuals by 30% and lowering BP will produce a further 20% reduction. In combination, both strategies would reduce the risk of an event from 56% to 25% in the male patient (treat 4 patients to prevent one event) and from 5.7% to 2.5% in the female patient (treat 40 patients to prevent one event). Thresholds for treatment vary in different countries. In the UK and North America, current guidelines recommend initiation of cholesterol and BP-lowering therapies in individuals with a 10-year cardiovascular risk of 7.5%–10%.

Secondary prevention

This involves targeting interventions at individuals who have had cardiovascular disease. Patients who recover from a clinical event such as an MI are usually keen to help themselves and are particularly receptive to lifestyle advice, such as dietary modification and smoking cessation. Additional interventions that should be introduced in patients with angina pectoris or an acute coronary syndrome are discussed in more detail below.

Angina pectoris

Angina pectoris is a symptom complex caused by transient myocardial ischaemia, which occurs whenever there is an imbalance between myocardial oxygen supply and demand (Box 16.38).

Pathogenesis

Coronary atherosclerosis is by far the most common cause of angina pectoris. Angina may also occur in aortic valve disease and hypertrophic cardiomyopathy, and when the coronary arteries are involved with vasculitis or aortitis. The underlying mechanisms and risk factors for atherosclerosis have already been discussed. Approximately 10%–20% of patients who report stable angina on effort have normal coronary arteries on angiography. The main causes are discussed in more detail below.

Coronary artery spasm

Angina may result from vasospasm of the coronary arteries. This may coexist with atherosclerosis, especially in unstable angina (see below), but may rarely occur as an isolated phenomenon in patients with normal coronary arteries on angiography. This is sometimes known as variant angina; when it is accompanied by transient ST elevation on the ECG, it is termed Prinzmetal angina.

16.38 Factors influencing myocardial oxygen supply and demand

Oxygen demand: cardiac work

- Heart rate
- Blood pressure
- Myocardial contractility
- Left ventricular hypertrophy
- Valve disease

Oxygen supply: coronary blood flow*

- Duration of diastole
- Coronary perfusion pressure (aortic diastolic minus coronary sinus or right atrial diastolic pressure)
- Coronary vasomotor tone
- Oxygenation:
- Haemoglobin
- Oxygen saturation

*Coronary blood flow occurs mainly in diastole.

Syndrome X and microvascular angina

The constellation of typical angina on effort and normal coronary arteries on angiography with objective evidence of myocardial ischaemia on stress testing is sometimes known as syndrome X or ischaemia with no obstructive coronary arteries (INOCA). Many of these patients (80%–90%) are women and the mechanisms of their symptoms are unclear. In a subset of patients, there is evidence of impaired myocardial vasodilatory reserve giving rise to the terms such as microvascular angina or angina with no obstructive coronary arteries (ANOCA). These disorders are poorly understood but, in the absence of coronary atherosclerosis, carry a good prognosis and respond variably to anti-anginal therapy.

Other causes

Angina can occur in association with aortic stenosis, hypertrophic obstructive cardiomyopathy and aortitis, all of which are discussed in more detail later in this chapter. It may also rarely be found in association with some types of systemic vasculitis (Ch. 25).

Clinical features

The history is the most important factor in making the diagnosis. Stable angina is categorised as typical angina, atypical angina or non-anginal chest pain (Box 16.39; see also Fig. 10.1). Some patients find the discomfort comes when they start walking and that later it does not return despite greater effort ('warm-up angina'). The Canadian Cardiovascular Society (CCS) scoring system is commonly used to grade the severity of angina (Box 16.40). This is of clinical value, not only in documenting the severity of angina but also in assessing prognosis.

16.39 Classification of angina pectoris and chest pain

Three characteristic features of angina

1. Constricting discomfort in the centre of the chest, or in the neck, shoulders, jaw or arms
2. Precipitated by physical exertion
3. Relieved by rest (or GTN) within 5 minutes

Classification

- **Typical angina**: All three features
- **Atypical angina**: Two features
- **Non-anginal chest pain**: One or no features

NICE classification

- **Possible angina**: Typical angina, atypical angina or non-anginal chest pain with an abnormal resting 12-lead ECG
- **Non-anginal chest pain**: Non-anginal chest pain with a normal resting 12-lead ECG

(ECG = electrocardiogram; GTN = glyceryl trinitrate; NICE = National Institute for Health and Care Excellence)

16.40 Canadian Cardiovascular Society (CCS) angina score

Class I

- Angina only during strenuous or prolonged physical activity

Class II

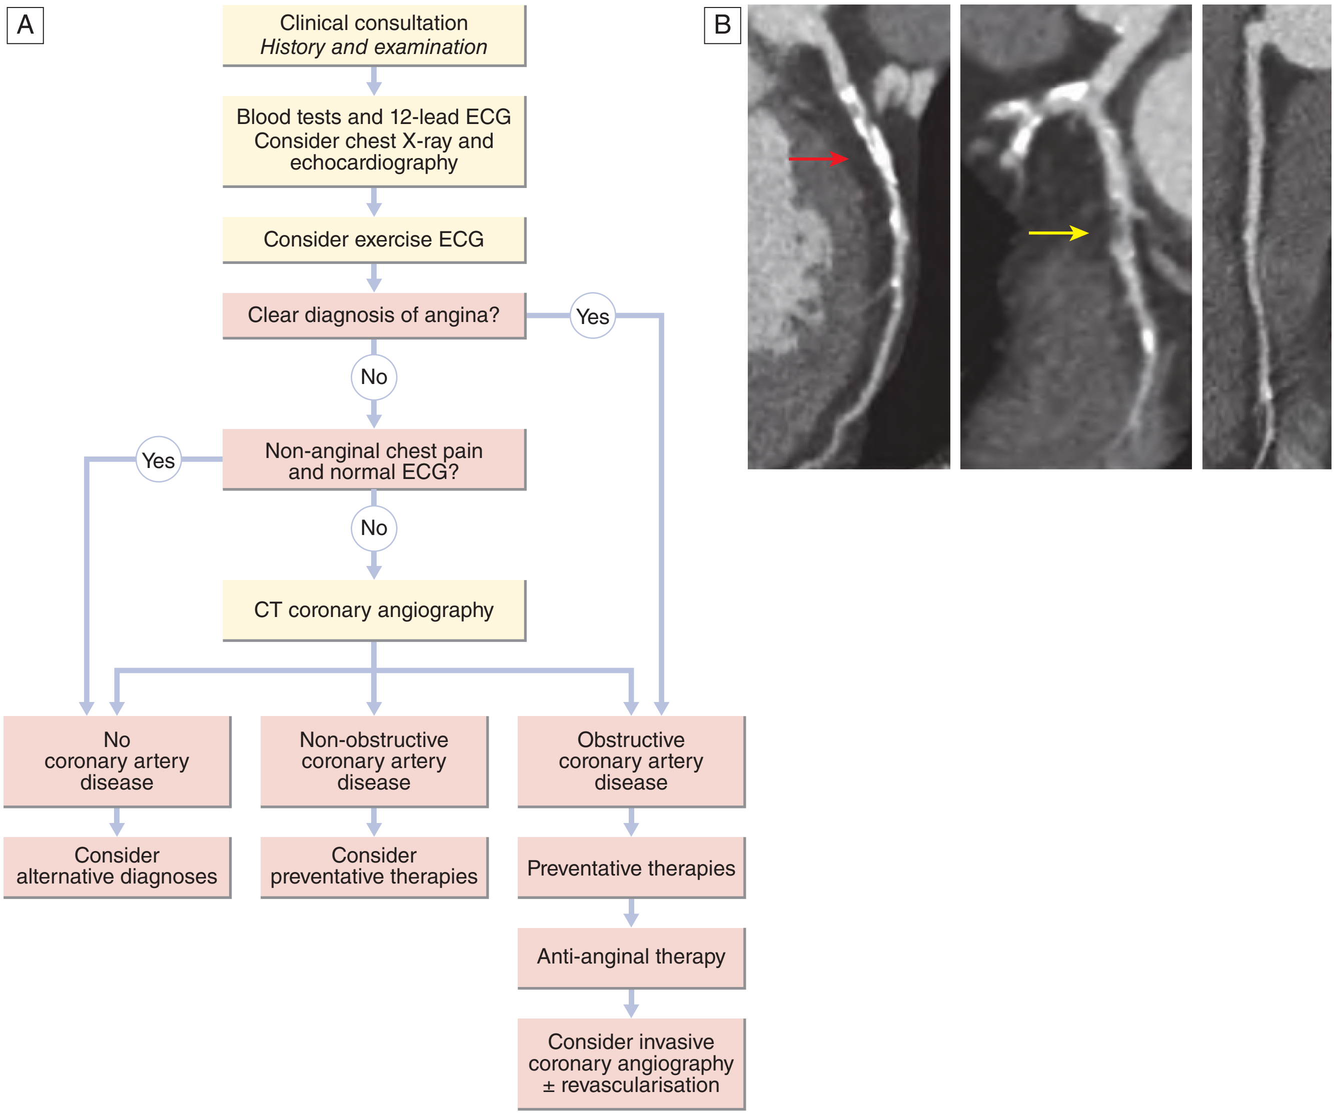
- Slight limitation, with angina only during vigorous physical activity

Class III

- Moderate limitation where symptoms occur with everyday activities

Class IV

- Inability to perform any activity without angina or angina at rest, i.e. severe limitation



A
Clinical consultation
History and examination
Blood tests and 12-lead ECG
Consider chest X-ray and echocardiography
Consider exercise ECG
Clear diagnosis of angina?
Yes
No
Non-anginal chest pain and normal ECG?
Yes
No
CT coronary angiography
No coronary artery disease
Non-obstructive coronary artery disease
Obstructive coronary artery disease
Consider alternative diagnoses
Consider preventative therapies
Preventative therapies
Anti-anginal therapy
Consider invasive coronary angiography ± revascularisation
B

Fig. 16.54 **A** A scheme for the investigation and treatment of stable angina on effort. This scheme is best adopted for patients without prior known coronary artery disease and possible angina. For patients with known coronary artery disease, further stress imaging (echocardiography, radionuclide perfusion or magnetic resonance perfusion) rather than computed tomography coronary angiography is recommended. **B** An example CT coronary angiogram showing coronary artery disease in all three vessels with evidence of 'soft' lipid-rich plaque (yellow arrow) and extensive calcified coronary atheroma (red arrow).

Physical examination is frequently unremarkable but should include a careful search for an ejection systolic murmur (particularly aortic stenosis and hypertrophic obstructive cardiomyopathy), important risk factors (hypertension, diabetes mellitus), left ventricular dysfunction (cardiomegaly, gallop rhythm), other manifestations of arterial disease (carotid bruits, peripheral arterial disease), and unrelated conditions that may exacerbate angina (anaemia, thyrotoxicosis).

Investigations

Exercise testing and non-invasive imaging are advisable to confirm the diagnosis and to risk stratify patients with possible angina (see Box 16.39). An algorithm for the investigation and treatment of patients with stable angina is shown in Figure 16.54. An exercise ECG is commonly performed using a standard treadmill or bicycle ergometer protocol while monitoring the patient's pulse, BP and general condition. Planar or down-sloping ST segment depression of 1 mm or more is indicative of ischaemia (Fig. 16.55). Up-sloping ST depression is less specific; it often occurs in normal individuals and false-positive results can occur with digoxin therapy, left ventricular hypertrophy, bundle branch block and WPW syndrome. Overall, the exercise ECG principally confirms the history of exertional angina and provides an objective measure of the patient's exercise tolerance. It may also indicate the underlying disease severity (Fig. 16.56) and can identify high-risk individuals with severe coronary disease in combination with other clinical features (Box 16.41). However, exercise testing may be normal in a substantial proportion of patients with CAD or may be inconclusive because of inadequate exercise tolerance due to reduced mobility or other non-cardiac problems. It cannot be relied upon to diagnose CAD.

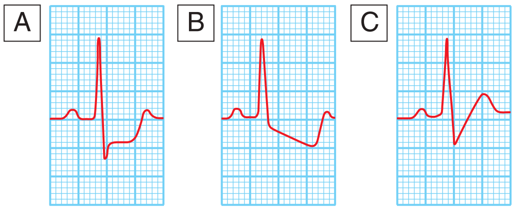


Fig. 16.55 Forms of exercise-induced ST depression. **A** Planar ST depression is usually indicative of myocardial ischaemia. **B** Down-sloping depression also usually indicates myocardial ischaemia. **C** Up-sloping depression may be a normal finding.

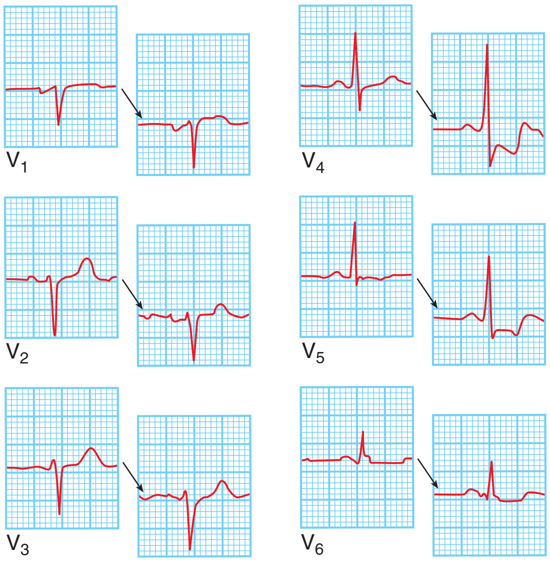

Fig. 16.56 A positive exercise test (chest leads only). The resting 12-lead ECG shows some minor T-wave changes in the inferolateral leads but is otherwise normal. After 3 minutes' exercise on a treadmill, there is marked planar ST depression in leads V_4 and V_5 (right-hand offset). Subsequent coronary angiography revealed critical three-vessel coronary artery disease.

i 16.41 Risk stratification in patients with stable angina[1]

High risk	Low risk
Recent-onset symptoms (< 6 months)	Long-standing symptoms
Class II to IV symptoms[2]	Class I symptoms[2]
Diabetes mellitus	
Comorbidity	
Post-infarct angina	Predictable exertional angina
Ischaemia at low workload	Ischaemia only at high workload
Left main or three-vessel disease	Single-vessel or two-vessel disease
Poor left ventricular function	Good left ventricular function

[1] Patients may fall between these two categories.
[2] Canadian Cardiovascular Society Classification.

To diagnose the presence of CAD, CT coronary angiography is the non-invasive imaging investigation of first choice. It clarifies the diagnosis and guides the use of preventative and anti-anginal therapies. It also serves as an excellent guide to the appropriate use of invasive cardiac catheterisation, reducing its use in those with normal coronary arteries (see Fig. 16.13) and targeting it to those with significant disease (see Fig. 16.54). Its use is also associated with a marked reduction in the future risk of MI, likely due to better targeted preventative interventions in those with previously unrecognised CAD.

In patients with known CAD, further imaging with myocardial perfusion scanning or stress echocardiography is indicated where there is uncertainty regarding the relationship between symptoms and myocardial ischaemia. A perfusion defect present during stress but not at rest provides evidence of reversible myocardial ischaemia (Fig. 16.57), whereas a persistent perfusion defect seen during both phases of the study is usually indicative of previous MI.

Coronary angiography provides detailed anatomical information about the extent of luminal obstruction by CAD (see Fig. 16.15). It is usually performed when coronary artery bypass graft surgery or percutaneous coronary intervention is being considered.

Management

This should begin with a careful explanation of the problem and a discussion of the lifestyle and medical interventions that can be deployed to relieve symptoms and improve prognosis (Box 16.42). Anxiety and misconceptions often contribute to disability. For example, some patients avoid all forms of exertion because they believe that each attack of angina is a 'mini-heart attack' that results in permanent damage. Education and reassurance can dispel these misconceptions and make a huge difference to the patient's quality of life.

The principles of management involve:

- advice on smoking cessation and healthier lifestyles (see Box 16.37)
- identification and treatment of risk factors
- introduction of drug treatment for symptom control
- a careful assessment of the extent and severity of CAD
- identification of high-risk patients for treatment to improve life expectancy.

All patients with angina secondary to CAD should receive antiplatelet therapy. Low-dose (75 mg) aspirin should be prescribed and continued indefinitely since it reduces the risk of MI. Clopidogrel (75 mg daily) is an equally effective alternative if aspirin causes dyspepsia or other side-effects. Similarly, all patients should be prescribed a statin, even if the serum cholesterol concentration is normal.

Anti-anginal drug therapy

The goal of anti-anginal therapy is to control symptoms using a regimen that is as simple as possible and does not cause side-effects. Five main drug groups are used in the treatment of angina but there is little evidence that one group is more effective than another. It is conventional to start therapy with sublingual glyceryl trinitrate (GTN) and a β-blocker, and then add a calcium channel antagonist or a long-acting nitrate if needed. If the combination of two drugs fails to achieve an acceptable symptomatic response, the addition of further classes of drug has modest additional benefits and coronary revascularisation should be considered.

Nitrates

Nitrates act directly on vascular smooth muscle to produce venous and arteriolar dilatation. Several preparations are available, as shown in Box 16.43. They help angina by lowering preload and afterload, which reduces myocardial oxygen demand, and by increasing myocardial oxygen supply through coronary vasodilatation. Sublingual GTN, administered from a metered-dose aerosol (400 μg per spray) or as a tablet (300 or 500 μg), is indicated for acute attacks and relieves symptoms in 2–3 minutes. It can also be used before taking exercise to avoid provoking symptoms. Sublingual GTN has a short duration of action and side-effects include headache, symptomatic hypotension and, rarely, syncope. A more prolonged therapeutic effect can be achieved by giving GTN transcutaneously as a patch (5–10 mg daily) or as a slow-release buccal tablet (1–5 mg 4 times daily). Isosorbide dinitrate (10–20 mg 3 times daily) and isosorbide mononitrate (20–60 mg once or twice daily) can be given by mouth, unlike GTN, which undergoes extensive metabolism in the liver. Headache is common with oral nitrates but tends to diminish if the patient perseveres with the treatment. Continuous nitrate therapy can cause pharmacological tolerance, but this can be avoided by a 6- to 8-hour nitrate-free period, best achieved at night when the patient is inactive. If nocturnal angina is a predominant symptom, long-acting nitrates can be taken at the end of the day.

Beta-blockers

These lower myocardial oxygen demand by reducing heart rate, BP and myocardial contractility, but they may provoke bronchospasm in patients with asthma. Dosages of commonly used β-blockers are shown in Box 16.18. In theory, non-selective β-blockers may aggravate coronary vasospasm by blocking coronary artery β_2-adrenoceptors, and so a once-daily cardioselective preparation, such as slow-release

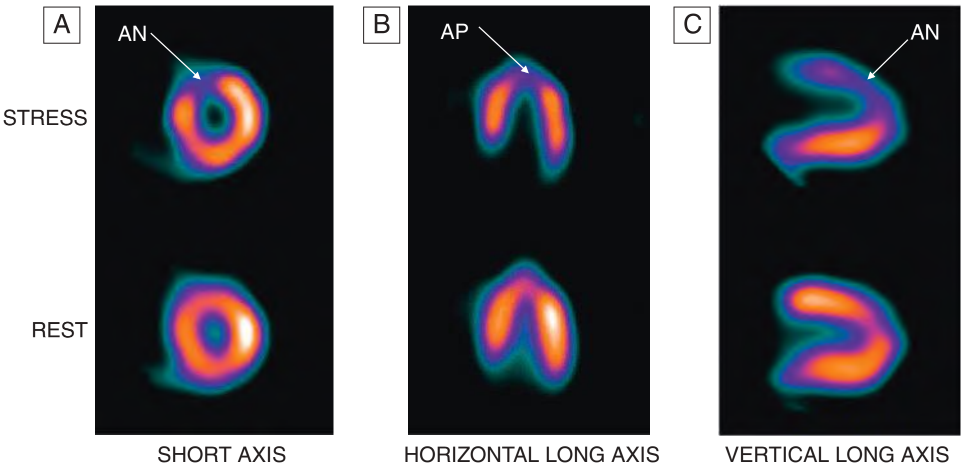

Fig. 16.57 A myocardial perfusion scan showing reversible anterior ischaemia of the anterior wall and apex. The images are cross-sectional tomograms of the left ventricle. The resting scans (below) show even uptake of the ^{99m}technetium-labelled tetrofosmin. During stress there is reduced uptake of tetrofosmin, particularly along the anterior wall (AN arrows), and apex (AP arrow).

i 16.42 Advice to patients with stable angina

- Do not smoke
- Aim for an ideal body weight
- Take regular exercise (exercise up to, but not beyond, the point of chest discomfort is beneficial and may promote collateral vessels)
- Avoid severe unaccustomed exertion, and vigorous exercise after a heavy meal or in very cold weather
- Take sublingual nitrate before undertaking exertion that may induce angina

i 16.43 Duration of action of some nitrate preparations

Preparation	Peak action	Duration of action
Sublingual GTN	4–8 mins	10–30 mins
Buccal GTN	4–10 mins	30–300 mins
Transdermal GTN	1–3 hrs	Up to 24 hrs
Oral isosorbide dinitrate	45–120 mins	2–6 hrs
Oral isosorbide mononitrate	45–120 mins	6–10 hrs

(GTN = glyceryl trinitrate)

i 16.44 Calcium channel antagonists used for the treatment of angina

Drug	Dose	Feature
Nifedipine	5–20 mg 3 times daily*	May cause marked tachycardia
Nicardipine	20–40 mg 3 times daily	May cause less myocardial depression than the other calcium antagonists
Amlodipine	2.5–10 mg daily	Long-acting
Verapamil	40–80 mg 3 times daily*	Commonly causes constipation; useful anti-arrhythmic properties
Diltiazem	60–120 mg 3 times daily*	Similar anti-arrhythmic properties to verapamil

*Once- or twice-daily sustained-release preparations are available.

metoprolol (50–200 mg daily) or bisoprolol (5–15 mg daily), is preferable. Beta-blockers should not be withdrawn abruptly, as rebound effects may precipitate dangerous arrhythmias, worsening angina or precipitate MI: the β-blocker withdrawal syndrome.

Calcium channel antagonists

These drugs lower myocardial oxygen demand by reducing BP and myocardial contractility. Since dihydropyridine calcium antagonists, such as nifedipine and amlodipine, may cause a reflex tachycardia, it is best to use them in combination with a β-blocker. In contrast, verapamil and diltiazem can be used as monotherapy because they slow SA node firing, inhibit conduction through the AV node and tend to cause bradycardia. They are particularly useful when β-blockers are contraindicated. Calcium channel antagonists reduce myocardial contractility and must be used with care in patients with poor LV function, since they can aggravate or precipitate heart failure. Other unwanted effects include peripheral oedema, flushing, headache and dizziness (Box 16.44).

Potassium channel activators

Nicorandil (10–20 mg twice daily orally) is the only drug in this class that is currently available for clinical use. It acts as a vasodilator with effects on the arterial and venous systems, and has the advantage that it does not exhibit the tolerance seen with nitrates.

I_f channel antagonist

Ivabradine (initial dose 2.5–5 mg twice daily orally) is the first in this class of drug. It induces bradycardia by modulating ion channels in the sinus node. It does not inhibit myocardial contractility and appears to be safe in patients with heart failure.

Ranolazine

Ranolazine (initial dose 375 mg twice daily) inhibits the late inward sodium current in coronary artery smooth muscle cells, with a secondary effect on calcium flux and vascular tone, reducing angina symptoms.

Non-pharmacological treatments

Percutaneous coronary intervention

Percutaneous coronary intervention (PCI) involves passing a fine guidewire across a coronary stenosis under radiographic control and using it to position a balloon, which is then inflated to dilate the stenosis (Fig. 16.58). This can be combined with deployment of a coronary stent, which is a piece of metallic 'scaffolding' that can be impregnated with drugs with antiproliferative properties and that helps to maximise and to maintain dilatation of a stenosed vessel. The routine use of stents in appropriate vessels reduces both acute complications and the incidence of clinically important restenosis (Fig. 16.59).

Treatment with PCI often provides excellent symptom control and is as effective as anti-anginal drug therapies. However, it does not reduce MI or improve survival in patients with chronic stable angina: a common misconception. It is mainly used in single- or two-vessel disease. Stenoses in bypass grafts can be dilated, as well as those in the native coronary arteries. The technique is often used to provide palliative therapy for patients with recurrent angina after coronary artery bypass grafting.

The main acute complications of PCI are occlusion of the coronary artery by thrombus or a loose flap of intima (coronary artery dissection), and consequent MI. This occurs in about 2% of procedures and can often be corrected by further intervention, although emergency coronary artery bypass grafting may occasionally be required. Mild myocardial damage, as indicated by elevation of cardiac troponin, occurs in up to 25% of cases. The main long-term complication of PCI is restenosis, in up to a fifth of cases. This is due to a combination of elastic recoil and smooth muscle proliferation and tends to occur within 3–6 months. Stenting substantially reduces the risk of restenosis, probably because it allows the operator to achieve more complete dilatation. Virtually all stents are now coated with an antiproliferative drug, such as sirolimus or paclitaxel, which elutes slowly from the stent coating and substantially reduces neo-intimal hyperplasia and in-stent restenosis. Recurrent angina (affecting up to 5%–10% of patients at 6 months) may require further PCI or bypass grafting.

The risk of complications and the likely success of the procedure are closely related to the complexity of the disease, the experience of the operator and the presence of important comorbidity, such as diabetes and peripheral arterial disease. A good outcome is less likely if the target lesion is complex, long, eccentric or calcified, lies on a bend or within a tortuous vessel, involves a branch or contains thrombus.

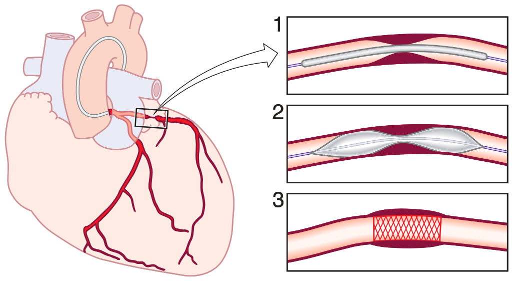

Fig. 16.58 **Percutaneous coronary intervention.** A guidewire is advanced from the radial (or femoral) artery to the coronary artery under radiographic control (1). A fine balloon catheter is then advanced over the guidewire to the stenotic coronary artery and the balloon is inflated to dilate the stenosis (2). When this has been achieved, a stent is usually placed at the site of the stenosis to maintain patency of the artery (3) (see text for more details).

Adjunctive therapy with a potent platelet inhibitor, such as the P2Y12 receptor antagonists (clopidogrel, prasugrel or ticagrelor), in combination with aspirin and heparin improves the outcome following PCI.

Coronary artery bypass grafting

The internal mammary arteries, radial arteries or reversed segments of the patient's own saphenous vein can be used to bypass coronary artery stenoses (Fig. 16.60). This usually involves major surgery under cardiopulmonary bypass but, in some cases, grafts can be applied to the beating heart: 'off-pump' surgery. The operative mortality is approximately 1% but risks are higher in older patients, those with poor left ventricular function and those with significant comorbidity, such as renal failure.

Approximately 90% of patients are free of angina 1 year after coronary artery bypass grafting (CABG), but fewer than 60% of patients are asymptomatic after 5 or more years. Early post-operative angina is usually due to graft failure arising from technical problems during the operation, or poor 'run-off' due to disease in the distal native coronary vessels. Late recurrence of angina may be caused by progressive disease in the native coronary arteries or graft degeneration. Fewer than 50% of vein grafts are patent 10 years after surgery. Arterial grafts have a much better long-term patency rate with more than 80% of internal mammary artery grafts patent at 10 years. This has led many surgeons to consider total arterial revascularisation during CABG surgery. Aspirin (75–150 mg daily) and clopidogrel (75 mg daily) both improve graft patency, and one or the other should be prescribed indefinitely. Intensive lipid-lowering therapy slows the progression of disease in the native coronary arteries and bypass grafts and reduces clinical cardiovascular events. There is substantial excess cardiovascular morbidity and mortality in patients who continue to smoke after bypass grafting. Persistent smokers are twice as likely to die in the 10 years following surgery than those who give up at surgery.

Survival is improved by CABG in symptomatic patients with left main stem stenosis or three-vessel coronary disease when the LAD, CX and right coronary arteries are involved, or two-vessel disease involving the proximal LAD coronary artery. Improvement in survival is most marked in those with left main stem disease, impaired left ventricular function or positive stress testing prior to surgery and in those who have undergone left internal mammary artery grafting.

Neurological complications are common, with a 1%–2% risk of peri-operative stroke. Between 30% and 80% of patients develop short-term cognitive impairment that typically resolves within 6 months. There are also reports of long-term cognitive decline that may be evident in more than 30% of patients at 5 years. PCI and CABG are compared in Box 16.45.

Fig. 16.60 Coronary artery bypass graft surgery. **A** Narrowed or stenosed arteries are bypassed using saphenous vein grafts connected to the aorta or by utilising the internal mammary artery. **B** Three-dimensional reconstruction of multidetector CT of the heart. The image shows the patent saphenous vein grafts (SVG) to the right coronary artery (RCA), obtuse marginal branch (OM) and diagonal branch (LADD), and left internal mammary artery graft (LIMA) to the left anterior descending (LAD) coronary artery.

16.45 Comparison of percutaneous coronary intervention (PCI) and coronary artery bypass grafting (CABG)

	PCI	CABG
Death	< 0.5%	< 1.5%
Myocardial infarction*	2%	10%
Hospital stay	6–18 hrs	5–8 days
Return to work	2–5 days	6–12 weeks
Recurrent angina	15%–20% at 6 months	10% at 1 year
Repeat revascularisation	10%–20% at 2 years	2% at 2 years
Neurological complications	Rare	Common (see text)
Other complications	Emergency CABG Vascular damage related to access site	Diffuse myocardial damage Infection (chest, wound) Wound pain

*Defined as CK-MB > 2× normal

16.46 Angina in old age

- **Incidence**: coronary artery disease increases in old age and affects women almost as often as men.
- **Comorbid conditions**: anaemia and thyroid disease are common and may worsen angina.
- **Calcific aortic stenosis**: common and should be sought in all older people with angina.
- **Atypical presentations**: when myocardial ischaemia occurs, age-related changes in myocardial compliance and diastolic relaxation can cause the presentation to be with symptoms of heart failure, such as breathlessness, rather than with chest discomfort.
- **Angioplasty and coronary artery bypass surgery**: provide symptomatic relief, although with increased procedure-related morbidity and mortality. Outcome is determined by the number of diseased vessels, severity of cardiac dysfunction and the number of concomitant diseases, as much as by age itself.

Prognosis

The prognosis of CAD is related to the burden of CAD and the degree of left ventricular dysfunction. A patient with single-vessel disease and good left ventricular function has a 5-year survival of more than 90%. In contrast, a patient with severe left ventricular dysfunction and extensive three-vessel disease has a 5-year survival of less than 30% unless revascularisation is performed. Although symptoms are a poor guide to prognosis, the 5-year mortality of patients with severe angina (CCS angina scale III or IV, see Box 16.40) is nearly double that of patients with mild symptoms.

Some considerations specific to angina in old age are listed in Box 16.46.

Acute coronary syndrome

Acute coronary syndrome is a term that encompasses both unstable angina and myocardial infarction. Unstable angina is characterised by new-onset or rapidly worsening angina (crescendo angina), angina on minimal exertion or angina at rest in the absence of myocardial injury. Myocardial infarction (MI) is distinguished from unstable angina by the occurrence of myocardial necrosis and is diagnosed when myocardial injury occurs in the presence of clinical evidence of acute myocardial ischaemia (Box 16.47). The diagnosis of a prior MI can be made when any one of the features shown in Box 16.48 is present.

Acute coronary syndrome may present as a new phenomenon in patients with no previous history of heart disease or against a background of chronic stable angina. Approximately 12% of patients with acute coronary syndrome die within 1 month and 20% within 6 months of the index event. The risk markers that are indicative of an adverse prognosis include recurrent ischaemia, extensive ECG changes at rest or during pain, raised plasma troponin I or T concentrations, arrhythmias and haemodynamic complications (hypotension, mitral regurgitation) during episodes of ischaemia. Careful assessment and risk stratification are important because these guide the use of more complex pharmacological and interventional treatments (Fig. 16.61 and see Fig. 16.69), which can improve outcome.

Pathogenesis

Acute coronary syndrome almost always occurs in patients who have coronary atherosclerosis. The culprit lesion that precipitates the acute event is usually a complex ulcerated or fissured atheromatous plaque with adherent platelet-rich thrombus and local coronary artery spasm (see Fig. 16.53). These vascular changes are dynamic, such that the degree of obstruction may either increase, leading to complete vessel occlusion, or regress due to the effects of platelet disaggregation and endogenous fibrinolysis.

16.47 Classification and criteria for diagnosis of acute myocardial infarction

Criteria for acute myocardial infarction

The term acute myocardial infarction (MI) should be used when there is acute myocardial injury with clinical evidence of acute myocardial ischaemia and with detection of a rise and/or fall of cardiac troponin values with at least one value above the 99th centile upper reference limit and at least one of the following:

- Symptoms of myocardial ischaemia
- New ischaemic ECG changes
- Development of pathological Q waves
- Imaging evidence of new loss of viable myocardium or new regional wall motion abnormality in a pattern consistent with an ischaemic aetiology
- Identification of a coronary thrombus by angiography or autopsy

Classification of acute myocardial infarction

- **Type 1 MI:** Acute atherothrombosis in the artery supplying the infarcted myocardium
- **Type 2 MI:** An imbalance between myocardial oxygen supply and demand unrelated to acute atherothrombosis
- **Type 3 MI:** Cardiac death in patients with symptoms suggestive of myocardial ischaemia and presumed new ischaemic ECG changes before cardiac troponin values become available or abnormal
- **Type 4 MI:** MI caused during percutaneous coronary intervention (PCI; type 4a). Other types include stent thrombosis (type 4b) and restenosis (type 4c) and are consistent with type 1 MI
- **Type 5 MI:** MI caused during coronary artery bypass grafting

Coronary procedure-related MI ≤ 48 hours after the index procedure is arbitrarily defined by an elevation of cardiac troponin values > 5× for type 4a MI and > 10× for type 5 MI of the 99th centile upper reference limit in patients with normal baseline values together with at least one of the following:

- New ischaemic ECG changes (this criterion is related to type 4a MI only)
- Development of new pathological Q waves
- Imaging evidence of loss of viable myocardium that is presumed to be new and consistent with an ischaemic aetiology
- Angiographic findings consistent with a procedural flow-limiting complication such as coronary dissection, occlusion of a major epicardial artery or graft, side-branch occlusion-thrombus, disruption of collateral flow or distal embolisation

Adapted from Thygesen K, Alpert JS, Jaffe AS, et al. Fourth universal definition of myocardial infarction. Eur Heart J 2019;40:237–269.

16.48 Criteria for diagnosis of a previously unrecognised myocardial infarction

- Abnormal Q waves with or without symptoms in the absence of non-ischaemic causes
- Imaging evidence of loss of viable myocardium in a pattern consistent with ischaemic aetiology
- Patho-anatomical findings of a prior MI

Adapted from Thygesen K, Alpert JS, Jaffe AS, et al. Fourth universal definition of myocardial infarction. Eur Heart J 2019;40:237–269.

Myocardial infarction

The criteria for diagnosis classification of acute MI and classification of subtypes of MI are shown in Box 16.47. In acute type 1 MI, occlusive thrombus is present at the site of rupture or erosion of an atheromatous plaque; so-called atherothrombosis. The thrombus may undergo spontaneous lysis over the course of the next few days, although irreversible myocardial damage will have occurred. Without treatment, the artery responsible for the type 1 MI remains permanently occluded in 20%–30% of patients. Since the process of infarction progresses over several hours (Fig. 16.62), most patients present when it is still possible to salvage myocardium and improve outcome.

Myocardial infarction may also occur as the result of an imbalance between the blood supply and metabolic demands of the heart (type 2 MI). This may occur because of the presence of CAD and major non-cardiac stress, such as sepsis in a patient with three-vessel CAD, or because there is overwhelming demand in the presence of unobstructed coronary arteries, such as an excessively fast heart rate from a primary arrhythmia. For the diagnosis of type 2 MI, there needs to be clinical evidence of ischaemia, such as ECG changes or symptoms of chest pain. This should be distinguished from myocardial injury where there is evidence of elevated cardiac troponin concentration (myocardial necrosis) without evidence of myocardial ischaemia, such as occurs in myocarditis. Myocardial injury can be acute or chronic depending upon its underlying cause.

The term type 3 MI is used to describe the situation where there is sudden death presumed to be due to MI. The terms type 4 and type 5 MI are used to describe the situations where MI occurs during or following the conduct of the coronary revascularisation procedures: PCI and CABG, respectively. In these situations, clinical evidence of ischaemia is required to distinguish MI from procedure-related myocardial injury.

Clinical features

The differential diagnosis of acute coronary syndrome is wide and includes most causes of central chest pain or collapse. Chest pain at rest is the cardinal symptom but breathlessness, vomiting and collapse are also common features (Box 16.49). The pain occurs in the same sites as angina but is usually more severe and lasts longer; it is often described as a tightness, heaviness or constriction in the chest. In acute MI, the pain can be excruciating, and the patient's expression and pallor may vividly convey the seriousness of the situation. Most patients are breathless, and in some, this is the only symptom. Painless or 'silent' MI may also occur and is particularly common in older patients or those with diabetes mellitus. If syncope occurs, it is usually caused by an arrhythmia or profound hypotension. Vomiting and sinus bradycardia are often due to vagal stimulation and are particularly common in patients with inferior MI. Nausea and vomiting may also be caused or aggravated by opiates given for pain relief. Sometimes infarction occurs in the absence of physical signs. Sudden death, from ventricular fibrillation or asystole, may occur immediately and often within the first hour. If the patient survives this most critical stage, the liability to dangerous arrhythmias remains, but diminishes as each hour goes by. It is vital that patients know not to delay calling for help if symptoms occur. Complications may occur in all forms of acute coronary syndrome but have become less frequent in the modern era of immediate or early coronary revascularisation. Specific complications of acute coronary syndromes and their management are discussed below.

Arrhythmias

Arrhythmias are common in patients with acute coronary syndrome (Box 16.50) but are often transient and of no haemodynamic or prognostic importance. The risk of arrhythmia can be minimised by adequate pain relief, rest and the correction of hypokalaemia. VF occurs in 5%–10% of patients who reach hospital and is thought to be the major cause of death in those who die before receiving medical attention. Prompt defibrillation restores sinus rhythm and is life-saving. The prognosis of patients with early VF (within the first 48 hours) who are successfully and promptly resuscitated is identical to that of patients who do not suffer VF. The presence of ventricular arrhythmias during the convalescent phase of acute coronary syndrome may be a marker of poor ventricular function and may herald sudden death. Selected patients may benefit from electrophysiological testing and specific anti-arrhythmic therapy, including ICDs, as discussed in the previous section on cardiac arrhythmias. AF is a common but frequently transient arrhythmia, and usually does not require emergency treatment. However, if it causes a rapid ventricular rate with hypotension or circulatory collapse, prompt cardioversion is essential. In other situations, digoxin or a β-blocker is usually the treatment of choice. AF may be a feature of impending or overt left ventricular failure, and therapy may be ineffective if heart failure is not recognised and treated appropriately. Anticoagulation is required if AF persists. Bradycardia may occur but does not require treatment unless there is hypotension or haemodynamic deterioration, in which case

1. Find points for each predictive factor

Killip class	Points	SBP (mmHg)	Points	Heart rate (beats/min)	Points	Age (years)	Points	Serum creatinine level (µmol/L)	Points
I	0	≤ 80	58	≤ 50	0	≤ 30	0	0–34	1
II	20	80–99	53	50–69	3	30–39	8	35–70	4

		160–199	10	150–199	38	70–79	75	177–353	21
		≥ 200	0	≥ 200	46	80–89	91	≥ 353	28
						≥ 90	100		

Other risk factors	Points
Cardiac arrest at admission	39
ST-segment deviation	28
Elevated cardiac biomarker concentrations	14

2. Sum points for all predictive factors

Killip class + SBP + Heart rate + Age + Creatinine level + Cardiac arrest at admission + ST-segment deviation + Elevated cardiac biomarker concentrations | Total points

3. Look up risk corresponding to total points

Total points	≤ 60	70	80	90	100	110	120	130	140	150	160	170	180	190	200	210	220	230	240	≥ 250
Probability of in-hospital death (%)	≤ 0.2	0.3	0.4	0.6	0.8	1.1	1.6	2.1	2.9	3.9	5.4	7.3	9.8	13	18	23	29	36	44	≥ 52

Examples

A patient has Killip class II, SBP of 99 mmHg, heart rate of 100 beats/min, is 65 years of age, has a serum creatinine level of 76 µmol/L, did not have a cardiac arrest at admission but did have ST-segment deviation and elevated cardiac troponin. His score would be: 20 + 53 + 15 + 58 + 7 + 0 + 28 + 14 = 195. This gives about a 16% risk of having an in-hospital death.

Similarly, a patient with Killip class I, SBP of 80 mmHg, heart rate of 60 beats/min, who is 55 years of age, has a serum creatinine level of 30 µmol/L, and no risk factors would have the following score: 0 + 58 + 3 + 41 + 1 = 103. This gives about a 0.9% risk of having an in-hospital death.

Fig. 16.61 Risk stratification in the acute coronary syndrome: the GRACE score. Killip class refers to a categorisation of the severity of heart failure based on easily obtained clinical signs. The main clinical features are as follows: class I = no heart failure; class II = crackles audible halfway up the chest; class III = crackles heard in all the lung fields; class IV = cardiogenic shock. To convert creatinine in µmol/L to mg/dL, divide by 88.4. (SBP = systolic blood pressure) *From Scottish Intercollegiate Guidelines Network (SIGN) Guideline no. 93 – Acute coronary syndromes; updated February 2013.*

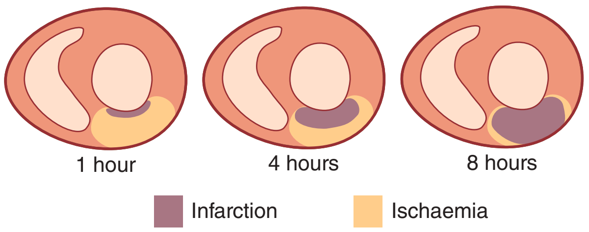

Fig. 16.62 The time course of myocardial infarction. The relative proportion of ischaemic, infarcting and infarcted tissue slowly changes over a period of 12 hours. In the early stages of myocardial infarction, a significant proportion of the myocardium in jeopardy is potentially salvageable.

atropine (0.6–1.2 mg IV) may be given. Inferior MI may be complicated by AV block, which is usually temporary and often resolves following reperfusion therapy. If there is clinical deterioration due to second-degree or complete AV block, a temporary pacemaker should be considered. AV block complicating anterior infarction is more serious because asystole may suddenly supervene. A prophylactic temporary pacemaker should be inserted in these patients.

16.49 Clinical features of acute coronary syndromes

Symptoms

- Prolonged cardiac pain: chest, throat, arms, epigastrium or back
- Anxiety and fear of impending death
- Nausea and vomiting
- Breathlessness
- Collapse/syncope

Physical signs

Signs of sympathetic activation

- Pallor
- Sweating
- Tachycardia

Signs of vagal activation

- Vomiting
- Bradycardia

Signs of impaired myocardial function

- Hypotension, oliguria, cold peripheries
- Narrow pulse pressure
- Raised jugular venous pressure
- Third heart sound
- Quiet first heart sound
- Diffuse apical impulse
- Lung crepitations

Low-grade fever

i 16.50 Common arrhythmias in acute coronary syndrome

- Ventricular fibrillation
- Ventricular tachycardia
- Accelerated idioventricular rhythm
- Ventricular ectopics
- Atrial fibrillation
- Sinus bradycardia (particularly after inferior myocardial infarction)
- Atrioventricular block

Recurrent angina

Patients who develop recurrent angina at rest or on minimal exertion following an acute coronary syndrome are at high risk and should be considered for prompt coronary angiography with a view to revascularisation. Patients with dynamic ECG changes and ongoing pain should be considered for treatment with intravenous glycoprotein IIb/IIIa receptor antagonists (tirofiban 400 ng/kg/min for 30 min, then 100 ng/kg/min for 48 hrs, or abciximab, initially 180 μg/kg, then 2 μg/kg/min for up to 72 hrs). Patients with resistant pain or marked haemodynamic changes should be considered for intra-aortic balloon counterpulsation and emergency coronary revascularisation. Post-infarct angina occurs in up to 50% of patients treated with thrombolysis. Most patients have a residual stenosis in the infarct-related vessel, despite successful thrombolysis, and this may cause angina if there is still viable myocardium downstream. For this reason, all patients who have received successful thrombolysis should be considered for early (within the first 24 hours) coronary angiography with a view to coronary revascularisation.

Acute heart failure

Acute heart failure usually reflects extensive myocardial damage and is associated with a poor prognosis. All the other complications of MI are more likely to occur when acute heart failure is present. The assessment and management of heart failure is discussed in more detail earlier in this chapter.

Pericarditis

This only occurs following infarction and is particularly common on the second and third days. The patient may recognise that a different pain has developed, even though it is at the same site, and that it is positional and tends to be worse or sometimes present only on inspiration. A pericardial rub may be audible. Opiate-based analgesia should be used. Non-steroidal (NSAIDs) and steroidal anti-inflammatory drugs may increase the risk of aneurysm formation and myocardial rupture in the early recovery period and should be avoided where possible.

Dressler syndrome

This syndrome is characterised by persistent fever, pericarditis and pleurisy, and is probably due to autoimmunity. The symptoms tend to occur a few weeks or even months after MI and often subside after a few days. If the symptoms are prolonged or severe, treatment with high-dose aspirin, NSAIDs or even glucocorticoid steroids may be required.

Papillary muscle rupture

This typically presents with acute pulmonary oedema and shock due to the sudden onset of severe mitral regurgitation. Examination usually reveals a pansystolic murmur and third heart sound, but the murmur may be quiet or absent in patients with severe regurgitation. The diagnosis is confirmed by echocardiography, and emergency valve replacement may be necessary. Lesser degrees of mitral regurgitation due to papillary muscle dysfunction are common and may be transient.

Ventricular septal rupture

This usually presents with sudden haemodynamic deterioration accompanied by a new loud pansystolic murmur radiating to the right sternal border, which may be difficult to distinguish from acute mitral regurgitation. Rupture of the intraventricular septum causes left-to-right shunting through a ventricular septal defect, which tends to cause acute right heart failure rather than pulmonary oedema. Doppler echocardiography and right heart catheterisation will confirm the diagnosis. Treatment is by emergency surgical repair; without which, the condition is usually fatal.

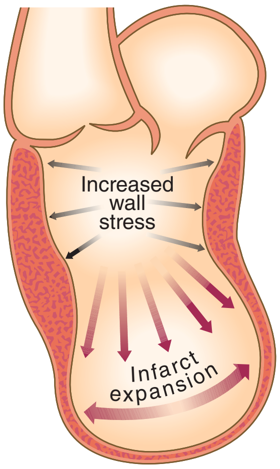

Fig. 16.63 Infarct expansion and ventricular remodelling. Full-thickness myocardial infarction causes thinning and stretching of the infarcted segment (infarct expansion), which leads to increased wall stress with progressive dilatation and hypertrophy of the remaining ventricle (ventricular remodelling).

Ventricular rupture

Rupture of the ventricle may lead to cardiac tamponade and is usually fatal, although it is occasionally possible to support a patient until emergency surgery can be performed.

Embolism

Thrombus often forms on the endocardial surface of freshly infarcted myocardium. This can lead to systemic embolism and occasionally causes a stroke or ischaemic limb. Venous thrombosis and pulmonary embolism may occur but have become less common with the use of prophylactic anticoagulants and early mobilisation.

Ventricular remodelling

This is a potential complication of an acute transmural MI due to thinning and stretching of the infarcted segment. This leads to an increase in wall stress with progressive dilatation and hypertrophy of the remaining ventricle (ventricular remodelling, Fig. 16.63). As the ventricle dilates, it becomes less efficient and heart failure may supervene. Infarct expansion occurs over a few days and weeks, but ventricular remodelling can take years. Beta-blocker, ACE inhibitor and mineralocorticoid receptor antagonist therapies can reduce late ventricular remodelling and prevent the onset of heart failure.

Ventricular aneurysm

Ventricular aneurysm develops in approximately 10% of patients with MI and is particularly common when there is persistent occlusion of the infarct-related vessel. Heart failure, ventricular arrhythmias, mural thrombus and systemic embolism are all recognised complications of aneurysm formation. Other features include a paradoxical impulse on the chest wall, persistent ST elevation on the ECG, and sometimes an unusual bulge from the cardiac silhouette on the chest X-ray. Echocardiography is diagnostic. Surgical removal of a left ventricular aneurysm carries a high morbidity and mortality but is sometimes necessary.

Investigations

Electrocardiogram

The standard 12-lead ECG is central to confirming the diagnosis and deciding immediate management but may be difficult to interpret if there

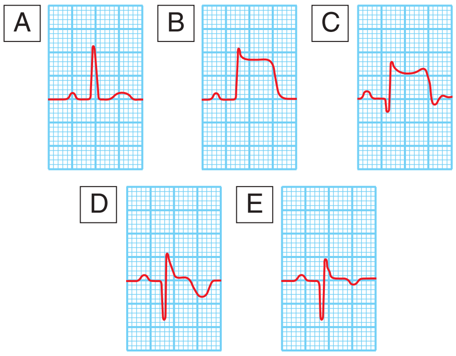

Fig. 16.64 The serial evolution of ECG changes in transmural myocardial infarction. **A** Normal ECG complex. **B** Acute ST elevation ('the current of injury'). **C** Progressive loss of the R wave, developing Q wave, resolution of the ST elevation and terminal T-wave inversion. **D** Deep Q wave and T-wave inversion. **E** Old or established infarct pattern; the Q wave tends to persist, but the T-wave changes become less marked. The rate of evolution is very variable but, in general, stage B appears within minutes, stage C within hours, stage D within days and stage E after several weeks or months. This should be compared with the 12-lead ECGs in Figures 16.65–16.67.

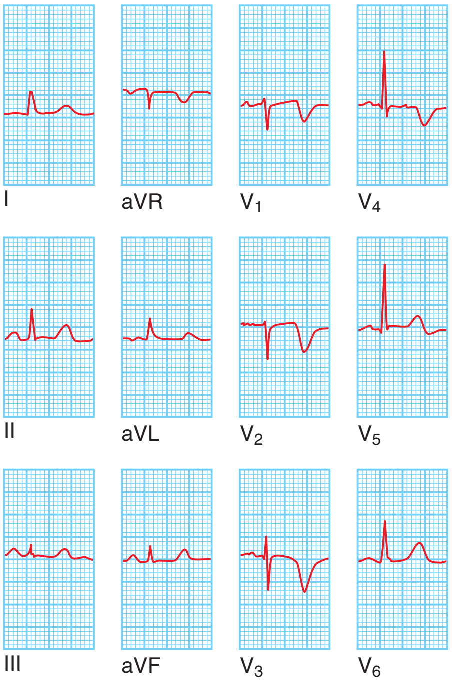

Fig. 16.65 Recent anterior non-ST elevation (subendocardial) myocardial infarction. This ECG demonstrates deep symmetrical T-wave inversion, together with a reduction in the height of the R wave in leads V_1, V_2, V_3 and V_4.

is bundle branch block or previous MI. The initial ECG may be normal or non-diagnostic in one-third of cases. Repeated ECGs are important, especially where the diagnosis is uncertain, or the patient has recurrent or persistent symptoms. The earliest ECG change is usually ST-segment deviation. With proximal occlusion of a major coronary artery, ST-segment elevation (or new bundle branch block) is seen initially, with later diminution in the size of the R wave and, in transmural (full-thickness) infarction, development of a Q wave. Subsequently, the T wave becomes inverted because of a change in ventricular repolarisation; this change persists after the ST segment has returned to normal. These sequential features (Fig. 16.64) are sufficiently reliable for the approximate age of the infarct to be deduced.

In non-ST segment elevation acute coronary syndrome, there is usually partial occlusion of a major vessel or complete occlusion of a minor vessel, causing unstable angina or partial-thickness (subendocardial) MI. This is associated with ST-segment depression and T-wave changes. In the presence of infarction, this may be accompanied by some loss of R waves in the absence of Q waves (Fig. 16.65).

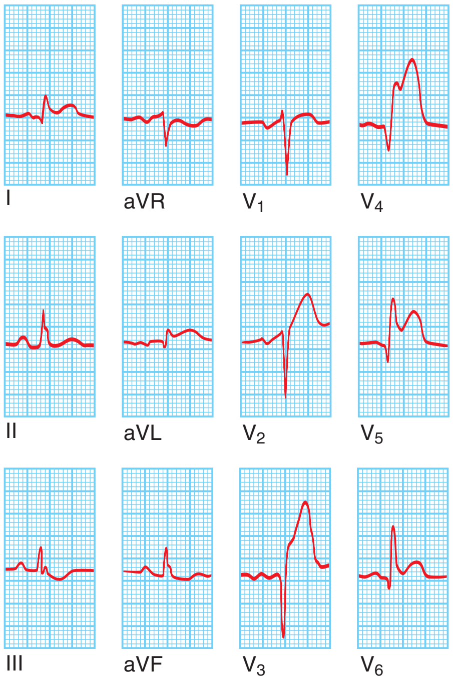

Fig. 16.66 Acute transmural anterior myocardial infarction. This ECG was recorded from a patient who had developed severe chest pain 6 hours earlier. There is ST elevation in leads I, aVL, V_2, V_3, V_4, V_5 and V_6, and there are Q waves in leads V_3, V_4 and V_5. Anterior infarcts with prominent changes in leads V_2, V_3 and V_4 are sometimes called 'anteroseptal' infarcts, as opposed to 'anterolateral' infarcts, in which the ECG changes are predominantly found in V_4, V_5 and V_6.

The ECG changes are best seen in the leads that 'face' the ischaemic or infarcted area. When there has been anteroseptal infarction, abnormalities are found in one or more leads from V_1 to V_4, while anterolateral infarction produces changes from V_4 to V_6, in aVL and in lead I. Inferior infarction is best shown in leads II, III and aVF, while, at the same time, leads I, aVL and the anterior chest leads may show 'reciprocal' changes of ST depression (Figs. 16.66 and 16.67). Infarction of the posterior wall of the LV does not cause ST elevation or Q waves in the standard leads but can be diagnosed by the presence of reciprocal changes (ST depression and a tall R wave in leads V_1–V_4). Some infarctions (especially inferior) also involve the RV. This may be identified by recording from additional leads placed over the right precordium.

Cardiac biomarkers

Serial measurements of cardiac troponin concentration should be taken. In unstable angina, there is no detectable rise in troponin and the diagnosis is made on the basis of the clinical features and investigations such as ECG or coronary angiography. In contrast, MI causes a rise in plasma concentrations of the structural proteins, troponin T and I, or cardiac muscle enzymes (Fig. 16.68 and see Box 16.47). Levels of troponins T and I increase within 3–6 hours, peak at about 12–36 hours and remain elevated for up to 2 weeks. A full blood count may reveal the presence of a leucocytosis, which reaches a peak on the first day. The erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP) are also elevated. Lipids should be measured within 24 hours of presentation because there is often a transient fall in cholesterol in the 3 months following infarction.

Radiography

A chest X-ray should be performed since this may demonstrate pulmonary oedema that is not evident on clinical examination (see Fig. 16.25). The heart size is often normal but there may be cardiomegaly due to pre-existing myocardial damage.

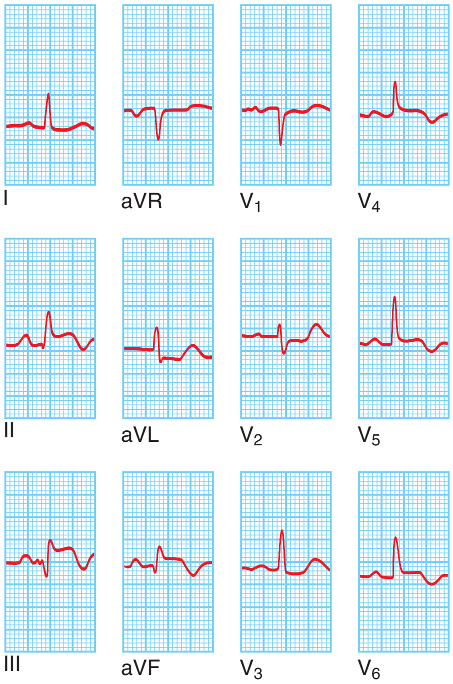

Fig. 16.67 Acute transmural inferolateral myocardial infarction. This ECG was recorded from a patient who had developed severe chest pain 4 hours earlier. There is ST elevation in inferior leads II, III and aVF and lateral leads V_4, V_5 and V_6. There is also 'reciprocal' ST depression in leads aVL and V_2.

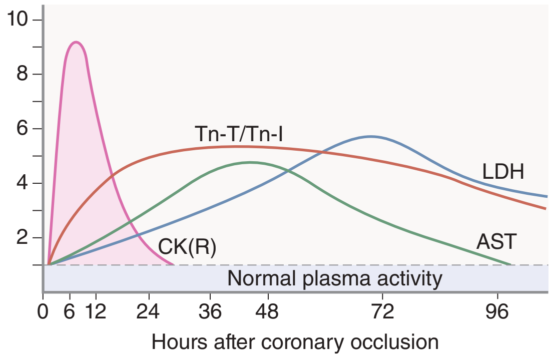

Fig. 16.68 Changes in plasma cardiac biomarker concentrations after myocardial infarction. Creatine kinase (CK) and troponins T (Tn-T) and I (Tn-I) are the first to rise, followed by aspartate aminotransferase (AST) and then lactate (hydroxybutyrate) dehydrogenase (LDH). In patients treated with reperfusion therapy, a rapid rise in plasma creatine kinase (curve CK(R)) occurs, due to a washout effect.

Echocardiography

Echocardiography is normally performed before discharge from hospital and is useful for assessing ventricular function and for detecting important complications, such as mural thrombus, cardiac rupture, ventricular septal defect, mitral regurgitation and pericardial effusion.

Coronary angiography

Coronary arteriography should be considered with a view to revascularisation in all patients at moderate or high risk of a further event, including those who fail to settle on medical therapy, those with extensive ECG changes, those with an elevated cardiac troponin and those with severe pre-existing stable angina (see Fig. 16.69). This often reveals disease that is amenable to PCI or urgent CABG (see below).

Management

All patients with suspected acute coronary syndrome should be admitted urgently to hospital because there is a risk of death or recurrent myocardial ischaemia during the early unstable phase. Appropriate medical therapy can reduce the incidence of these complications by at least 60%. The key elements of immediate in-hospital management are shown in Figure 16.69. Patients should ideally be managed in a dedicated cardiac unit, where the necessary expertise, monitoring and resuscitation facilities are available. Clinical risk factor analysis using tools such as the GRACE score (see Fig. 16.61) should be performed to identify patients that should be selected for intensive therapy, and specifically early inpatient coronary angiography (thresholds vary, but a score of 140 points or more supports early intervention). If there are no complications and the risk is low, the patient can be mobilised from the second day and discharged after 2–3 days. Low-risk patients without spontaneous angina may be considered for an exercise tolerance test or outpatient coronary angiography 4–6 weeks after the acute coronary syndrome. This will help to identify those individuals who may require further intervention and may help to boost the confidence of the remainder. Management of the acute event is discussed below, and the principles of long-term management are summarised in Box 16.51.

Analgesia

Adequate analgesia is essential, not only to relieve distress but also to lower adrenergic drive and thereby reduce vascular resistance, BP, infarct size and susceptibility to ventricular arrhythmias. Intravenous opiates (initially, morphine sulphate 5–10 mg or diamorphine 2.5–5 mg) and antiemetics (initially, metoclopramide 10 mg) should be administered, and titrated until the patient is comfortable. Intramuscular injections should be avoided because the clinical effect may be delayed by poor skeletal muscle perfusion, and a painful haematoma may form following thrombolytic or antithrombotic therapy.

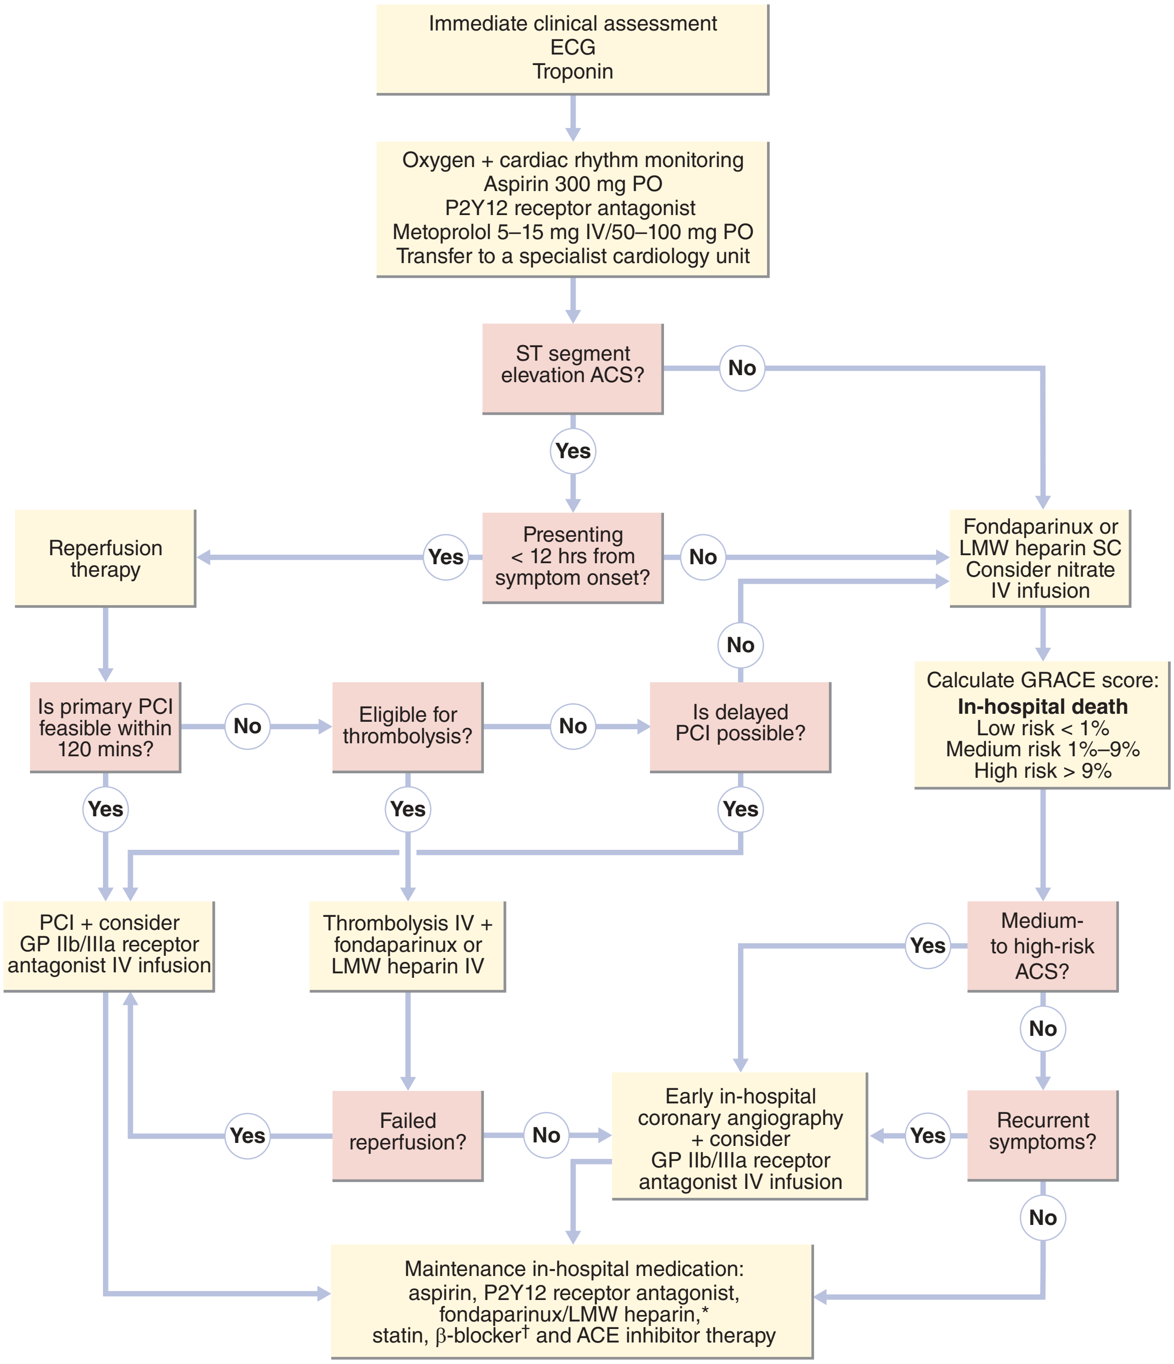
Reperfusion therapy

Immediate reperfusion therapy with PCI (see Fig. 16.59) is indicated when the ECG shows new bundle branch block or characteristic ST-segment elevation in two contiguous leads of 1 mm or more in the limb leads or 2 mm or more in the chest leads. This is the treatment of choice for those presenting within 12 hours of symptom onset (see Fig. 16.69). If PCI cannot be performed within 120 minutes for any reason, and thrombolysis is contraindicated, the procedure should be performed as soon as practically possible. Patients should be considered for PCI within the first 24 hours, even if they have reperfused spontaneously or with thrombolytic therapy. Coronary artery patency is restored in over 95% of patients undergoing PCI. The procedure preserves left ventricular function with a marked reduction in the progression to heart failure, more than halves rates of recurrent MI and dramatically improves mortality with more than 95% 1-year survival rates in clinical trials. Successful therapy is also associated with rapid pain relief, resolution of acute ST elevation and occasional transient arrhythmias.

Reperfusion therapy with PCI confers no mortality benefit in patients with non-ST segment elevation acute coronary syndrome but can reduce rehospitalisation with recurrent non-fatal myocardial infarction although these benefits are more limited in elderly patients (> 75 years). Selected medium- to high-risk patients do benefit from in-hospital coronary angiography and coronary revascularisation, but this does not need to take place in the first 12 hours unless there are high-risk features, such as ongoing chest pain or ECG changes.

Thrombolytic therapy

If primary PCI cannot be achieved in a timely manner in patients with ST-segment elevation MI (see Fig. 16.69), thrombolytic therapy should be administered. Although the survival advantage is not as good as primary PCI, mortality is reduced, and this is maintained for at least 10 years. The benefit of thrombolytic therapy is greatest in those patients who



Immediate clinical assessment
ECG
Troponin
Oxygen + cardiac rhythm monitoring

Maintenance in-hospital medication: aspirin, P2Y12 receptor antagonist, fondaparinux/LMW heparin,* statin, β-blocker† and ACE inhibitor therapy

Fig. 16.69 Summary of treatment for acute coronary syndrome (ACS). *Not required following PCI. †β-blocker should be continued only if evidence of left ventricular systolic dysfunction. For details of the GRACE score, see Figure 16.61. (ACE = angiotensin-converting enzyme; ECG = electrocardiogram; GP = glycoprotein; IV = intravenous; LMW = low-molecular-weight; PCI = percutaneous coronary intervention; PO = by mouth; SC = subcutaneous) *Adapted from Scottish Intercollegiate Guidelines Network (SIGN) Guideline no. 93 – Acute coronary syndromes, February 2007 and updated in SIGN 148, April 2016.*

receive treatment within the first 12 hours and especially the first 2 hours. Modern thrombolytic agents, such as tenecteplase (TNK) and reteplase (rPA), are analogues of human tissue plasminogen activator and can be given as an intravenous bolus, allowing prompt treatment to be given in the emergency department or in the pre-hospital setting. The major hazard of thrombolytic therapy is bleeding. Cerebral haemorrhage causes 4 extra strokes per 1000 patients treated, and the incidence of other major bleeds is between 0.5% and 1%. Accordingly, the treatment should be withheld if there is a significant risk of serious bleeding (Box 16.52). For some patients, thrombolytic therapy is contraindicated or fails to achieve coronary arterial reperfusion (see Fig. 16.69). Emergency PCI may then be considered, particularly where there is evidence of cardiogenic shock. Even where thrombolysis successfully achieves reperfusion, PCI should be considered within 24 hours to prevent recurrent infarction and improve outcome.

Antithrombotic therapy

Oral administration of 75–325 mg aspirin daily improves survival, with a 25% relative risk reduction in mortality. The first tablet (300 mg) should be given orally within the first 12 hours and therapy should be continued indefinitely if there are no side-effects. A P2Y12 receptor antagonist (ticagrelor (180 mg, followed by 90 mg twice daily), prasugrel (60 mg, followed by 10 mg daily) or clopidogrel (300 mg, followed by 75 mg daily)) should be given in combination with aspirin for up to 12 months. Glycoprotein

16.51 Late management of myocardial infarction

Risk stratification and further investigation

See text for details

Lifestyle modification

- Diet (weight control, lipid-lowering, 'Mediterranean diet')
- Cessation of smoking
- Regular exercise

Secondary prevention drug therapy

- Antiplatelet therapy (aspirin and/or clopidogrel)
- β-blocker*
- ACE inhibitor/ARB
- Statin
- Additional therapy for control of diabetes and hypertension
- Mineralocorticoid receptor antagonist

Rehabilitation

Devices

- Implantable cardiac defibrillator (high-risk patients)

*Only in patients with left ventricular systolic dysfunction.
(ACE = angiotensin-converting enzyme; ARB = angiotensin receptor blocker)

16.52 Relative contraindications to thrombolytic therapy

- Active internal bleeding
- Previous subarachnoid or intracerebral haemorrhage
- Uncontrolled hypertension
- Recent surgery (within 1 month)
- Recent trauma (including traumatic resuscitation)
- High probability of active peptic ulcer
- Pregnancy

IIb/IIIa receptor antagonists, such as tirofiban and abciximab, block the final common pathway of platelet aggregation and are potent inhibitors of platelet-rich thrombus formation. They are of particular benefit in high-risk patients with acute coronary syndromes who undergo PCI, especially those with a high thrombus burden at angiography or who have received inadequate prior antiplatelet therapy. Anticoagulation further reduces the risk of thromboembolic complications and prevents re-infarction in the absence of reperfusion therapy or after successful thrombolysis. Anticoagulation can be achieved using unfractionated heparin, fractioned (low-molecular-weight) heparin or a pentasaccharide, such as subcutaneous fondaparinux (2.5 mg daily). Comparative clinical trials show that the pentasaccharides have the best safety and efficacy profile but low-molecular-weight heparin, such as subcutaneous enoxaparin (1 mg/kg twice daily), is a reasonable alternative. Anticoagulation should be continued for 8 days or until discharge from hospital or coronary revascularisation has been completed. A period of treatment with an oral anticoagulant should be considered if there is persistent AF or evidence of extensive anterior infarction with mural thrombus because these patients are at increased risk of systemic thromboembolism.

Anti-anginal therapy

Sublingual glyceryl trinitrate (300–500 µg) is a valuable first-aid measure in unstable angina or threatened infarction, and intravenous nitrates (glyceryl trinitrate 0.6–1.2 mg/hr or isosorbide dinitrate 1–2 mg/hr) are useful for the treatment of left ventricular failure and the relief of recurrent or persistent ischaemic pain. Intravenous β-blockade (atenolol 5–10 mg or metoprolol 5–15 mg given over 5 min) relieves pain, reduces arrhythmias and improves short-term mortality in patients who present within 12 hours of symptom onset (see Fig. 16.69). However, they should be avoided if there is heart failure (pulmonary oedema), hypotension (systolic BP < 105 mmHg) or bradycardia (heart rate < 65/min). Nifedipine or amlodipine can be added if there is persistent chest discomfort, but these drugs may cause tachycardia if used alone. Verapamil and diltiazem can be used if β-blockade is contraindicated. In the longer term, treatment with an oral β-blocker reduces long-term mortality by approximately 25% among the survivors of an acute MI, but not in those who have normal left ventricular function. Patients with left ventricular systolic dysfunction or heart failure combined with COPD or peripheral arterial disease appear to derive similar secondary preventative benefits from β-blocker therapy and should receive maintenance therapy unless poorly tolerated. Unfortunately, a minority of patients do not tolerate β-blockade because of bradycardia, AV block, hypotension or asthma.

Renin–angiotensin blockade

Long-term treatment with ACE inhibitors, such as enalapril (10 mg twice daily) or ramipril (2.5–5 mg twice daily), can counteract ventricular remodelling, prevent the onset of heart failure, improve survival, reduce recurrent MI and avoid rehospitalisation. The benefits are greatest in those with overt heart failure (clinical or radiological) but extend to patients with asymptomatic left ventricular systolic dysfunction and those with preserved left ventricular function. They should be considered in all patients with acute coronary syndrome. Caution must be exercised in hypovolaemic or hypotensive patients because ACE inhibition may exacerbate hypotension and impair coronary perfusion. In patients intolerant of ACE inhibitors, ARBs such as valsartan (40–160 mg twice daily) or candesartan (4–16 mg daily) are alternatives that are better tolerated.

Mineralocorticoid receptor antagonists

Patients with acute MI and left ventricular dysfunction (ejection fraction < 35%) and either pulmonary oedema or diabetes mellitus further benefit from additional mineralocorticoid receptor antagonists (eplerenone 25–50 mg daily, or spironolactone 25–50 mg daily).

Lipid-lowering therapy

The benefits of lowering serum cholesterol following acute coronary syndrome have been demonstrated in several large-scale randomised trials. All patients should receive therapy with HMG CoA reductase enzyme inhibitors, such as atorvastatin (80 mg daily), after acute coronary syndrome, irrespective of serum cholesterol concentrations. Other agents, such as ezetimibe, fibrates, anion exchange resins and injectable PCSK9 inhibitors, may be used in cases where total cholesterol or LDL cholesterol cannot be lowered adequately using statins alone (target of LDL cholesterol ≤ 2.0 mmol/L).

Smoking cessation

The 5-year mortality of patients who continue to smoke cigarettes is double that of those who quit smoking at the time of their acute coronary syndrome. Giving up smoking is the single most effective contribution a patient can make to their future. The success of smoking cessation can be increased by supportive advice and pharmacological therapy.

Diet and exercise

Maintaining an ideal body weight, eating a Mediterranean-style diet, taking regular exercise, and achieving good control of hypertension and diabetes mellitus may all improve the long-term outlook.

Rehabilitation

When there are no complications, the patient can mobilise on the second day, return home in 2–3 days and gradually increase activity, with the aim of returning to work in 4 weeks. The majority of patients may resume driving after 1–4 weeks, although, in most countries, drivers of heavy goods and public service vehicles require special assessment before returning to work. Emotional problems, such as denial, anxiety and depression, are common and must be addressed. Some patients are severely and even permanently incapacitated as a result of the psychological effects of acute coronary syndrome rather than the physical ones, and all benefit from thoughtful explanation, counselling and reassurance. Many patients mistakenly believe that stress was the cause of their heart attack and may restrict their activity inappropriately. The patient's spouse or partner will also require emotional support, information and counselling.

Formal rehabilitation programmes, based on graded exercise protocols with individual and group counselling, are often very successful and, in some cases, have been shown to improve quality of life and long-term outcome.

Implantable defibrillators

These devices are of benefit in preventing sudden cardiac death in patients who have severe left ventricular impairment (ejection fraction $\leq$30%) after MI. More details are provided in the section on treatment of cardiac arrhythmias.

Type 2 myocardial infarction

The optimal management and treatment of patients with type 2 MI has yet to be established. There is currently no evidence that treatments for type 1 MI are effective in the setting of type 2 MI. The focus for patients with type 2 MI should be on treating the underlying cause of their presentation and, where applicable, their previously undiagnosed concomitant CAD.

Prognosis

The prognosis of patients who have survived an acute coronary syndrome is related to the extent of residual myocardial ischaemia, the degree of myocardial damage and the presence of ventricular arrhythmias. In almost one-quarter of all cases of MI, death occurs within a few minutes without medical care. Half the deaths occur within 24 hours of the onset of symptoms and about 40% of all affected patients die within the first month. The prognosis of those who survive to reach hospital is much better, with a 28-day survival of more than 85%. Patients with unstable angina have a mortality of approximately half that of patients with MI. Early death is usually due to an arrhythmia and is independent of the extent of MI. However, late outcomes are determined by the extent of myocardial damage, and unfavourable features include poor left ventricular function, AV block and persistent ventricular arrhythmias. The prognosis is worse for anterior than for inferior infarcts. Bundle branch block and high cardiac marker concentrations both indicate extensive myocardial damage. Old age, depression and social isolation are also associated with a higher mortality. Of those who survive an acute attack, more than 80% live for a further year, about 75% for 5 years, 50% for 10 years and 25% for 20 years.

Some considerations specific to myocardial infarction in old age are listed in Box 16.53.

Non-cardiac surgery in patients with heart disease

Non-cardiac surgery, particularly major vascular, abdominal or thoracic surgery, can precipitate serious perioperative cardiac complications, such as MI and death, in patients with CAD and other forms of heart disease. Careful pre-operative cardiac assessment may help to determine the balance of benefit versus risk on an individual basis and to identify measures that minimise the operative risk (Box 16.54).

A hypercoagulable state is part of the normal physiological response to surgery and may promote coronary thrombosis leading to an acute coronary syndrome in the early post-operative period. Patients with a history of recent PCI or acute coronary syndrome are at greatest risk and, whenever possible, elective non-cardiac surgery should be avoided for 3 months after such an event. Where possible, antiplatelet, statin and β-blocker therapies should be continued throughout the perioperative period.

Careful attention to fluid balance during and after surgery is particularly important in patients with impaired left ventricular function and valvular heart disease because vasopressin is released as part of the normal physiological response to surgery and, in these circumstances, the excessive administration of intravenous fluids can easily precipitate heart failure. Patients with severe valvular heart disease, particularly aortic stenosis and mitral stenosis, are also at increased risk because they may not be able to increase their cardiac output in response to the stress of surgery.

16.53 Myocardial infarction in old age

- **Atypical presentation**: often with anorexia, fatigue, weakness, delirium or falls rather than chest pain.
- **Case fatality**: rises steeply. Hospital mortality exceeds 25% in those over 75 years old, which is five times greater than that seen in those aged less than 55 years.
- **Survival benefit of treatments**: not influenced by age. The absolute benefit of evidence-based treatments may therefore be greatest in older people.
- **Hazards of treatments**: rise with age (for example, increased risk of intracerebral bleeding after thrombolysis) and are due partly to increased comorbidity.
- **Quality of evidence**: older patients, particularly those with significant comorbidity, were under-represented in many of the randomised controlled clinical trials that helped to establish the treatment of myocardial infarction. The balance of risk and benefit for many treatments, such as thrombolysis and primary percutaneous transluminal coronary angiography, in frail older people is uncertain.

16.54 Major risk factors for cardiac complications of non-cardiac surgery

- Recent (<6 months) myocardial infarction or unstable angina
- Severe coronary artery disease: left main stem or three-vessel disease
- Severe stable angina on effort
- Severe left ventricular dysfunction
- Severe valvular heart disease (especially aortic stenosis)

Atrial fibrillation is a common post-operative complication in patients with pre-existing heart disease which may be triggered by hypoxia, myocardial ischaemia or heart failure. It usually terminates spontaneously when the precipitating factors have been eliminated, but digoxin or β-blockers can be prescribed to control the heart rate if necessary.

Peripheral arterial disease

Peripheral arterial disease (PAD) has been estimated to affect about 20% of individuals aged 55–75 years in the UK. Only 25% of patients present with symptoms, the commonest of which is intermittent claudication (IC). About 1%–2% of patients with IC per year progress to a point where amputation or revascularisation is required. However, the annual mortality rate of people with IC is about 5%, which is 2–3 times higher than the general population of the same age and sex. The cause of death is typically an MI or stroke, reflecting the fact that IC nearly always occurs in association with widespread atherosclerosis.

Pathogenesis

In developed countries, almost all PAD is due to atherosclerosis and the risk factors are the same as described in patients with CAD. As with CAD, plaque rupture is responsible for the most serious manifestations of PAD, and not infrequently occurs in a plaque that hitherto has been asymptomatic. The clinical manifestations depend on the anatomical site, the presence or absence of a collateral supply, the speed of onset and the mechanism of injury (Box 16.55). Approximately 5%–10% of patients with PAD have diabetes but this proportion increases to 30%–40% in those with severe limb ischaemia. The mechanism of PAD in diabetes is atheroma affecting the medium to large-sized arteries rather than obstructive microangiopathy and diabetes is not a contraindication to lower limb revascularisation. Nevertheless, patients with diabetes and PAD pose a number of particular problems (Box 16.56).

Clinical features

Symptomatic PAD affects the legs about eight times more commonly than the arms. Several locations may be affected, including the aorto-iliac vessels, the femoropopliteal vessels and the infrapopliteal vessels.

16.55 Factors influencing the clinical manifestations of peripheral arterial disease (PAD)

Anatomical site

Cerebral circulation

- TIA, amaurosis fugax, vertebrobasilar insufficiency

Renal arteries

- Hypertension and renal failure

Mesenteric arteries

- Mesenteric angina, acute intestinal ischaemia

Limbs (legs >> arms)

- Intermittent claudication, critical limb ischaemia, acute limb ischaemia

Collateral supply

- In a patient with a complete circle of Willis, occlusion of one carotid artery may be asymptomatic
- In a patient without cross-circulation, stroke is likely

Speed of onset

- Where PAD develops slowly, a collateral supply will develop
- Sudden occlusion of a previously normal artery is likely to cause severe distal ischaemia

Mechanism of injury

Haemodynamic

- Plaque must reduce arterial diameter by 70% (‘critical stenosis’) to reduce flow and pressure at rest. On exertion a moderate stenosis may become ‘critical’. This mechanism tends to have a relatively benign course due to collateralisation

Thrombotic

- Occlusion of a long-standing critical stenosis may be asymptomatic due to collateralisation. However, acute rupture and thrombosis of a non-haemodynamically significant plaque usually has severe consequences

Atheroembolic

- Symptoms depend on embolic load and size
- Carotid (TIA, amaurosis fugax or stroke) and peripheral arterial (blue toe/finger syndrome) plaque are common examples

Thromboembolic

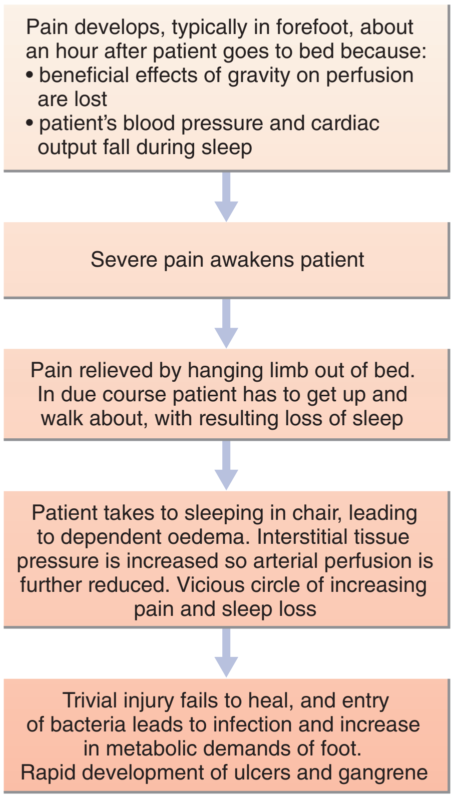
- Usually secondary to atrial fibrillation
- The consequences are usually dramatic, as the thrombus load is often large and occludes a major, previously healthy, non-collateralised artery suddenly and completely

(TIA = transient ischaemic attack)

16.56 Peripheral vascular disease in diabetes

Feature	Difficulty
Arterial calcification	Spuriously high ABPI due to incompressible ankle vessels. Inability to clamp arteries for the purposes of bypass surgery. Resistant to angioplasty
Immunocompromise	Prone to rapidly spreading cellulitis, gangrene and osteomyelitis
Multisystem arterial disease	Coronary and cerebral arterial disease increase the risks of intervention
Distal disease	Diabetic vascular disease has a predilection for the calf vessels. Although vessels in the foot are often spared, performing a satisfactory bypass or angioplasty to these small vessels is a technical challenge
Sensory neuropathy	Even severe ischaemia and/or tissue loss may be completely painless. Diabetic patients often present late with extensive destruction of the foot. Loss of proprioception leads to abnormal pressure loads and worsens joint destruction (Charcot joints)
Motor neuropathy	Weakness of the long and short flexors and extensors leads to abnormal foot architecture, abnormal pressure loads, callus formation and ulceration
Autonomic neuropathy	Leads to a dry foot deficient in sweat that normally lubricates the skin and is antibacterial. Scaling and fissuring create a portal of entry for bacteria. Abnormal blood flow in the bones of the ankle and foot may also contribute to osteopenia and bony collapse

(ABPI = ankle–brachial pressure index)



Pain develops, typically in forefoot, about an hour after patient goes to bed because:
- beneficial effects of gravity on perfusion are lost
- patient’s blood pressure and cardiac output fall during sleep

Severe pain awakens patient

Pain relieved by hanging limb out of bed. In due course patient has to get up and walk about, with resulting loss of sleep

Patient takes to sleeping in chair, leading to dependent oedema. Interstitial tissue pressure is increased so arterial perfusion is further reduced. Vicious circle of increasing pain and sleep loss

Trivial injury fails to heal, and entry of bacteria leads to infection and increase in metabolic demands of foot. Rapid development of ulcers and gangrene

Fig. 16.70 Progressive night pain and the development of tissue loss.

One or more of these segments may be affected in a variable and asymmetric manner. In the arm, the subclavian artery is the commonest site of disease. Peripheral artery disease can present clinically in a variety of ways, as detailed below.

Intermittent claudication

This is the most common presentation of PAD affecting the lower limbs. It is characterised by ischaemic pain affecting the muscles of the leg. The pain is usually felt in the calf because the disease most commonly affects the superficial femoral artery, but it may be felt in the thigh or buttock if the iliac arteries are involved. Typically, the pain comes on after walking, often once a specific distance has been covered, and rapidly subsides on resting. Resumption of walking leads to a return of the pain. Most patients describe a cyclical pattern of exacerbation and resolution due to the progression of disease and the subsequent development of collaterals. When PAD affects the upper limbs, arm claudication may occur, although this is uncommon.

Critical limb ischaemia

Critical limb ischaemia (CLI) is defined as rest pain requiring opiate analgesia, or ulceration or gangrene that has been present for more than 2 weeks, in the presence of an ankle BP of less than 50 mmHg. The typical progression of symptoms in CLI is summarised in Figure 16.70. Rest pain only, with ankle pressures above 50 mmHg, is known as subcritical limb ischaemia (SCLI). The term severe limb ischaemia (SLI) is used to describe the situation where either CLI and SCLI occurs. Whereas IC is usually due to single-segment plaque, SLI is always due to multilevel disease. Many patients with SLI have not previously sought medical advice, principally because they have other comorbidity that prevents them from walking to a point where IC develops. Patients with SLI are at high risk of losing their limb, and sometimes their life, in a matter of weeks or months without surgical bypass or endovascular revascularisation by angioplasty or stenting. Treatment of these patients is difficult because most are older adults with extensive and severe disease and major multisystem comorbidities.

Acute limb ischaemia

This is most frequently caused by acute thrombotic occlusion of a pre-existing stenotic arterial segment, thromboembolism and trauma that may be iatrogenic. The typical presentation is with paralysis (inability to wiggle toes or fingers) and paraesthesia (loss of light touch over the dorsum of the foot or hand); the so-called 'Ps of acute ischaemia' (Box 16.57). These features are non-specific and inconsistently related to its severity. Pain on squeezing the calf indicates muscle infarction and impending irreversible ischaemia. All patients with suspected acutely ischaemic limbs must be discussed immediately with a vascular surgeon; a few hours can make the difference between death or amputation and complete recovery of limb function. If there are no contraindications (acute aortic dissection or trauma, particularly head injury), an intravenous bolus of heparin (3000–5000 U) should be administered to limit propagation of thrombus and protect the collateral circulation. Distinguishing thrombosis from embolism is frequently difficult but is important because treatment and prognosis are different (Box 16.58). Acute limb ischaemia due to thrombosis in situ can usually be treated medically in the first instance with intravenous heparin (target activated partial thromboplastin time (APTT) 2.0–3.0), antiplatelet agents, high-dose statins, intravenous fluids to avoid dehydration, correction of anaemia, oxygen and sometimes prostaglandins, such as iloprost. Embolism will normally result in extensive tissue necrosis within 6 hours unless the limb is revascularised. The indications for thrombolysis, if any, remain controversial. Irreversible ischaemia mandates early amputation or palliative care.

16.57 Symptoms and signs of acute limb ischaemia

Symptoms/signs	Comment
Pain	May be absent in complete acute ischaemia, and can be present in chronic ischaemia
Pallor	
Pulselessness	
Perishing cold	Unreliable, as the ischaemic limb takes on the ambient temperature
Paraesthesia	Important features of impending irreversible ischaemia
Paralysis	

16.58 Distinguishing features of embolism and thrombosis in peripheral arteries

Clinical features	Embolism	Thrombosis
Severity	Complete (no collaterals)	Incomplete (collaterals)
Onset	Seconds or minutes	Hours or days
Limb	Leg 3:1 arm	Leg 10:1 arm
Multiple sites	Up to 15%	Rare
Embolic source	Present (usually atrial fibrillation)	Absent
Previous claudication	Absent	Present
Palpation of artery	Soft, tender	Hard, calcified
Bruits	Absent	Present
Contralateral leg pulses	Present	Absent
Diagnosis	Clinical	Angiography
Treatment	Embolectomy, warfarin	Medical, bypass, thrombolysis
Prognosis	Loss of life > loss of limb	Loss of limb > loss of life

Atheroembolism

This may be a presenting feature of PAD affecting the subclavian arteries. The presentation is with blue fingers, which are due to small emboli lodging in digital arteries. This may be confused with Raynaud phenomenon but the symptoms of atheroembolism are typically unilateral rather than bilateral as in Raynaud syndrome.

Subclavian steal

This can be a feature of PAD affecting the upper limbs. The presentation is with dizziness, cortical blindness or collapse, which occurs when the arm is used and is thought to be caused by diversion (or steal) of blood from the brain to the limbs via the vertebral artery.

Investigations

The presence and severity of ischaemia can usually be determined by clinical examination (Box 16.59) and measurement of the ankle–brachial pressure index (ABPI), which is the ratio between the highest systolic ankle and brachial blood pressures. In health, the ABPI is over 1.0, in IC typically 0.5–0.9 and in CLI usually less than 0.5. Further investigation with duplex ultrasonography, MRI or CT with intravenous injection of contrast agents may be used to characterise the sites of involvement further. Intra-arterial digital subtraction angiography (IA-DSA) is used for those undergoing endovascular revascularisation. Other investigations should look for evidence of treatable secondary causes including a full blood count (for thrombocythaemia), lipids (for hyperlipidaemia) and blood glucose (for diabetes mellitus).

Management

Key elements of medical management are summarised in Box 16.60. This consists of smoking cessation (if applicable), taking regular exercise, antiplatelet therapy with low-dose aspirin or clopidogrel, statin therapy, and treatment of coexisting disease such as diabetes, hypertension or polycythaemia. Low-dose factor Xa inhibition (rivaroxaban 2.5 mg twice

16.59 Clinical features of chronic lower limb ischaemia

- Pulses: diminished or absent
- Bruits: denote turbulent flow but bear no relationship to the severity of the underlying disease
- Reduced skin temperature
- Pallor on elevation and rubor on dependency (Buerger's sign)
- Superficial veins that fill sluggishly and empty ('gutter') on minimal elevation
- Muscle-wasting
- Skin and nails: dry, thin and brittle
- Loss of hair

16.60 Medical therapy for peripheral arterial disease

- Smoking cessation
- Regular exercise (30 mins of walking, three times per week)
- Antiplatelet agent (aspirin 75 mg or clopidogrel 75 mg daily)
- Consider low-dose factor Xa inhibitor (rivaroxaban 2.5 mg twice daily)
- Reduction of cholesterol: statins
- Diet and weight loss
- Diagnosis and treatment of diabetes mellitus
- Diagnosis and treatment of associated conditions:
  Hypertension
  Anaemia
  Heart failure

16.61 Atherosclerotic vascular disease in old age

- **Prevalence**: related almost exponentially to age in developed countries, although atherosclerosis is not considered part of the normal ageing process.
- **Statin therapy**: no role in the primary prevention of atherosclerotic disease in those over 75 years but reduces cardiovascular events in those with established vascular disease, albeit with no reduction in overall mortality.
- **Presentation in the frail**: frequently with advanced multisystem arterial disease, along with a host of other comorbidities.
- **Intervention in the frail**: in those with extensive disease and limited life expectancy, the risks of surgery may outweigh the benefits, and symptomatic care is all that should be offered.

daily) when used in combination with aspirin can further reduce cardiovascular events, ischaemic limb events and mortality in patients with PAD although there is a modest increase in bleeding risk. The peripheral vasodilator cilostazol can improve walking distance and should be considered in patients who do not respond adequately to best medical therapy. Intervention with angioplasty, stenting, endarterectomy or bypass is usually considered only after medical therapy has been given for at least 6 months to effect symptomatic improvement, and then just in patients who are severely disabled or whose livelihood is threatened by their disability. Subclavian artery disease is usually treated by means of angioplasty and stenting, as carotid–subclavian bypass surgery can be technically difficult.

Some considerations specific to atherosclerotic vascular disease in old age are listed in Box 16.61.

Buerger disease

Buerger disease or thromboangiitis obliterans is an inflammatory disease of the arteries that is distinct from atherosclerosis and usually presents in young (20–30 years) male smokers. It is commonest in those from the Mediterranean and North Africa. It characteristically affects distal arteries, giving rise to claudication in the feet or rest pain in the fingers or toes. Wrist and ankle pulses are absent but brachial and popliteal pulses are present. It may also affect the veins, giving rise to superficial thrombophlebitis. It often remits if the patient stops smoking. Symptomatic therapy with vasodilators such as prostacyclin and calcium antagonists or sympathectomy may also be helpful. Major limb amputation is the most frequent outcome if patients continue to smoke.

Raynaud syndrome

This common disorder affects 5%–10% of young women aged 15–30 years in temperate climates. It does not progress to ulceration or infarction, and significant pain is unusual. The underlying cause is unclear, and no investigation is necessary. The patient should be reassured and advised to avoid exposure to cold. Usually, no other treatment is required, although vasodilators such as nifedipine may be helpful if symptoms are troublesome. More severe Raynaud syndrome can also occur in association with digital ulceration in patients with connective tissue disease.

Diseases of the aorta

Aortic aneurysm

Aortic aneurysm is defined as an abnormal dilatation of the aortic lumen. The commonest site is the infrarenal abdominal aorta. The suprarenal abdominal aorta and a variable length of the descending thoracic aorta may be affected in 10%–20% of patients but the ascending aorta is usually spared. Abdominal aortic aneurysms (AAAs) affect men three times more commonly than women and are estimated to occur in about 5% of men over the age of 60 years.

Pathogenesis

The commonest cause of aortic aneurysm is atherosclerosis, the risk factors for which have previously been described. However, smoking and hypertension predominate with 90%–95% of patients having one or both risk factors. There also appears to be an additional and specific genetic component since aortic aneurysm tends to run in families. This may explain in part why only some patients with risk factors for atheroma develop aneurysmal disease. Marfan syndrome is an inherited disorder of connective tissue that is associated with aortic aneurysm and aortic dissection.

Clinical features

The clinical presentation is dependent on the site of the aneurysm. Thoracic aneurysms may typically present with acute severe chest pain but other features, including aortic regurgitation, compressive symptoms such as stridor (trachea, bronchus), hoarseness (recurrent laryngeal nerve) and superior vena cava syndrome, may occur (Fig. 16.71A). If the aneurysm erodes into an adjacent structure, such as the oesophagus or bronchus, the presentation may be with massive bleeding. AAAs affect the infrarenal segment of the aorta. They can present in several ways, as summarised in Box 16.62. The usual age at presentation is 65–75 years for elective presentations and 75–85 years for emergency presentations.

Investigations

Ultrasound is the best way of establishing the diagnosis of an abdominal aneurysm and of following up patients with asymptomatic aneurysms that are not yet large enough to warrant surgical repair. In the UK, a national screening programme for men over 65 years of age has been introduced using ultrasound scanning. For every 10 000 men scanned, 65 ruptures are prevented, and 52 lives saved. CT provides more accurate information about the size and extent of the aneurysm, the surrounding structures and the presence of any other intra-abdominal pathology. It is the standard pre-operative investigation but is not suitable for surveillance because of the high cost and radiation dose.

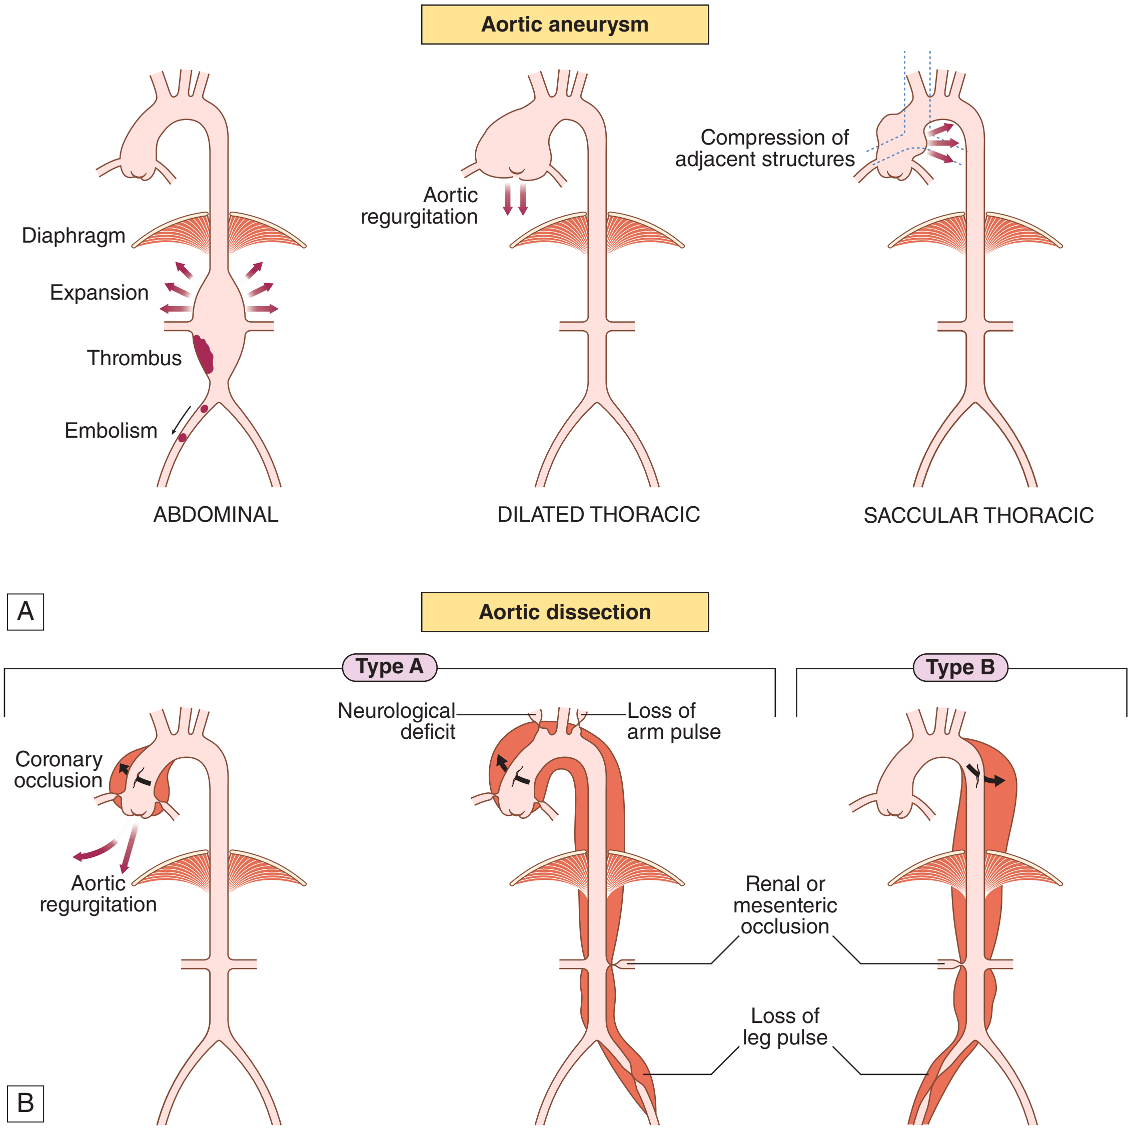
Management

The risks of surgery generally outweigh the risks of rupture until an asymptomatic AAA has reached a maximum of 5.5 cm in diameter. All symptomatic AAAs should be considered for repair, not only to rid the patient of symptoms but also because pain often predates rupture. Distal embolisation is a strong indication for repair, regardless of size, because otherwise limb loss is common. Most patients with a ruptured AAA do not survive to reach hospital, but if they do and surgery is thought to be appropriate, there must be no delay in getting them to the operating theatre to clamp the aorta.

Open AAA repair has been the treatment of choice in both the elective and the emergency settings, and entails replacing the aneurysmal segment with a prosthetic (usually Dacron) graft. The 30-day mortality for this procedure is approximately 5%–8% for elective asymptomatic AAA, 10%–20% for emergency symptomatic AAA and 50% for ruptured AAA. However, patients who survive the operation to leave hospital have a long-term survival approaching that of the normal population. Increasingly, endovascular aneurysm repair (EVAR), using a stent graft introduced via the femoral arteries in the groin, is replacing open surgery. It is cost-effective and likely to become the treatment of choice for infrarenal AAA. It is possible to treat many suprarenal and thoraco-abdominal aneurysms by EVAR too. If the aneurysm is secondary to Marfan syndrome, treatment with β-blockers reduces the rate of aortic dilatation and the risk of rupture. Elective replacement of the ascending aorta may also be considered in patients with evidence of progressive aortic dilatation but carries a mortality of 5%–10%.

Aortic dissection

Aortic dissection occurs when a breach in the integrity of the aortic wall allows arterial blood to enter the media, which is then split into two layers,



Aortic aneurysm
Diaphragm
Expansion
Thrombus
Embolism
ABDOMINAL
Aortic regurgitation
DILATED THORACIC

Fig. 16.71 Types of aortic disease and their complications. A Types of aortic aneurysm. B Types of aortic dissection.

i 16.62 Abdominal aortic aneurysm (AAA): common presentations

Incidental

- On physical examination, plain X-ray or, most commonly, abdominal ultrasound
- Even large AAAs can be difficult to feel, so many remain undetected until they rupture
- Studies are currently underway to determine whether screening will reduce the number of deaths from rupture

Pain

- In the central abdomen, back, loin, iliac fossa or groin

Thromboembolic complications

- Thrombus within the aneurysm sac may be a source of emboli to the lower limbs
- Less commonly, the aorta may undergo thrombotic occlusion

Compression

- Surrounding structures such as the duodenum (obstruction and vomiting) and the inferior vena cava (oedema and deep vein thrombosis)

Rupture

- Into the retroperitoneum, the peritoneal cavity or surrounding structures (most commonly the inferior vena cava, leading to an aortocaval fistula)

creating a false lumen alongside the existing or true lumen (Fig. 16.71B). The aortic valve may be damaged, and the branches of the aorta may be compromised. Typically, the false lumen eventually re-enters the true lumen, creating a double-barrelled aorta, but it may also rupture into the left pleural space or pericardium with fatal consequences. The peak incidence is in the sixth and seventh decades, but dissection can occur in younger patients, usually in association with Marfan syndrome, pregnancy or trauma; men are affected twice as frequently as women.

Pathogenesis

The primary event is often a spontaneous or iatrogenic tear in the intima of the aorta; multiple tears or entry points are common. Other dissections are triggered by primary haemorrhage in the media of the aorta, which then ruptures through the intima into the true lumen. This form of spontaneous bleeding from the vasa vasorum is sometimes confined to the aortic wall, when it may present as a painful intramural haematoma. Aortic disease and hypertension are the most important aetiological factors, but other conditions may also be implicated (Box 16.63). Chronic dissections may lead to aneurysmal dilatation of the aorta, and thoracic aneurysms may be complicated by dissection. It can therefore be difficult to identify the primary pathology.

Aortic dissection is classified anatomically and for management purposes into type A and type B (see Fig. 16.71B), involving or sparing the

i 16.63 Risk factors for aortic dissection

- Hypertension (in 80%)
- Atherosclerosis
- Coarctation
- Genetic:
  - Marfan syndrome
  - Ehlers–Danlos syndrome
- Loeys–Dietz syndrome
- Fibromuscular dysplasia
- Previous cardiac surgery:
  - CABG
  - Aortic valve replacement
- Pregnancy (usually third trimester)
- Trauma
- Iatrogenic:
  - Cardiac catheterisation
  - Intra-aortic balloon pumping

(CABG = coronary artery bypass grafting)

ascending aorta respectively. Type A dissections account for two-thirds of cases and frequently also extend into the descending aorta.

Clinical features

Involvement of the ascending aorta typically gives rise to anterior chest pain, and involvement of the descending aorta to intrascapular back pain. The pain is typically described as 'tearing' and very abrupt in onset; collapse is common. Unless there is major haemorrhage, the patient is invariably hypertensive. There may be asymmetry of the brachial, carotid or femoral pulses and signs of aortic regurgitation. Occlusion of aortic branches may cause MI (coronary), stroke (carotid), paraplegia (spinal), mesenteric infarction with an acute abdomen (coeliac and superior mesenteric), renal failure (renal) and acute limb (usually leg) ischaemia.

Investigations

The investigations of choice are CT or MR angiography (Figs. 16.72 and 16.73), both of which are highly specific and sensitive. A chest X-ray should be performed. It characteristically shows broadening of the upper mediastinum and distortion of the aortic 'knuckle' but these findings are absent in 10% of cases. A left-sided pleural effusion is common. The ECG may show left ventricular hypertrophy in patients with hypertension or, rarely, changes of acute MI (usually inferior). Doppler echocardiography may show aortic regurgitation, a dilated aortic root and, occasionally, the flap of the dissection. TOE is particularly helpful because transthoracic echocardiography can provide images of the first 3–4 cm of the ascending aorta only (Fig. 16.74).

Management

The early mortality of acute dissection is approximately 1%–5% per hour and so treatment is urgently required. Initial management comprises pain control and antihypertensive treatment. Type A dissections require emergency surgery to replace the ascending aorta. Type B dissections are treated medically unless there is actual or impending external rupture, or vital organ (gut, kidneys) or limb ischaemia, as the morbidity and mortality associated with surgery are very high. The aim of medical management is to maintain a mean arterial pressure (MAP) of 60–75 mmHg to reduce the force of the ejection of blood from the LV. First-line therapy is with β-blockers; the additional α-blocking properties of labetalol make it especially useful. Rate-limiting calcium channel blockers, such as verapamil or diltiazem, are used if β-blockers are contraindicated. Sodium nitroprusside may be considered if these fail to control BP adequately.

Percutaneous or minimal access endoluminal repair is sometimes possible and involves either 'fenestrating' (perforating) the intimal flap so that blood can return from the false to the true lumen (so decompressing the former) or implanting a stent graft placed from the femoral artery (see Fig. 16.73).

Aortitis

Syphilis is a rare cause of aortitis that characteristically produces saccular aneurysms of the ascending aorta containing calcification. Other conditions that may be associated with aortitis include Takayasu disease, giant cell arteritis and axial spondyloarthritis, all of which are discussed in more detail in Chapter 25).

Marfan syndrome

Marfan syndrome is a rare (0.02% of the population) inherited autosomal dominant disorder of connective tissue with a high risk of aortic aneurysm and dissection. It is caused by mutations of the *FBN1* gene, which leads to deficiency of fibrillin-1 leading to reduced microfibril formation. This disrupts the mechanical integrity of connective tissue, giving rise to a wide range of clinical features.

Clinical features

Aortic dissection and aneurysm are the most serious complications of Marfan syndrome, but many other clinical manifestations may be observed. These include aortic and mitral valve regurgitation; skin laxity and joint hypermobility; abnormalities of body habitus, including long arms, legs and fingers (arachnodactyly), scoliosis, pectus excavatum and a high-arched palate; ocular abnormalities, such as lens dislocation and retinal detachment; and an increased risk of pneumothorax.

Investigations

The diagnosis is usually suspected on the basis of the characteristic clinical features and can be confirmed by genetic testing. Imaging by chest X-ray may reveal evidence of aortic dilatation but echocardiography is more sensitive and can also demonstrate valvular disease, if present. Patients with Marfan syndrome should undergo serial monitoring of the aortic root by echocardiography; if evidence of dilatation is observed, then elective surgery should be considered.

Management

Treatment with β-blockers or ARBs may reduce the risk of aortic dilatation and should be given in all patients with Marfan syndrome. Activities that are associated with increases in cardiac output are best avoided. Surgery to replace the aortic root can be performed in patients with progressive aortic dilatation.

Coarctation of the aorta

Coarctation of the aorta is the term used to describe a narrowing distal to the origin of the left subclavian artery. It is most commonly due to congenital heart disease, but narrowing of the aorta leading to similar symptoms can occur in other conditions such as Takayasu arteritis and trauma. Diagnosis and management of coarctation are discussed later in this chapter in the section on congenital heart disease.

Hypertension

The risk of cardiovascular diseases such as stroke and CAD is closely related to levels of BP, which follows a normal distribution in the general population. Although there is no specific cut-off above which the risk of cardiovascular risk suddenly increases, the diagnosis of hypertension is made when systolic and diastolic values rise above a specific threshold that corresponds to the level of BP at which the risk of cardiovascular complications and benefits of treatment outweigh the treatment costs and potential side-effects of therapy. The British Hypertension Society classification, provided in Box 16.64, defines hypertension as existing when the BP is above 140/90 mmHg. Similar thresholds have been published by the European Society of Hypertension and the WHO–International Society of Hypertension. The cardiovascular risks associated with high BP depend on the combination of risk factors in an individual, such as age, sex, weight, physical activity, smoking, family history, serum cholesterol, diabetes mellitus and pre-existing vascular disease.

Pathogenesis

Many factors may contribute to the regulation of BP and the development of hypertension, including renal dysfunction, peripheral resistance, vessel tone, endothelial dysfunction, autonomic tone, insulin resistance and neurohumoral factors. In more than 95% of cases, no specific underlying

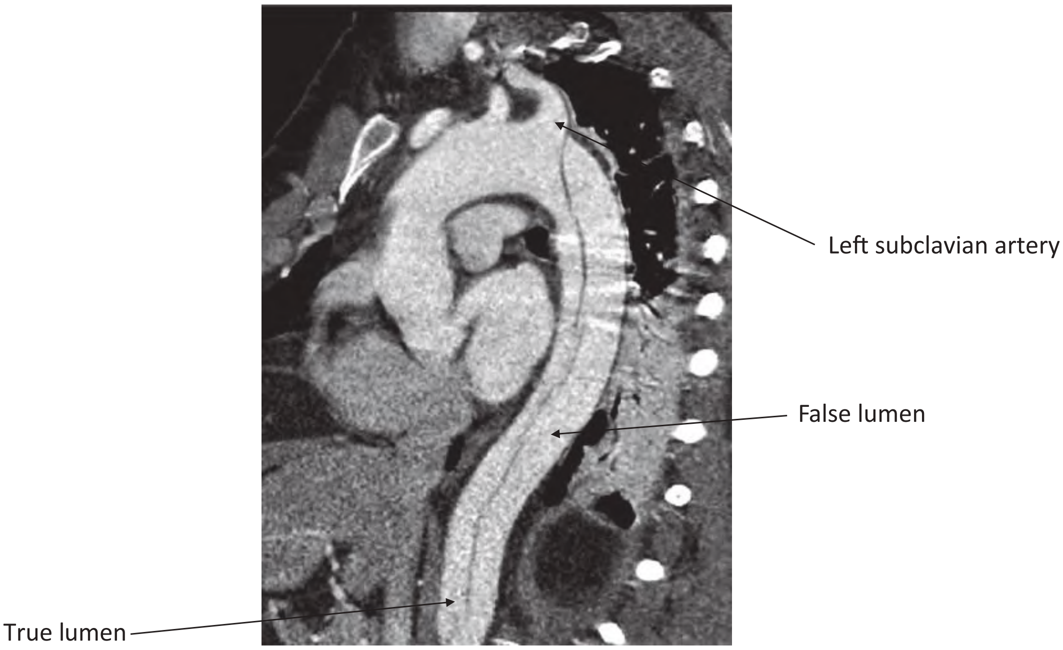

Fig. 16.72 **Sagittal view of a CT scan from a patient with a type B aortic dissection, illustrating a biluminal aorta.**

Lawton.*

cause of hypertension can be found. Such patients are said to have essential hypertension. Hypertension is more common in some ethnic groups, particularly African Americans and Japanese, and approximately 40%–60% is explained by genetic factors. Age is a strong risk factor in all ethnic groups. Important environmental factors include a high salt intake, heavy consumption of alcohol, obesity and lack of exercise. Impaired intrauterine growth and low birth weight are associated with an increased risk of hypertension later in life. In about 5% of cases, hypertension is secondary to a specific disease, as summarised in Box 16.65.

Hypertension has several adverse effects on the cardiovascular system. In larger arteries (>1 mm in diameter), the internal elastic lamina is thickened, smooth muscle is hypertrophied, and fibrous tissue is deposited. The vessels dilate and become tortuous, and their walls become less compliant. In smaller arteries (<1 mm), hyaline arteriosclerosis occurs in the wall, the lumen narrows and aneurysms may develop. Widespread atheroma develops and may lead to coronary and cerebrovascular disease, particularly if other risk factors are present. These structural changes in the vasculature often perpetuate

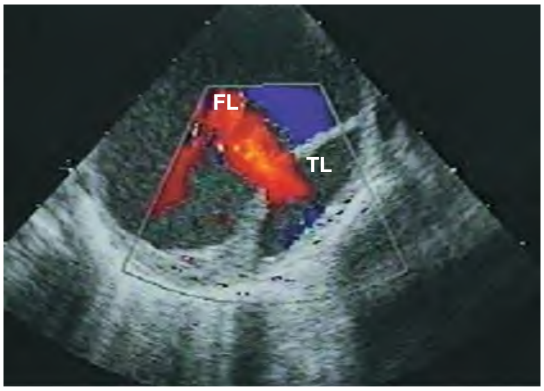

Fig. 16.74 Echocardiograms from a patient with a chronic aortic dissection. Colour-flow Doppler shows flow from the larger false lumen (FL) into the true lumen (TL), characteristic of chronic disease.

16.64 Definition of hypertension

Category	Systolic blood pressure (mmHg)	Diastolic blood pressure (mmHg)
Blood pressure		
Optimal	< 120	< 80
Normal	< 130	85
High normal	130–139	85–89
Hypertension		
Grade 1 (mild)	140–159	90–99
Grade 2 (moderate)	160–179	100–109
Grade 3 (severe)	≥ 180	> 110
Isolated systolic hypertension		
Grade 1	140–159	< 90
Grade 2	≥ 160	< 90

16.65 Causes of secondary hypertension

Alcohol

Obesity

Pregnancy

Renal disease

- Parenchymal renal disease: glomerular or tubulointerstitial disease
- Polycystic kidney disease
- Renal vascular disease: macrovascular (atherosclerosis, fibromuscular dysplasia or vasculitis) or microvascular (small vessel vasculitis or thrombotic microangiopathies)

Endocrine disease

- Phaeochromocytoma
- Cushing syndrome
- Primary hyperaldosteronism (Conn syndrome)
- Glucocorticoid-suppressible hyperaldosteronism
- Hyperparathyroidism
- Acromegaly
- Primary hypothyroidism
- Thyrotoxicosis
- Congenital adrenal hyperplasia due to 11β-hydroxylase or 17α-hydroxylase deficiency
- Liddle syndrome
- 11β-hydroxysteroid dehydrogenase deficiency

Drugs

Coarctation of the aorta

and aggravate hypertension by increasing peripheral vascular resistance and reducing renal blood flow, thereby activating the renin–angiotensin–aldosterone axis.

Clinical features

Hypertension is usually asymptomatic until the diagnosis is made at a routine physical examination or when a complication arises. Reflecting this fact, a BP check is advisable every 5 years in adults over 40 years of age to pick up occult hypertension. Sometimes clinical features may be observed that can give a clue to the underlying cause of hypertension. These include radio-femoral delay in patients with coarctation of the aorta (see Fig. 16.88), enlarged kidneys in patients with polycystic kidney disease, abdominal bruits that may suggest renal artery stenosis and the characteristic facies and habitus of Cushing syndrome (see Box 16.65). Examination may also reveal evidence of risk factors for hypertension, such as central obesity and hyperlipidaemia. Other signs may be observed that are due to the complications of hypertension. These include signs of left ventricular hypertrophy, accentuation of the aortic component of the second heart sound, and a fourth heart sound. AF is common and may be due to diastolic dysfunction caused by left ventricular hypertrophy or the effects of CAD.

Severe hypertension can cause left ventricular failure in the absence of CAD, particularly when there is an impairment of renal function. The optic fundi are often abnormal (see Fig. 16.75 below) and there may be evidence of generalised atheroma or specific complications, such as aortic aneurysm, PAD or stroke. Examination of the optic fundi reveals a gradation of changes linked to the severity of hypertension; fundoscopy can provide an indication of the arteriolar damage occurring elsewhere (Box 16.66). 'Cotton wool' exudates are associated with retinal ischaemia or infarction, and fade in a few weeks (Fig. 16.75A). 'Hard' exudates (small, white, dense deposits of lipid) and microaneurysms ('dot' haemorrhages) are more characteristic of diabetic retinopathy (see Fig. 28.5). Hypertension is also associated with central retinal vein thrombosis (Fig. 16.75B).

Investigations

A decision to embark on antihypertensive therapy effectively commits the patient to life-long treatment, so readings must be as accurate as possible. The objectives are to:

- confirm the diagnosis by obtaining accurate, representative BP measurements
- identify contributory factors and any underlying causes
- assess other risk factors and quantify cardiovascular risk
- detect any complications that are already present
- identify comorbidity that may influence the choice of antihypertensive therapy.

Blood pressure measurements

Measurements should be made to the nearest 2 mmHg, in the sitting position with the arm supported, and repeated after 5 minutes of rest if the first recording is high (Box 16.67). To avoid spuriously high readings in obese subjects, the cuff should contain a bladder that encompasses at least two-thirds of the arm circumference. Exercise, anxiety, discomfort and unfamiliar surroundings can all lead to a transient rise in BP. Sphygmomanometry, particularly when performed by a doctor, can cause a transient elevation in BP, which has been termed 'white coat' hypertension. It has been estimated that up to 20% of patients with a raised BP at outpatient clinics have a normal BP when it is recorded by automated devices used at home. The risk of cardiovascular disease in these patients is less than that in patients with sustained hypertension but greater than that in normotensive subjects. If clinic BP measurements show borderline levels or if white coat hypertension is suspected, then ambulatory measurement or home-based measurements are of value in confirming the diagnosis.

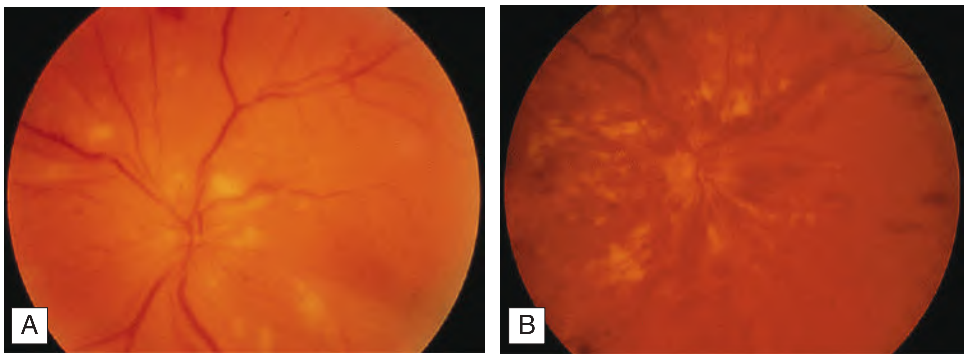

Fig. 16.75 Retinal changes in hypertension. A Grade 4 hypertensive retinopathy showing swollen optic disc, retinal haemorrhages and multiple cotton wool spots (infarcts). B Central retinal vein thrombosis showing swollen optic disc and widespread fundal haemorrhage, commonly associated with systemic hypertension. *(A and B) Courtesy of Dr B. Cullen.*

16.66 Hypertensive retinopathy

Grade 1

- Arteriolar thickening, tortuosity and increased reflectiveness ('silver wiring')

Grade 2

- Grade 1 plus constriction of veins at arterial crossings ('arteriovenous nipping')

Grade 3

- Grade 2 plus evidence of retinal ischaemia (flame-shaped or blot haemorrhages and 'cotton wool' exudates)

Grade 4

- Grade 3 plus papilloedema

16.67 How to measure blood pressure

- Use a machine that has been validated, well maintained and properly calibrated
- Measure sitting BP routinely, with additional standing BP in older and diabetic patients and those with possible postural hypotension; rest the patient for 2 minutes
- Remove tight clothing from the arm
- Support the arm at the level of the heart
- Use a cuff of appropriate size (the bladder must encompass more than two-thirds of the arm)
- Lower the pressure slowly (2 mmHg per second)
- Read the BP to the nearest 2 mmHg
- Use phase V (disappearance of sounds) to measure diastolic BP
- Take two measurements at each visit

Ambulatory blood pressure measurements

A series of automated ambulatory BP measurements obtained over 24 hours or longer provide a better profile than a limited number of clinic readings and correlate more closely with evidence of target organ damage than casual BP measurements. Treatment thresholds and targets (see Box 16.71) must be adjusted downwards, because ambulatory BP readings are systematically lower (approximately 12/7 mmHg) than clinic measurements. The average ambulatory daytime (not 24-hour or night-time) BP should be used to guide management decisions.

Home blood pressure measurements

Patients can measure their own BP at home using a range of commercially available semi-automatic devices. The value of such measurements is dependent on the environment and timing of the readings measured. Home or ambulatory BP measurements are particularly helpful in patients with unusually labile BP, those with refractory hypertension, those who may have symptomatic hypotension, and those in whom white coat hypertension is suspected.

16.68 Investigation of hypertension

- Urinalysis for blood, protein and glucose
- Blood urea, electrolytes and creatinine
  Hypokalaemic alkalosis may indicate primary hyperaldosteronism but is usually due to diuretic therapy
- Blood glucose
- Serum total and HDL cholesterol
- Thyroid function tests
- 12-lead ECG (left ventricular hypertrophy, coronary artery disease)

(HDL = high-density lipoprotein)

16.69 Specialised investigation of hypertension

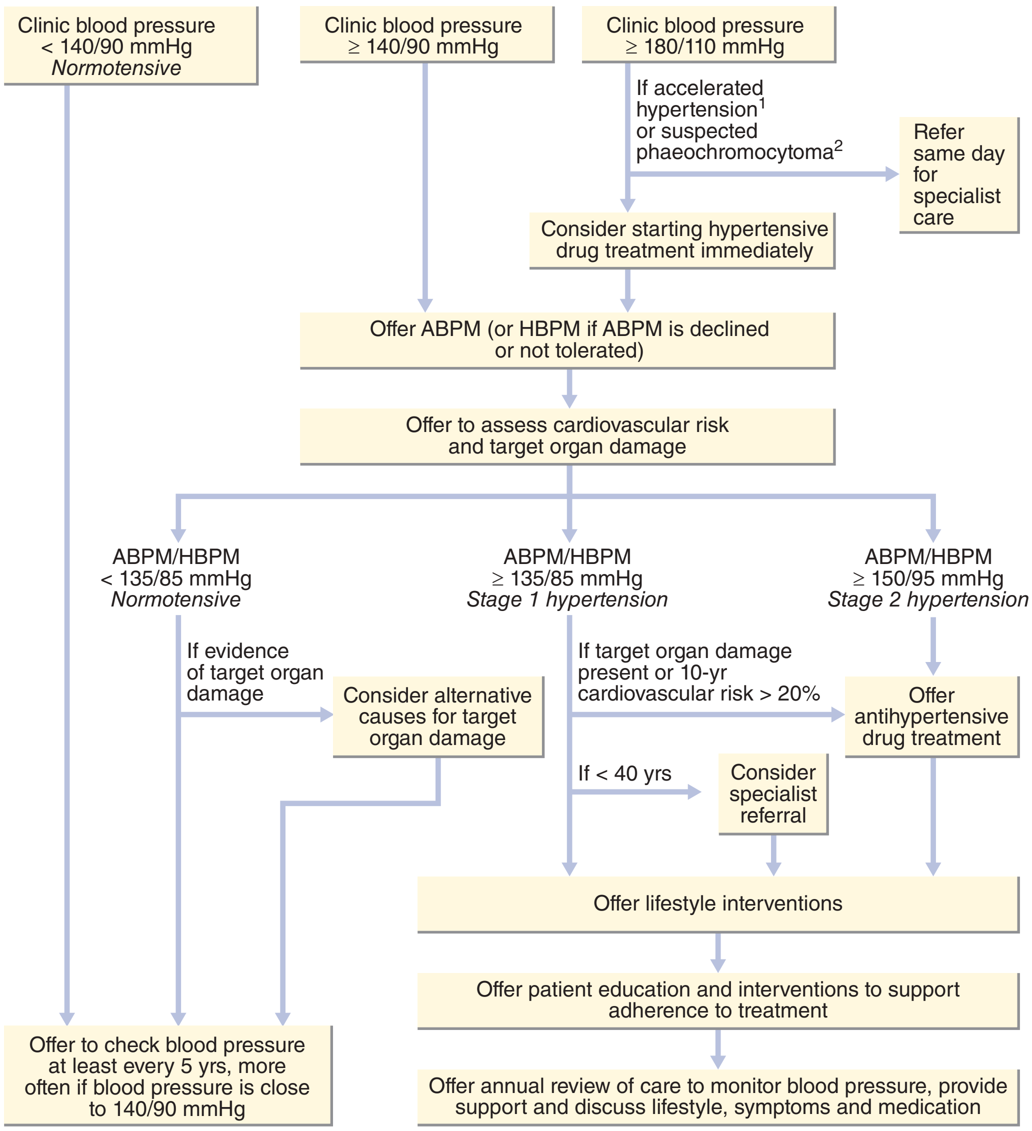
- Chest X-ray: to detect cardiomegaly, heart failure, coarctation of the aorta
- Ambulatory BP recording: to assess borderline or 'white coat' hypertension
- Echocardiogram: to detect or quantify left ventricular hypertrophy
- Renal ultrasound: to detect possible renal disease
- Renal angiography: to detect or confirm the presence of renal artery stenosis
- Urinary catecholamines: to detect possible phaeochromocytoma
- Urinary cortisol and dexamethasone suppression test: to detect possible Cushing syndrome
- Plasma renin activity and aldosterone: to detect possible primary aldosteronism

Other investigations

All hypertensive patients should undergo a limited number of investigations (Box 16.68) but additional investigations are appropriate in patients younger than 40 years of age or those with resistant hypertension (Box 16.69). Family history, lifestyle (exercise, salt intake, smoking habit) and other risk factors should also be recorded. A careful history will identify those patients with drug- or alcohol-induced hypertension and may elicit the symptoms of other causes of secondary hypertension, such as phaeochromocytoma (paroxysmal headache, palpitation and sweating) or complications such as CAD.

Management

The objective of antihypertensive therapy is to reduce the incidence of adverse cardiovascular events, particularly CAD, stroke and heart failure. Randomised controlled trials have demonstrated that antihypertensive therapy can reduce the incidence of stroke and, to a lesser extent, CAD. The relative benefits (approximately 30% reduction in risk of stroke and 20% reduction in risk of CAD) are similar in all patient groups, so the absolute benefit of treatment (total number of events prevented) is greatest in those at highest risk. For example, to extrapolate from the Medical Research Council (MRC) Mild Hypertension Trial (1985), 566 young patients would have to be treated with bendroflumethiazide for 1 year to prevent 1 stroke, while in the MRC trial of antihypertensive treatment in older adults (1992), 1 stroke was prevented for every 286 patients treated for 1 year.



Clinic blood pressure
< 140/90 mmHg
Normotensive
Clinic blood pressure
≥ 140/90 mmHg
Clinic blood pressure
≥ 180/110 mmHg
If accelerated hypertension¹ or suspected phaeochromocytoma²
Refer same day for specialist care
Consider starting hypertensive drug treatment immediately
Offer ABPM (or HBPM if ABPM is declined or not tolerated)
Offer to assess cardiovascular risk and target organ damage
ABPM/HBPM
< 135/85 mmHg
Normotensive
ABPM/HBPM
≥ 135/85 mmHg
Stage 1 hypertension
ABPM/HBPM
≥ 150/95 mmHg
Stage 2 hypertension
If evidence of target organ damage
Consider alternative causes for target organ damage
If target organ damage present or 10-yr cardiovascular risk > 20%
Offer antihypertensive drug treatment
If < 40 yrs
Consider specialist referral
Offer lifestyle interventions
Offer patient education and interventions to support adherence to treatment
Offer annual review of care to monitor blood pressure, provide support and discuss lifestyle, symptoms and medication
Offer to check blood pressure at least every 5 yrs, more often if blood pressure is close to 140/90 mmHg

Fig. 16.76 Management of hypertension. ¹Signs of papilloedema or retinal haemorrhage. ²Labile or postural hypotension, headache, palpitations, pallor and diaphoresis. (ABPM = ambulatory blood pressure monitoring; HBPM = home blood pressure monitoring) *Adapted from 2020 International Society of Hypertension Global Hypertension Practice Guidelines.*

Intervention thresholds

Systolic BP and diastolic BP are both powerful predictors of cardiovascular risk. The British Hypertension Society management guidelines use both readings, and treatment should be initiated if they exceed the given threshold (Fig. 16.76).

Patients with diabetes or cardiovascular disease are at particularly high risk and the threshold for initiating antihypertensive therapy is therefore lower (≤130/80 mmHg) in these patient groups. The thresholds for treatment in older adults are the same as for younger patients (Box 16.70).

Treatment targets

The optimum BP for reduction of major cardiovascular events has been found to be 139/83 mmHg, and even lower in patients with diabetes mellitus. The targets suggested by the British Hypertension Society (Box 16.71) are ambitious. Primary care strategies have been devised to improve screening and detection of hypertension that, in the past, remained undetected in up to half of affected individuals. Application of new guidelines should help establish patients on appropriate treatment and allow step-up if lifestyle modification and first-line drug therapy fail to control hypertension.

16.70 Hypertension in old age

- **Prevalence**: hypertension affects more than half of all people over the age of 60 years (including isolated systolic hypertension).
- **Risks**: hypertension is the most important risk factor for myocardial infarction, heart failure and stroke in older people.
- **Benefit of treatment**: absolute benefit from therapy is greatest in older people (at least up to age 80 years).
- **Target blood pressure**: targets may be relaxed in older people to 150/90 mmHg.
- **Tolerance of treatment**: antihypertensives are tolerated as well as in younger patients.
- **Drug of choice**: low-dose thiazides but, in the presence of coexistent disease such as gout or diabetes, other agents may be more appropriate.

Patients taking antihypertensive therapy require follow-up at regular intervals to monitor BP, minimise side-effects and reinforce lifestyle advice.

Non-drug therapy

Appropriate lifestyle measures may obviate the need for drug therapy in patients with borderline hypertension, reduce the dose or the number

16.71 Optimal target blood pressures[1]

Age	Clinic BP (mmHg)	Ambulatory or home BP (mmHg)[2]
< 80 years	< 140/90	< 135/85
≥ 80 years	< 150/90	< 140/85

[1] Both systolic and diastolic values should be attained.
[2] Average BP during waking hours.

of drugs required in patients with established hypertension, and directly reduce cardiovascular risk.

Correcting obesity, reducing alcohol intake, restricting salt intake, taking regular physical exercise and increasing consumption of fruit and vegetables can all lower BP. Moreover, stopping smoking, eating oily fish and adopting a diet that is low in saturated fat may produce further reductions in cardiovascular risk that are independent of changes in BP.

Drug therapy

Thiazides The mechanism of action of these drugs is incompletely understood and it may take up to a month for the maximum effect to be observed. An appropriate daily dose is 2.5 mg bendroflumethiazide or 0.5 mg cyclopenthiazide. More potent loop diuretics, such as furosemide (40 mg daily) or bumetanide (1 mg daily), have few advantages over thiazides in the treatment of hypertension, unless there is substantial renal impairment, or they are used in conjunction with an ACE inhibitor.

ACE inhibitors ACE inhibitors (enalapril 5–40 mg daily, ramipril 5–10 mg daily or lisinopril 10–40 mg daily) are effective and usually well tolerated. They should be used with care in patients with impaired renal function or renal artery stenosis because they can reduce glomerular filtration rate and precipitate renal failure. Electrolytes and creatinine should be checked before and 1–2 weeks after commencing therapy. Side-effects include first-dose hypotension, cough, rash, hyperkalaemia and renal dysfunction.

Angiotensin receptor blockers ARBs (irbesartan 75–300 mg daily, valsartan 40–160 mg daily) have similar efficacy to ACE inhibitors but they do not cause cough and are better tolerated.

Calcium channel antagonists Amlodipine (5–10 mg daily) and nifedipine (30–90 mg daily) are effective and usually well tolerated antihypertensive drugs that are particularly useful in older people. Side-effects include flushing, palpitations and fluid retention. The rate-limiting calcium channel antagonists (diltiazem 200–500 mg daily, verapamil 240–480 mg daily in divided doses) can be useful when hypertension coexists with angina but may cause bradycardia. The main side-effect of verapamil is constipation.

Beta-blockers These are no longer used as first-line antihypertensive therapy, except in patients with another indication for the drug, such as angina. Metoprolol (100–200 mg daily), atenolol (50–100 mg daily) and bisoprolol (5–10 mg daily), which preferentially block cardiac β_1-adrenoceptors, should be used rather than non-selective agents that also block β_2-adrenoceptors, which mediate vasodilatation and bronchodilatation.

Combined β- and α-blockers Labetalol (200 mg–2.4 g daily in divided doses) and carvedilol (6.25–25 mg twice daily) are combined β- and α-adrenoceptor antagonists that are sometimes more effective than pure β-blockers. Labetalol can be used as an infusion in malignant phase hypertension (see below).

Other vasodilators A variety of other vasodilators may be used. These include the α_1-adrenoceptor antagonists, prazosin (0.5–20 mg daily in divided doses), indoramin (25–100 mg twice daily) and doxazosin (1–16 mg daily), and drugs that act directly on vascular smooth muscle, such as hydralazine (25–100 mg twice daily) and minoxidil (10–50 mg daily). Side-effects include first dose and postural hypotension, headache, tachycardia and fluid retention. Minoxidil also causes increased facial hair and is therefore unsuitable for female patients.

Aspirin Antiplatelet therapy is a powerful means of reducing cardiovascular risk but may cause bleeding, particularly intracerebral haemorrhage, in a small number of patients. The benefits are thought to outweigh the risks in hypertensive patients aged 50 years or over who have well-controlled BP and either target organ damage or diabetes or a 10-year CAD risk of at least 15% (or 10-year cardiovascular disease risk of at least 20%).

Statins Treating hyperlipidaemia can produce a substantial reduction in cardiovascular risk. These drugs are strongly indicated in patients who have established vascular disease, or hypertension with a high (at least 10% in 10 years) risk of developing cardiovascular disease.

Choice of antihypertensive drug

Trials that have compared thiazides, calcium antagonists, ACE inhibitors and ARBs have not shown consistent differences in outcome, efficacy, side-effects or quality of life. Beta-blockers, which previously featured as first-line therapy in guidelines, have a weaker evidence base. The choice of antihypertensive therapy is initially dictated by the patient's age and ethnic background, although cost and convenience will influence the exact drug and preparation used. Response to initial therapy and side-effects guide subsequent treatment. Comorbid conditions also have an influence on initial drug selection (Box 16.72); for example, a β-blocker might be the most appropriate treatment for a patient with angina. Thiazide diuretics and dihydropyridine calcium channel antagonists are the most suitable drugs for treatment in older people.

Combination therapy

Although some patients can be treated with a single antihypertensive drug, a combination of drugs is often required to achieve optimal control (Fig. 16.77). Combination therapy may be desirable for other reasons; for example, low-dose therapy with two drugs may produce fewer unwanted effects than treatment with the maximum dose of a single drug. Some drug combinations have complementary or synergistic actions; for example, thiazides increase activity of the renin–angiotensin system, while ACE inhibitors block it.

Resistant hypertension

Resistant hypertension refers to the situation where multiple drug treatments do not give adequate control of BP. Although this may be due to genuine resistance to therapy in some cases, a more common cause of treatment failure is non-adherence to drug therapy. Resistant hypertension can also be caused by failure to recognise an underlying cause, such as renal artery stenosis or phaeochromocytoma. There is no easy solution to problems with adherence, but simple treatment regimens, attempts to improve rapport with the patient and careful supervision can all help. Spironolactone is a particularly useful addition in patients with treatment-resistant hypertension.

Accelerated hypertension

Accelerated or malignant hypertension is a rare condition that can complicate hypertension of any aetiology. It is characterised by accelerated microvascular damage with necrosis in the walls of small arteries and arterioles (fibrinoid necrosis) and by intravascular thrombosis. The diagnosis is based on evidence of high BP and rapidly progressive end-organ damage, such as retinopathy (grade 3 or 4), renal dysfunction (especially proteinuria) and hypertensive encephalopathy (see above). Left ventricular failure may occur and death occurs within months if untreated.

16.72 The influence of comorbidity on choice of antihypertensive drug therapy

Class of drug	Compelling indications	Possible indications	Caution	Compelling contraindications
α-blockers	Benign prostatic hypertrophy	–	Postural hypotension, heart failure[1]	Urinary incontinence
ACE inhibitors	Heart failure	Chronic kidney disease	Renal impairment[2]	Pregnancy
	Left ventricular dysfunction, post-MI or established CAD	Type 2 diabetic nephropathy	PAD[3]	Renovascular disease[2]
	Type 1 diabetic nephropathy			
	Secondary stroke prevention[4]			
ARBs	ACE inhibitor intolerance	Left ventricular dysfunction after MI	Renal impairment[2]	Pregnancy
	Type 2 diabetic nephropathy	Intolerance of other antihypertensive drugs	PAD[3]	
	Hypertension with left ventricular hypertrophy	Proteinuric or chronic renal disease[2]		
	Heart failure in ACE-intolerant patients, after MI	Heart failure		
β-blockers	MI, angina	–	Heart failure[5]	Asthma or chronic obstructive pulmonary disease
	Heart failure[5]		PAD	Heart block
			Diabetes (except with CAD)	
Calcium channel blockers (dihydropyridine)	Older patients, isolated systolic hypertension	Angina	Peripheral oedema	–
Calcium channel blockers (rate-limiting)	Angina	Older patients	Combination with β-blockade	Atrioventricular block, heart failure
Thiazides or thiazide-like diuretics	Older patients, isolated systolic hypertension, heart failure, secondary stroke prevention	–	–	Gout[6]

[1] In heart failure when used as monotherapy.
[2] ACE inhibitors or ARBs may be beneficial in chronic renal failure and renovascular disease but should be used with caution, close supervision and specialist advice when there is established and significant renal impairment.
[3] Caution with ACE inhibitors and ARBs in PAD because of association with renovascular disease.
[4] In combination with a thiazide or thiazide-like diuretic.
[5] β-blockers are used increasingly to treat stable heart failure but may worsen acute heart failure.
[6] Thiazides or thiazide-like diuretics may sometimes be necessary to control BP in people with a history of gout, ideally used in combination with allopurinol.
(ACE = angiotensin-converting enzyme; ARBs = angiotensin II receptor blockers; CAD = coronary artery disease; MI = myocardial infarction; PAD = peripheral arterial disease)

Management

In accelerated phase hypertension, lowering BP too quickly may compromise tissue perfusion due to altered autoregulation and can cause cerebral damage, including occipital blindness, and precipitate coronary or renal insufficiency. Even in the presence of cardiac failure or hypertensive encephalopathy, a controlled reduction to a level of about 150/90 mmHg over a period of 24–48 hours is ideal.

In most patients, it is possible to avoid parenteral therapy and bring BP under control with bed rest and oral drug therapy. Intravenous or intramuscular labetalol (2 mg/min to a maximum of 200 mg), intravenous GTN (0.6–1.2 mg/hr), intramuscular hydralazine (5 or 10 mg aliquots repeated at half-hourly intervals) and intravenous sodium nitroprusside (0.3–1.0 µg/kg body weight/min) are all effective but require careful supervision, preferably in a high-dependency unit.

Diseases of the heart valves

The heart valves allow forward movement of blood through the cardiac chambers when they are open and prevent backward flow when they are closed. A diseased valve may become narrowed, obstructing forward flow, or become leaky, causing backward flow or regurgitation. Breathlessness is a common symptom of valve disease, and acute severe breathlessness may be a presenting symptom of sudden valve failure. The causes of this are shown in Box 16.73. Predisposition to valvular disease may be genetically determined, can arise as the result of rheumatic fever or infections, or can occur in association with dilatation of the cardiac chambers in heart failure. The principal causes of valvular disease are summarised in Box 16.74.

Rheumatic heart disease

Acute rheumatic fever

Acute rheumatic fever usually affects children and young adults between the ages of 5 and 15 years. It is now rare in developed countries, but remains endemic in developing countries where the incidence can range between 13 and 150 cases per 100 000 population per year. Rheumatic heart disease is currently responsible for around 300 000 deaths per year worldwide.

Pathogenesis

The condition is triggered by an immune-mediated delayed response to infection with *Streptococcus pyogenes*, a group A streptococcus, which has antigens that cross-react with cardiac myosin and sarcolemmal membrane proteins. Antibodies produced against the streptococcal antigens cause inflammation in the endocardium, myocardium and pericardium, as well as the joints and skin.

Clinical features

Acute rheumatic fever is a multisystem disorder that usually presents with fever, anorexia, lethargy and joint pain, 2–3 weeks after an episode

Fig. 16.77 **Antihypertensive drug combinations.** *Does not apply to those who are of mixed race. [1]A = Angiotensin-converting enzyme (ACE) inhibitor or consider angiotensin II receptor blocker (ARB); choose a low-cost ARB. [2]C = calcium channel blocker (CCB); a CCB is preferred but consider a thiazide-like diuretic if a CCB is not tolerated or the person has oedema, evidence of heart failure or a high risk of heart failure. [3]D = thiazide-type diuretic. [4]Consider a low dose of spironolactone or higher doses of a thiazide-like diuretic. [5]Consider an α- or β-blocker if further diuretic therapy is not tolerated or is contraindicated or ineffective. *Adapted from 2020 International Society of Hypertension Global Hypertension Practice Guidelines.*

16.73 Causes of acute valve failure

Aortic regurgitation

- Aortic dissection
- Infective endocarditis

Mitral regurgitation

- Papillary muscle rupture due to acute myocardial infarction
- Infective endocarditis
- Rupture of chordae due to myxomatous degeneration

Prosthetic valve failure

- Mechanical valves: fracture, jamming, thrombosis, dehiscence
- Biological valves: degeneration with cusp tear

16.74 Principal causes of valve disease

Valve regurgitation

- Congenital
- Acute rheumatic carditis
- Chronic rheumatic carditis
- Infective endocarditis
- Cardiac failure*
- Syphilitic aortitis/ aortic root dilatation
- Traumatic valve rupture
- Senile degeneration
- Damage to chordae and papillary muscles

Valve stenosis

- Congenital
- Rheumatic carditis
- Senile degeneration

*Causes dilatation of the mitral and tricuspid valve rings.

16.75 Jones criteria for the diagnosis of rheumatic fever

Major manifestations

- Carditis
- Polyarthritis
- Chorea
- Erythema marginatum
- Subcutaneous nodules

Minor manifestations

- Fever
- Arthralgia
- Raised erythrocyte sedimentation rate or C-reactive protein
- Previous rheumatic fever
- Leucocytosis
- First-degree atrioventricular block

Plus

- Supporting evidence of preceding streptococcal infection: recent scarlet fever, raised antistreptolysin O or other streptococcal antibody titre, positive throat culture*

*Evidence of recent streptococcal infection is particularly important if there is only one major manifestation.

of streptococcal pharyngitis although there may be no history of sore throat. Arthritis occurs in approximately 75% of patients. Other features include rashes, subcutaneous nodules, carditis and neurological changes. Using the revised Jones criteria (Box 16.75), the diagnosis is based on two or more major manifestations, or one major and two or more minor manifestations, along with evidence of preceding streptococcal infection. A presumptive diagnosis of acute rheumatic fever can be made without evidence of preceding streptococcal infection in cases of isolated chorea or pancarditis, providing other causes have been excluded. In cases of established rheumatic heart disease or prior rheumatic fever, acute rheumatic fever can be diagnosed based only on the presence of multiple minor criteria and evidence of preceding group A streptococcal pharyngitis.

Carditis

Rheumatic fever causes a pancarditis involving the endocardium, myocardium and pericardium to varying degrees more commonly seen in younger patients. It may manifest as breathlessness (due to myocardial or valve dysfunction or pericardial effusion), palpitations or chest pain (due to pericarditis, pleurisy, or pancarditis). Other features include tachycardia, cardiac enlargement and new or changed murmurs. Both systolic and diastolic mitral murmurs, due to regurgitation and stenosis respectively, can be heard. Aortic regurgitation occurs in 50% of cases but the tricuspid and pulmonary valves are rarely involved. ECGs can show non-specific ST and T-wave changes, but conduction defects, including symptomatic AV block, can occur.

Arthritis

This is the commonest major manifestation and occurs early when streptococcal antibody titres are high. An acute painful, asymmetric and migratory inflammation of the large joints typically affects the knees, ankles, elbows and wrists.

Skin lesions

Erythema marginatum occurs in less than 5% of patients. The lesions start as red macules that fade in the centre but remain red at the edges, occurring mainly on the trunk and proximal extremities but not the face. Subcutaneous nodules occur in 5%–7% of patients. They are small (0.5–2.0 cm), firm and painless, and are best felt over extensor surfaces of bone or tendons and typically appear after other clinical features.

Sydenham chorea

Sydenham chorea, also known as St Vitus dance, is a late neurological manifestation that appears at least 3 months after the episode of acute rheumatic fever, when other signs may have disappeared. It occurs in up

16.76 Investigations in acute rheumatic fever

Evidence of a systemic illness

- Leucocytosis, raised erythrocyte sedimentation rate and C-reactive protein

Evidence of preceding streptococcal infection

- Throat swab culture: group A β-haemolytic streptococci (also from family members and contacts)
- Antistreptolysin O antibodies (ASO titres): rising titres, or levels of >200 U (adults) or >300 U (children)

Evidence of carditis

- Chest X-ray: cardiomegaly; pulmonary congestion
- ECG: first- and, rarely, second-degree atrioventricular block; features of pericarditis; T-wave inversion; reduction in QRS voltages
- Echocardiography: cardiac dilatation and valve abnormalities

to one-third of cases and is more common in females. Emotional lability may be the first feature and is typically followed by purposeless, involuntary, choreiform movements of the hands, feet or face. Speech may be explosive and halting. Spontaneous recovery usually occurs within a few months. Approximately one-quarter of affected patients will go on to develop chronic rheumatic valve disease.

Investigations

Blood should be taken for measurement of ESR and CRP since these are useful for monitoring progress of the disease (Box 16.76). Throat cultures should be taken but positive results are obtained in only 10%–25% of cases since the infection has often resolved by the time of presentation. Serology for antistreptolysin O antibodies (ASO) should be performed and provide supportive evidence for the diagnosis but are normal in one-fifth of adult cases of acute rheumatic fever and most cases of chorea. Echocardiography should be carried out and typically shows mitral regurgitation with dilatation of the mitral annulus and prolapse of the anterior mitral leaflet; it may also demonstrate aortic regurgitation and pericardial effusion. Cardiac biomarkers (e.g. troponin and BNP) can be elevated.

Management

The aims of management are to limit cardiac damage and relieve symptoms.

Bed rest

Bed rest lessens joint pain and reduces cardiac workload. The duration should be guided by symptoms, along with temperature, leucocyte count and ESR, and should be continued until these have settled. Patients can return to normal physical activity when fully recovered.

Treatment of cardiac failure

Cardiac failure due to valve dysfunction, usually severe mitral and/or aortic regurgitation, can occur. If heart failure does not respond to medical treatment, valve replacement may be necessary. Occasionally, AV block may occur but usually resolves spontaneously. Rarely, pacemaker insertion may be required.

Antibiotic therapy

A single dose of benzathine benzylpenicillin (1.2 million U IM) or oral phenoxymethylpenicillin (250 mg 4 times daily for 10 days) should be given on diagnosis to eliminate any residual streptococcal infection. If the patient is penicillin-allergic, erythromycin or a cephalosporin can be used. Patients are susceptible to further attacks of rheumatic fever if another streptococcal infection occurs, and long-term prophylaxis should be given with oral phenoxymethylpenicillin (250 mg twice daily) or as benzathine benzylpenicillin (1.2 million U IM monthly), if adherence is in doubt. Sulfadiazine or erythromycin may be used if the patient is allergic to penicillin. Further attacks of rheumatic fever are unusual after the age of 21, when antibiotic treatment can usually be stopped but can be continued if evidence of recurrent infection, or the patient lives in an area of high prevalence or is at high risk of recurrent exposure to streptococcal infections (i.e. school teacher or carer). In those with residual heart disease, prophylaxis should continue until 10 years after the last episode or 40 years of age, whichever is later. While long-term antibiotic prophylaxis prevents further attacks of acute rheumatic fever, it does not protect against infective endocarditis.

Aspirin

This usually relieves the symptoms of arthritis rapidly and a response within 24 hours helps confirm the diagnosis. High doses of 60 mg/kg body weight/day, divided into six doses are used. Aspirin should be continued until the ESR has fallen and then gradually tailed off.

Glucocorticoids

These produce more rapid symptomatic relief than aspirin and are indicated in cases with carditis or severe arthritis. Prednisolone (1.0–2.0 mg/kg per day in divided doses) should be continued until the ESR is normal and then gradually reduced.

Chronic rheumatic heart disease

Chronic valvular heart disease develops in at least half of those affected by rheumatic fever with carditis. Two-thirds of cases occur in women. Some episodes of rheumatic fever pass unrecognised and it is possible to elicit a history of rheumatic fever or chorea in only about half of all patients with chronic rheumatic heart disease.

The mitral valve is affected in more than 90% of cases; the aortic valve is the next most frequently involved, followed by the tricuspid and then the pulmonary valve. Isolated mitral stenosis accounts for about 25% of all cases, and an additional 40% have mixed mitral stenosis and regurgitation.

Pathogenesis

The heart valves become affected with progressive fibrosis. Fusion of the mitral valve commissures and shortening of the chordae tendineae may lead to mitral stenosis with or without regurgitation. Similar changes in the aortic and tricuspid valves produce distortion and rigidity of the cusps, leading to stenosis and regurgitation. Once a valve has been damaged, the altered haemodynamic stresses perpetuate and extend the damage, even in the absence of a continuing rheumatic process.

Mitral valve disease

Mitral stenosis

Mitral stenosis is almost always rheumatic in origin, although in older people it can be caused by heavy calcification of the mitral valve. There is also a rare form of congenital mitral stenosis.

Pathogenesis

In rheumatic mitral stenosis, the mitral valve orifice is slowly diminished by progressive fibrosis, calcification of the valve leaflets, and fusion of the cusps and subvalvular apparatus. The mitral valve orifice is normally about $5\,\text{cm}^2$ in diastole but can be reduced to $<1\,\text{cm}^2$ in severe mitral stenosis. The patient is usually asymptomatic until the orifice is $<2\,\text{cm}^2$. As stenosis progresses, left ventricular filling becomes more dependent on left atrial contraction. There is dilatation and hypertrophy of the LA and left atrial pressure rises, leading to pulmonary venous congestion and breathlessness. Any increase in heart rate shortens diastole when the mitral valve is open and produces a further rise in left atrial pressure. Situations that demand an increase in cardiac output, such as pregnancy and exercise, also increase left atrial pressure and are poorly tolerated.

AF is very common due to progressive dilatation of the LA. Its onset often precipitates a sudden haemodynamic deterioration due to loss of atrial contraction and tachycardia leading to a rapid rise in left atrial pressure and the development of pulmonary oedema. In the absence of

i 16.77 Clinical features of mitral stenosis

Clinical feature	Cause
Symptoms	
Breathlessness	Pulmonary congestion, low cardiac output
Fatigue	Low cardiac output

Mid-diastolic murmur	
Crepitations	Left heart failure
Pulmonary oedema	
Pleural effusions	
Right ventricular heave, loud P_2	Pulmonary hypertension

AF, a more gradual rise in left atrial pressure may occur and is tolerated better. Pulmonary hypertension may occur, which can protect the patient from pulmonary oedema, but leads to right ventricular hypertrophy and dilatation, tricuspid regurgitation and right heart failure. Fewer than 20% of patients remain in sinus rhythm but many of these have a small fibrotic LA and severe pulmonary hypertension.

Clinical features

Effort-related dyspnoea is usually the dominant symptom (Box 16.77). Typically, exercise tolerance diminishes gradually over years and patients often underestimate the extent of their disability until the diagnosis is made and their valve disease is treated. Acute pulmonary oedema or pulmonary hypertension can lead to haemoptysis. Fatigue is a common symptom due to a low cardiac output. Thromboembolism is a common complication, especially in patients with AF and dilated atria. Prior to the advent of anticoagulant therapy, emboli caused one-quarter of all deaths.

The physical signs of mitral stenosis are often found before symptoms develop and their recognition is of particular importance in pregnancy. The forces that open and close the mitral valve increase as left atrial pressure rises. The first heart sound (S1) is therefore loud and can be palpable (tapping apex beat). An opening snap may be audible and moves closer to the second sound (S2) as the stenosis becomes more severe and left atrial pressure rises. However, the first heart sound and opening snap may be inaudible if the valve is heavily calcified.

Turbulent flow produces the characteristic low-pitched mid-diastolic murmur and sometimes a thrill (Fig. 16.78). The murmur is accentuated by exercise and during atrial systole (pre-systolic accentuation) in those who remain in sinus rhythm. Early in the disease a pre-systolic murmur may be the only auscultatory abnormality, but in patients with

- Pulmonary artery pressure
- Left ventricular function

Cardiac catheterisation

- Coronary artery disease
- Pulmonary artery pressure
- Mitral stenosis and regurgitation

symptoms, the murmur extends from the opening snap to the first heart sound. Coexisting mitral regurgitation causes a pansystolic murmur that radiates towards the axilla.

Pulmonary hypertension may ultimately lead to right ventricular hypertrophy and dilatation with secondary tricuspid regurgitation, which causes a parasternal lift, and a systolic murmur and giant '*v* waves' in the venous pulse.

Investigations

Doppler echocardiography is the investigation of choice for evaluation of suspected mitral stenosis (see Fig. 16.78). Cardiac catheterisation may also be required if surgery or valvuloplasty is being considered, to screen for coexisting conditions such as CAD. The ECG may show either AF or bifid P waves (P mitrale) associated with left atrial hypertrophy (Box 16.78).

Management

Patients with mild symptoms can be treated medically but intervention by balloon valvuloplasty, mitral valvotomy or mitral valve replacement should be considered if the patient remains symptomatic despite medical treatment or if pulmonary hypertension develops.

Medical management

This consists of anticoagulation to reduce the risk of systemic embolism, ventricular rate control with digoxin, β-blockers or rate-limiting calcium antagonists for AF, and diuretics to control pulmonary congestion. Patients with AF in the context of rheumatic mitral stenosis require anticoagulation with a vitamin K antagonist and not a DOAC.

Mitral balloon valvuloplasty and valve replacement

Valvuloplasty is the treatment of choice if specific criteria are fulfilled (Box 16.79 and Fig. 16.79), although surgical closed or open mitral valvotomy is an acceptable alternative. Patients who have undergone mitral valvuloplasty or valvotomy should be followed up at 1- to 2-yearly intervals because restenosis may occur. Clinical symptoms and signs are a guide to the severity of mitral restenosis, but Doppler echocardiography provides a more accurate assessment.

Valve replacement is indicated if there is substantial mitral reflux or if the valve is rigid and calcified.

16.79 Criteria for mitral valvuloplasty*

- Significant symptoms
- Isolated mitral stenosis
- No (or trivial) mitral regurgitation
- Mobile, non-calcified valve/subvalve apparatus on echo
- Left atrium free of thrombus

*For comprehensive guidelines on valvular heart disease, see www.acc.org.

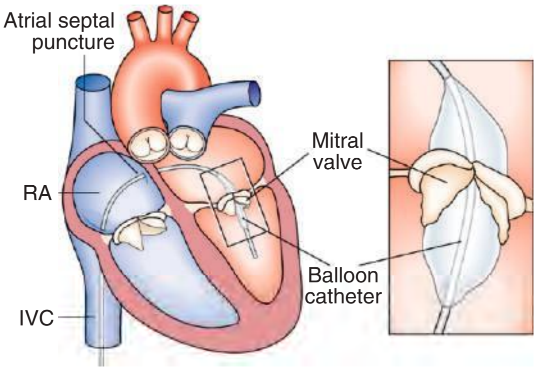

Fig. 16.79 Mitral valvuloplasty. A guidewire is introduced into the right atrium (RA) from the femoral vein and the inferior vena cava (IVC). The interatrial septum is punctured, providing access to the left atrium and mitral valve. A balloon catheter is then advanced over the guidewire across the mitral valve, and the balloon is dilated to stretch the valve and reduce the degree of stenosis.

16.80 Causes of mitral regurgitation

- Mitral valve prolapse
- Dilatation of the left ventricle and mitral valve ring ('functional' mitral regurgitation due to coronary artery disease, cardiomyopathy)
- Damage to valve cusps and chordae (rheumatic heart disease, endocarditis)
- Ischaemia or infarction of the papillary muscle
- Myocardial infarction

Mitral regurgitation

Rheumatic disease is the principal cause in countries where rheumatic fever is common but elsewhere, including in the UK, other causes are more important (Box 16.80). Mitral regurgitation may also follow mitral valvotomy or valvuloplasty.

Pathogenesis

Mitral regurgitation can be due to pathology of the valve or valve apparatus ('primary' MR), or due to failure of leaflet coaptation due to pathology affecting the left ventricle +/– dilatation of the mitral valve annulus ('secondary' or 'functional' MR). Chronic mitral regurgitation causes gradual dilatation of the LA with little increase in pressure and relatively few symptoms. Nevertheless, the LV dilates slowly and the left ventricular diastolic and left atrial pressures gradually increase because of chronic volume overload of the LV. In contrast, acute mitral regurgitation causes a rapid rise in left atrial pressure (because left atrial compliance is normal) and marked symptomatic deterioration, often with acute pulmonary oedema.

Mitral valve prolapse

This is also known as 'floppy' mitral valve and is a common cause of mild mitral regurgitation (Fig. 16.80). Some cases are thought to be due to a developmental abnormality of the mitral valve and others due to degenerative myxomatous change in a normal mitral valve. Rarely, mitral valve prolapse may occur in association with Marfan syndrome.

In its mildest forms, the valve remains competent but bulges back into the atrium during systole, causing a mid-systolic click but no murmur. In the presence of a regurgitant valve, the click is followed by a late systolic murmur, which lengthens as the regurgitation becomes more severe. A

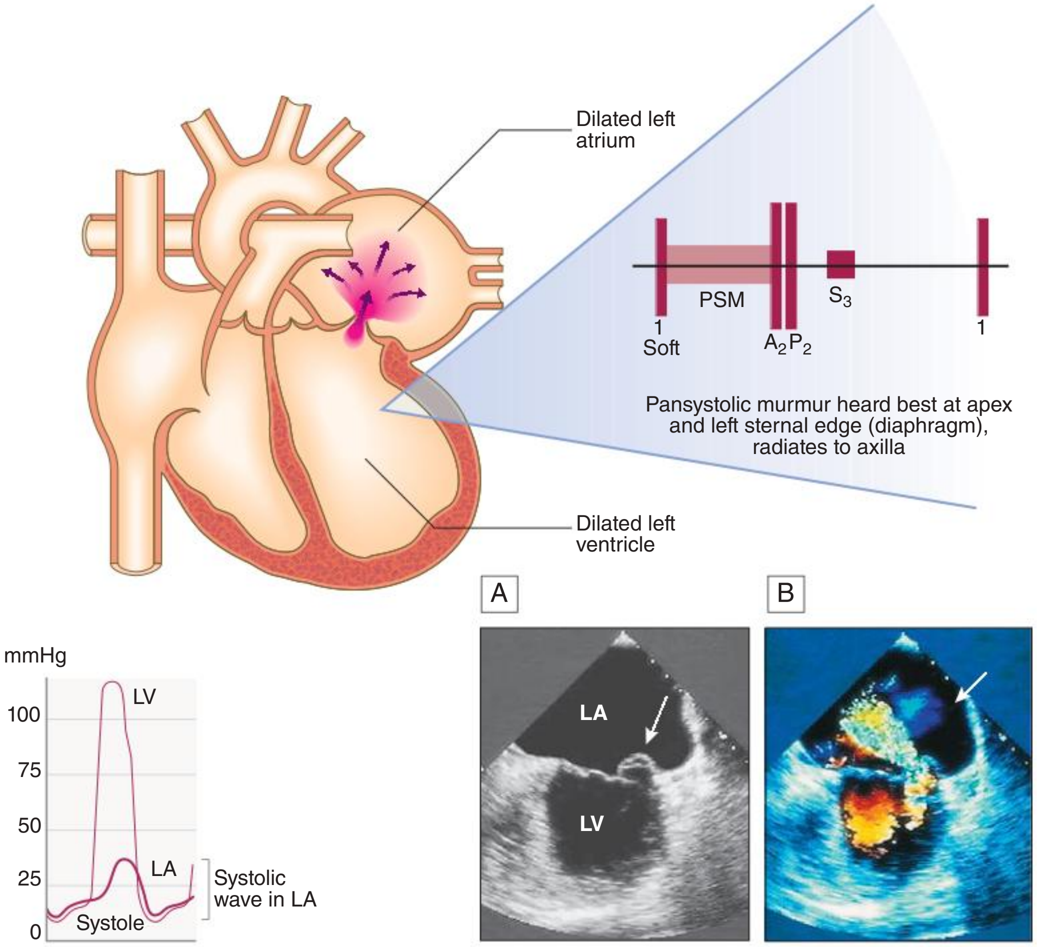

Fig. 16.80 Mitral regurgitation: murmur and systolic wave in left atrial pressure. The first sound is normal or soft and merges with a pansystolic murmur (PSM) extending to the second heart sound. A third heart sound occurs with severe regurgitation. **A** A transoesophageal echocardiogram shows mitral valve prolapse, with one leaflet bulging towards the left atrium (LA, arrow). **B** This results in a jet of mitral regurgitation on colour Doppler (arrow). (LV = left ventricle)

click is not always audible, and the physical signs may vary with both posture and respiration. Progressive elongation of the chordae tendineae leads to increasing mitral regurgitation, and if chordal rupture occurs, regurgitation suddenly becomes severe. This is rare before the fifth or sixth decade of life.

Mitral valve prolapse is associated with a variety of typically benign arrhythmias (although an association with malignant arrhythmias is emerging), atypical chest pain and a very small risk of embolic stroke or transient ischaemic attack (TIA). Nevertheless, the overall long-term prognosis is good.

Other causes of mitral regurgitation

Mitral valve function depends on the chordae tendineae and their papillary muscles; dilatation of the LV distorts the geometry of these and may cause mitral regurgitation (see Box 16.80). Dilated cardiomyopathy and heart failure from CAD are common causes of so-called ‘functional’ mitral regurgitation. Endocarditis is an important cause of acute mitral regurgitation.

Clinical features

Symptoms and signs depend on the underlying cause and how suddenly the regurgitation develops (Box 16.81). Chronic mitral regurgitation produces a symptom complex that is similar to that of mitral stenosis, but sudden-onset mitral regurgitation usually presents with acute pulmonary

Fig. 16.81 Aortic stenosis. Pressure traces show the systolic gradient between left ventricle (LV) and aorta. The 'diamond-shaped' murmur is heard best with the diaphragm in the aortic outflow and at the apex. An ejection click (EC) may be present in young patients with a bicuspid aortic valve but not in older patients with calcified valves. Aortic stenosis may lead to left ventricular hypertrophy with a fourth sound at the apex and post-stenotic dilatation of the aortic arch. Figure 16.11 shows the typical Doppler signal with aortic stenosis.

oedema. Due the direction of the regurgitant jet, the murmur associated with posterior leaflet prolapse is often heard best in the anterior precordium, and anterior leaflet prolapse is best heard into the axilla. Functional regurgitation usually causes an apical pansystolic murmur (Fig. 16.81), which radiates into the axilla and may be accompanied by a thrill. Increased forward flow through the mitral valve causes a loud third heart sound and even a short mid-diastolic murmur. The apex beat feels active and rocking due to left ventricular volume overload and is usually displaced due to left ventricular dilatation.

Investigations

Echocardiography is a pivotal investigation. The severity of regurgitation can be assessed by Doppler and information may also be gained on papillary muscle function and valve prolapse. An ECG should be performed and commonly shows AF, due to atrial dilatation. Cardiac catheterisation is indicated when surgery is being considered (Box 16.82).

Management

Mitral regurgitation of moderate severity can be treated medically with diuretics and vasodilators. Digoxin and anticoagulation should be given if AF is present, the latter depending on the CHA_2DS_2-VA score (Box 16.83). If systemic hypertension is present, it should be treated with vasodilators such as ACE inhibitors or ARBs, since high afterload may worsen the degree of regurgitation. All patients should be reviewed at regular intervals, both clinically and by echocardiography. Worsening symptoms, progressive cardiomegaly or echocardiographic evidence of deteriorating left ventricular function are indications for mitral valve replacement or repair. Mitral valve repair is now the treatment of choice for severe mitral regurgitation, because early repair appears to prevent irreversible left ventricular damage. Mitral regurgitation often accompanies left ventricular failure associated with CAD. If such patients undergo CABG surgery, it is common practice to repair the valve and restore mitral valve function by inserting an annuloplasty ring to tighten the mitral annulus and improve leaflet coaptation. In patients with left ventricular impairment and dilatation and mitral regurgitation, it can be difficult to determine what the predominant problem is. If ventricular dilatation is the underlying cause of mitral regurgitation, then mitral valve repair or replacement may worsen ventricular function, as the ventricle can no

Symptoms

- Mild or moderate stenosis: usually asymptomatic
- Exertional dyspnoea
- Angina
- Exertional syncope
- Sudden death
- Episodes of acute pulmonary oedema

Signs

- Ejection systolic murmur
- Slow-rising carotid pulse
- Heaving apex beat (left ventricular pressure overload)
- Narrow pulse pressure
- Signs of pulmonary venous congestion

longer empty into the low-pressure LA. In heart failure patients eligible for cardiac resynchronisation therapy pacemakers, these can help improve left ventricular function and dilatation, and reduce functional mitral regurgitation. Percutaneous transcatheter edge to edge repair (TEER) procedures can improve leaflet coaptation especially in those not suitable for cardiac surgery.

Aortic valve disease

Aortic stenosis

There are several causes of aortic stenosis but the age at which patients present can give a clue to the most likely diagnosis (Box 16.84). In congenital aortic stenosis, obstruction is present from birth or becomes apparent during infancy. With bicuspid aortic valves, obstruction may take years to develop as the valve becomes fibrotic and calcified, and these patients present as young to middle-aged adults or coincidentally found to have a systolic murmur during physical examination. Rheumatic disease of the aortic valve presents at a similar age but is usually accompanied by mitral valve disease. In older people, tricuspid aortic valves may become stenotic as the result of fibrosis and calcification. Stenosis develops slowly, typically occurring at 30–60 years in those with rheumatic disease, 50–60 years in those with bicuspid aortic valves and 70–90 years in those with calcific aortic disease.

Pathogenesis

Cardiac output is initially maintained in patients with aortic stenosis at the cost of a steadily increasing pressure gradient across the aortic valve. With progression of the stenosis, the LV becomes increasingly hypertrophied and coronary blood flow may be inadequate to supply the myocardium, such that angina can develop even in the absence of coexisting CAD. The fixed outflow obstruction limits the increase in cardiac output required on exercise, which is when patients usually first experience symptoms. Eventually, the LV can no longer overcome the outflow tract obstruction and left ventricular failure results, leading to pulmonary oedema.

Clinical features

The ejection systolic murmur of aortic stenosis is commonly picked up in asymptomatic patients during routine clinical examination but the three cardinal symptoms are angina, breathlessness and syncope (Box 16.85). Angina arises either because of the increased demands of the hypertrophied LV working against the high-pressure outflow tract obstruction, or the presence of coexisting CAD, which affects over 50% of patients. Exertional breathlessness suggests cardiac decompensation due to excessive pressure overload placed on the LV. Syncope usually occurs on exertion when cardiac output fails to rise to meet demand, leading to a fall in BP. Syncope can also be due to arrhythmias which are usually poorly tolerated in those with haemodynamically significant aortic stenosis. If patients with severe aortic stenosis do not complain of symptoms, a careful exercise test may reveal symptoms or objective evidence of hypotension or ischaemia on modest exertion.

The characteristic clinical signs of severe aortic stenosis are shown in Box 16.85. A harsh ejection systolic murmur radiates to the neck, with a soft second heart sound, particularly in those with calcific valves. The murmur is often likened to a saw cutting wood and may (especially in older patients) have a musical quality like the ‘mew’ of a seagull (see Fig. 16.81). The severity of aortic stenosis may be difficult to gauge clinically, as older patients with a non-compliant ‘stiff’ arterial system may have an apparently normal carotid upstroke in the presence of severe aortic stenosis. Milder degrees of stenosis may be difficult to distinguish from aortic sclerosis, in which the valve is thickened or calcified but not obstructed. A careful examination should be made for other valve lesions, particularly in rheumatic heart disease, when there is frequently concomitant mitral valve disease. In contrast to patients with mitral stenosis, which tends to progress very slowly, patients with aortic stenosis typically remain asymptomatic for many years but deteriorate rapidly when symptoms develop and can succumb to cardiac failure, syncope and sudden death.

Investigations

Echocardiography is a pivotal investigation in patients suspected of having aortic stenosis. It can demonstrate restricted valve opening (Fig. 16.82) and Doppler assessment permits calculation of the systolic gradient across the aortic valve, from which the severity of stenosis can be assessed (see Fig. 16.11). In patients with impaired left ventricular function, velocities across the aortic valve may be diminished because of a reduced stroke volume; this is called ‘low-flow’ aortic stenosis. In this situation, dobutamine stress echocardiography can help distinguish those with truly severe aortic stenosis from those who have reduced aortic valve excursion due to poor LV function (‘pseudosevere’ aortic stenosis). When marked aortic regurgitation or elevated cardiac output is present, velocities are increased because of an increased stroke volume, and this may overestimate stenosis severity on Doppler echocardiography. In advanced cases, ECG features of left ventricular hypertrophy (Box 16.86) are often pronounced (Fig. 16.83), and down-sloping ST segments and T inversion (‘strain pattern’) are seen in the lateral leads, reflecting left ventricular fibrosis. Nevertheless, the ECG can be normal, despite severe stenosis. Occasionally, there is evidence of AV block due to the encroachment of the fibrocalcific process on the adjacent AV node and His–Purkinje system, an occasional cause of syncope in these patients. Assessment of valve calcification (‘calcium score’) using CT may be useful in assessing the degree of valve calcification where there is uncertainty surrounding disease severity.

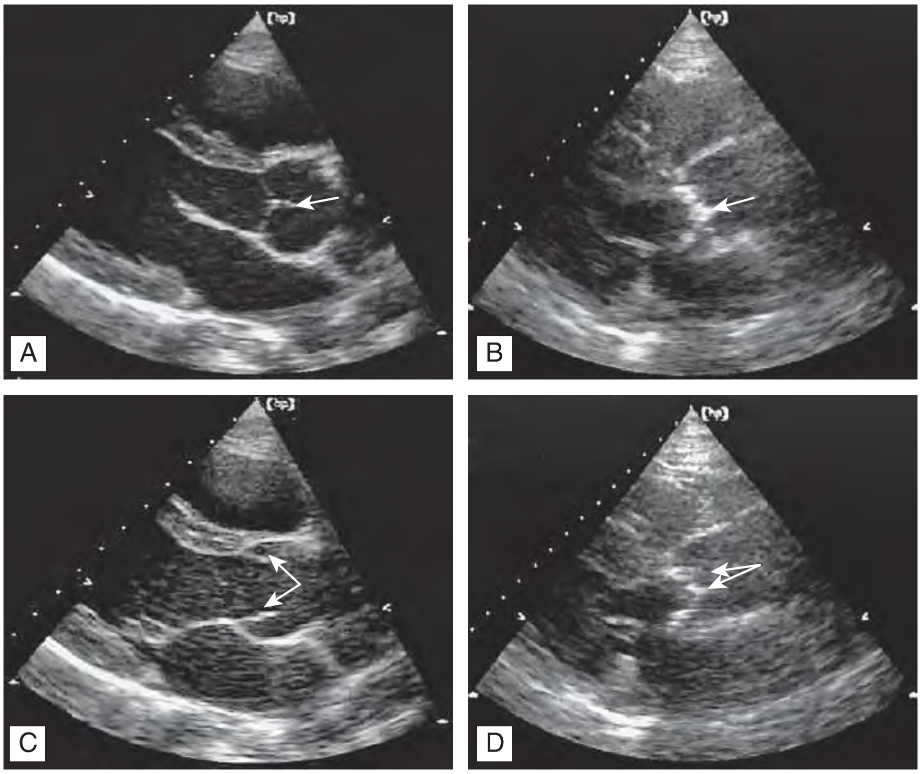

Fig. 16.82 Two-dimensional echocardiogram comparing a normal individual and a patient with calcific aortic stenosis. **A** Normal individual in diastole; the aortic leaflets are closed and thin, and a point of coaptation is seen (arrow). **B** Calcific aortic stenosis in diastole; the aortic leaflets are thick and calcified (arrow). **C** Normal in systole; the aortic leaflets are open (arrows). **D** Calcific aortic stenosis in systole; the thickened leaflets have barely moved (arrows). *From Newby D, Grubb N. Cardiology: an illustrated colour text. Edinburgh: Churchill Livingstone, Elsevier Ltd; 2005.*

16.86 Investigations in aortic stenosis

ECG

- Left ventricular hypertrophy
- Left bundle branch block

Chest X-ray

- May be normal; sometimes enlarged left ventricle and dilated ascending aorta on postero-anterior view, calcified valve on lateral view

Echo

- Calcified valve with restricted opening, hypertrophied left ventricle

Doppler

- Measurement of severity of stenosis
- Detection of associated aortic regurgitation

Cardiac catheterisation

- Mainly to identify associated coronary artery disease
- May be used to measure gradient between left ventricle and aorta

Management

Irrespective of the severity of valve stenosis, patients with asymptomatic aortic stenosis have a good immediate prognosis and conservative management is appropriate. Such patients should be kept under review, as the development of symptoms has a poor prognosis and is an indication for prompt surgery. In practice, patients with moderate or severe stenosis should be evaluated every 6–12 months with Doppler echocardiography to detect evidence of progression in severity. The intervals between reviews should be more frequent (typically 3- to 6-monthly) in older patients with heavily calcified valves and in those with increasingly severe stenosis or more rapid progression.

Patients with symptomatic severe aortic stenosis should have prompt aortic valve replacement. Delay exposes the patient to the risk of sudden death or irreversible deterioration in ventricular function. Old age is not a contraindication to valve replacement and results are very good in experienced centres, even for those in their eighties (Box 16.87). This is especially the case with transcatheter aortic valve implantation (TAVI, see Fig. 16.85). Aortic balloon valvuloplasty is useful in congenital aortic stenosis but has limited value in older patients with calcific aortic stenosis.

Anticoagulation with vitamin K antagonists is required in all patients with a mechanical prosthesis.

Aortic regurgitation

This condition can result from disease of the aortic valve cusps, infection, trauma or dilatation of the aortic root. The causes are summarised in Box 16.88.

Pathogenesis

Regurgitation of blood through the aortic valve causes the LV to dilate as cardiac output increases to maintain the demands of the circulation and the regurgitant volume. The stroke volume of the LV may eventually be doubled, and the major arteries are then conspicuously pulsatile. As the disease progresses, left ventricular failure develops, leading to a rise in left ventricular end-diastolic pressure and pulmonary oedema.

Clinical features

Until the onset of breathlessness, the only symptom may be an awareness of the heart beat (Box 16.89), particularly when lying on the left side, which results from the increased stroke volume. Paroxysmal nocturnal dyspnoea is sometimes the first symptom, and peripheral oedema

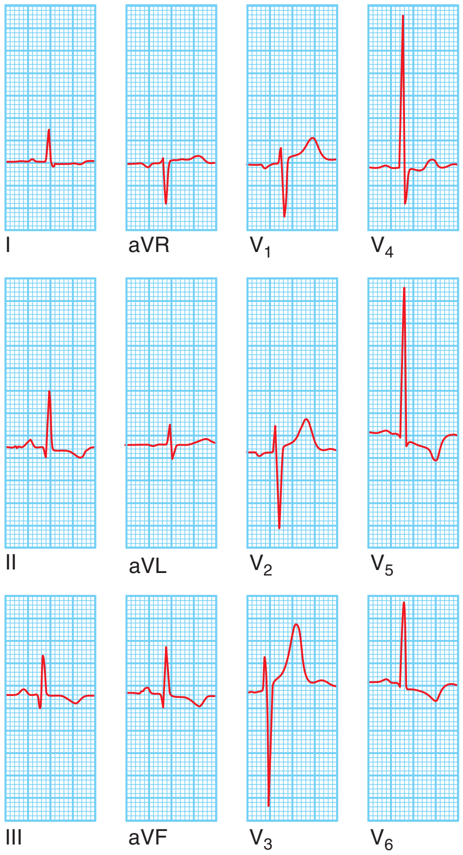

Fig. 16.83 **Left ventricular hypertrophy.** QRS complexes in limb leads have increased amplitude with very large R waves in V_4 and V_5 and a deep S wave in V_3. There is ST depression and T-wave inversion in leads II, III, aVF, V_5 and V_6: a 'left ventricular strain' pattern.

16.87 Aortic stenosis in the elderly

- **Incidence**: the most common form of valve disease.
- **Symptoms**: a common cause of syncope, angina and heart failure.
- **Signs**: because of increasing stiffening in the central arteries, low pulse pressure and a slow-rising pulse may not be present.
- **Transcatheter aortic valve implantation (TAVI)**: a good option in older individuals because less invasive than surgery.
- **Surgery**: can be successful in those aged 80 years or more in the absence of comorbidity, but with a higher operative mortality. The prognosis without surgery is poor once symptoms have developed.
- **Valve replacement type**: a biological valve is often preferable to a mechanical one because this obviates the need for anticoagulation, and the durability of biological valves usually exceeds the patient's anticipated life expectancy.

16.88 Causes of aortic regurgitation

Congenital

- Bicuspid valve or disproportionate cusps

Acquired

- Rheumatic disease
- Infective endocarditis
- Trauma
- Causes of aortic dilatation:
    - Marfan syndrome
    - Aneurysm
    - Aortic dissection
    - Syphilis
    - Ankylosing spondylitis

16.89 Clinical features of aortic regurgitation

Symptoms

Mild to moderate aortic regurgitation

- Often asymptomatic
- Palpitations

Severe aortic regurgitation

- Breathlessness
- Angina

Signs

Pulses

- Large-volume or 'collapsing' pulse
- Low diastolic and increased pulse pressure
- Bounding peripheral pulses
- Capillary pulsation in nail beds: Quincke sign
- Femoral bruit ('pistol shot'): Traube sign
- Femoral systolic and diastolic (to-and-fro) murmur: Duroziez sign
- Head nodding with pulse: de Musset sign

Murmurs

- Early diastolic murmur
- Systolic murmur (increased stroke volume)
- Austin Flint murmur (soft mid-diastolic)

Other signs

- Displaced, thrusting apex beat (volume overload)
- Pre-systolic impulse
- Third heart sound
- Crepitations (pulmonary venous congestion)

or angina may occur. The characteristic diastolic murmur is best heard to the left of the sternum during held expiration (Fig. 16.84) and can even extend into the apex; a thrill is rare. A systolic murmur due to the increased stroke volume is common and does not necessarily indicate stenosis. The regurgitant jet causes fluttering of the mitral valve and, if severe, causes partial closure of the anterior mitral leaflet, leading to functional mitral stenosis and a soft mid-diastolic (Austin Flint) murmur.

Acute severe regurgitation may occur as the result of perforation or tear of an aortic cusp in endocarditis. In this circumstance there may be no time for compensatory left ventricular hypertrophy and dilatation to develop and the features of heart failure may predominate. The classical signs of aortic regurgitation in such patients may be masked by tachycardia and an abrupt rise in left ventricular end-diastolic pressure. The pulse pressure may also be normal or near normal and the diastolic murmur may be short or even absent.

Investigations

Doppler echocardiography is the investigation of first choice for detecting regurgitation (Box 16.90). In severe acute aortic regurgitation, the rapid rise in left ventricular diastolic pressure may cause premature mitral valve closure. MRI can be helpful in quantifying the degree of regurgitation and MRI or CT can also be useful in assessing the degree and extent of aortic dilatation if this is suspected. Invasive coronary angiography may be required if the patient requires cardiac surgery.

Management

Treatment may be required for underlying conditions, such as endocarditis or syphilis. Aortic valve replacement is indicated if aortic regurgitation causes symptoms, and this may need to be combined with aortic root replacement and coronary bypass surgery. Those with chronic aortic regurgitation can remain asymptomatic for many years because compensatory ventricular dilatation and hypertrophy occur but should be advised to report the development of any symptoms of breathlessness or angina. Asymptomatic patients should also be followed up annually with echocardiography. If the end-systolic dimension increases to 50 mm or more or left ventricular ejection fraction is less than 50%, then aortic valve replacement should be undertaken. If systemic hypertension is present, non-rate-limiting vasodilators, such as nifedipine, should

Fig. 16.84 Aortic regurgitation. The early diastolic murmur is best heard at the left sternal border and may be accompanied by an ejection systolic ('to-and-fro') murmur. The aortic arch and left ventricle (LV) may become dilated. The inset shows a Doppler echocardiogram with the regurgitant jet (arrows). *Inset (Colour Doppler echo) From Newby D, Grubb N. Cardiology: an illustrated colour text. Edinburgh: Churchill Livingstone, Elsevier Ltd; 2005.*

16.90 Investigations in aortic regurgitation

ECG

- Initially normal, later left ventricular hypertrophy and T-wave inversion

Chest X-ray

- Cardiac dilatation, maybe aortic dilatation
- Features of left heart failure

Echo

- Dilated left ventricle
- Hyperdynamic left ventricle
- Doppler detects reflux
- Fluttering anterior mitral leaflet

Cardiac catheterisation*

- Dilated left ventricle
- Aortic regurgitation
- Dilated aortic root

*Not always required.

be used to control systolic BP. When aortic root dilatation is the cause of aortic regurgitation, as can occur in Marfan syndrome, aortic root replacement is usually necessary.

Tricuspid valve disease

Tricuspid stenosis

Tricuspid stenosis is usually rheumatic in origin and is rare in developed countries. Tricuspid disease occurs in fewer than 5% of patients with rheumatic heart disease and then nearly always occurs in association with mitral and aortic valve disease. Tricuspid stenosis and regurgitation may also occur in the carcinoid syndrome.

Clinical features and investigations

Although the symptoms of mitral and aortic valve disease predominate, tricuspid stenosis may cause symptoms of right heart failure, including hepatic discomfort and peripheral oedema.

16.91 Causes of tricuspid regurgitation

Primary

- Rheumatic heart disease
- Endocarditis, particularly in intravenous drug users
- Ebstein congenital anomaly (see Box 16.102)

Secondary

- Right ventricular failure
- Right ventricular infarction
- Pulmonary hypertension, secondary to chronic pulmonary disease

The main clinical feature is a raised JVP with a prominent *a* wave, and a slow *y* descent due to the loss of normal rapid right ventricular filling. There is also a mid-diastolic murmur, best heard at the lower left or right sternal border. This is generally higher pitched than the murmur of mitral stenosis and is increased by inspiration. Right heart failure causes hepatomegaly with pre-systolic pulsation (large *a* wave), ascites and peripheral oedema. The diagnosis can be confirmed by Doppler echocardiography, which shows similar appearances to those of rheumatic mitral stenosis.

Management

In patients who require surgery to other valves, the tricuspid valve can either be replaced or treated with valvotomy. Balloon valvuloplasty can be used to treat rare cases of isolated tricuspid stenosis.

Tricuspid regurgitation

Tricuspid regurgitation is common, and is most frequently functional, occurring due to right ventricular dilatation due to right heart failure or biventricular failure. It may also be the result of other conditions, as summarised in Box 16.91.

Clinical features

Symptoms are usually non-specific, with tiredness related to reduced cardiac output, and oedema and hepatic enlargement due to venous congestion. The most prominent sign is a ‘giant’ *v* wave in the jugular venous pulse (a *cv* wave replaces the normal *x* descent). Other features include a pansystolic murmur at the left sternal border and a pulsatile liver. Echocardiography may reveal dilatation of the RV. If the valve has been affected by rheumatic disease, the leaflets will appear thickened and, in endocarditis, vegetations may be seen.

Management

Tricuspid regurgitation due to right ventricular dilatation often improves when the cardiac failure is treated. Patients with a normal pulmonary artery pressure tolerate isolated tricuspid regurgitation well, and valves damaged by endocarditis do not usually need to be replaced. Patients undergoing mitral valve replacement, who have tricuspid regurgitation due to marked dilatation of the tricuspid annulus, benefit from valve repair with an annuloplasty ring to bring the leaflets closer together. Those with rheumatic damage may require tricuspid valve replacement. Percutaneous transcatheter edge to edge repair (TEER) procedures improve leaflet coaptation and reduce tricuspid regurgitation and improve quality of life. Similar TEER procedures are available for treating mitral regurgitation.

Pulmonary valve disease

Pulmonary stenosis

This can occur in the carcinoid syndrome but is usually congenital, in which case it may be isolated or associated with other abnormalities, such as Fallot tetralogy.

Clinical features

The principal finding on examination is an ejection systolic murmur, loudest at the left upper sternum and radiating towards the left shoulder. There may be a thrill, best felt when the patient leans forwards and breathes out. The murmur is often preceded by an ejection sound (click). Delay in right ventricular ejection may cause wide splitting of the second heart sound. Severe pulmonary stenosis is characterised by a loud, harsh murmur, an inaudible pulmonary closure sound (P_2), an increased right ventricular heave, and prominent *a* waves in the jugular pulse.

Investigations

Doppler echocardiography is the definitive investigation. ECG may show evidence of right ventricular hypertrophy, and post-stenotic dilatation in the pulmonary artery may be observed on the chest X-ray.

Management

Mild to moderate isolated pulmonary stenosis is relatively common and does not usually progress or require treatment. Severe pulmonary stenosis (resting gradient > 50 mmHg with a normal cardiac output) can be treated by percutaneous pulmonary balloon valvuloplasty or, if this is not available, by surgical valvotomy. Long-term results are very good. Postoperative pulmonary regurgitation is common but benign, unless haemodynamically significant.

Pulmonary regurgitation

This is rare in isolation and is usually associated with pulmonary artery dilatation due to pulmonary hypertension. It may complicate mitral stenosis, producing an early diastolic decrescendo murmur at the left sternal border that is difficult to distinguish from aortic regurgitation (Graham Steell murmur). The pulmonary hypertension may be secondary to other disease of the left side of the heart, primary pulmonary vascular disease or Eisenmenger syndrome. Trivial pulmonary regurgitation is a frequent finding in normal individuals and has no clinical significance.

Prosthetic valves

Diseased heart valves can be replaced with mechanical or biological prostheses. The three main types of mechanical prosthesis are the ball and cage, tilting single disc and tilting bi-leaflet valves. All generate prosthetic sounds or clicks on auscultation. Pig or allograft valves mounted on a supporting stent are commonly used biological valves. They generate near normal heart sounds, but all prosthetic valves used in the aortic position produce a systolic flow murmur.

i 16.92 Anticoagulation targets and prosthetic heart valves

Mechanical valves	Target INR
Ball and cage (e.g. Starr–Edwards)	3.0–4.0
Tilting disc (e.g. Björk–Shiley)	
Bi-leaflet (e.g. St Jude)	2.5–3.0
Biological valves with atrial fibrillation	2.0–3.0

(INR = International Normalised Ratio)

All mechanical valves require long-term anticoagulation with vitamin K antagonists because they can cause systemic thromboembolism or may develop valve thrombosis or obstruction (Box 16.92); the prosthetic clicks may become inaudible if the valve malfunctions. Biological valves have the advantage of not requiring anticoagulants to maintain proper function although many patients undergoing valve replacement surgery, especially mitral valve replacement, will have AF that requires anticoagulation anyway. Biological valves are less durable than mechanical valves and may degenerate 7 or more years after implantation, particularly when used in the mitral position. They are more durable in the aortic position and in older patients, so are particularly appropriate for patients over 65 undergoing aortic valve replacement. Younger patients wishing to avoid a mechanical valve due to the lifetime risks associated with taking vitamin K antagonists can opt for a biological valve but will require redo aortic valve surgery, or a valve-in-valve procedure (where a TAVI is implanted inside the initial biological valve), in later life when the first biological valve degenerates.

Transcatheter aortic valve implantation

For patients being considered for aortic valve surgery, especially due to aortic stenosis, transcatheter aortic valve implantation (TAVI) is an alternative to surgical aortic valve replacement. The native valve is not removed but is compressed by the new bioprosthetic valve, which is implanted within it. The bioprosthetic valve is mounted on a large stent-like structure and is implanted through a catheter inserted in the femoral artery (Fig. 16.85). TAVI has several major advantages. It avoids the need for a sternotomy, is associated with a short recovery period, can be used in high-risk and otherwise inoperable patients, and is much better tolerated by older patients. Complications include stroke (2%) and heart block necessitating pacemaker implantation (5%–15%).

Prosthetic valve dysfunction

Symptoms or signs of unexplained heart failure in a patient with a prosthetic heart valve may be due to valve dysfunction, and urgent assessment is required. Mechanical valves can suffer strut fracture and fail, causing catastrophic regurgitation. Alternatively, they may thrombose and cause systemic thromboembolism or valve obstruction, especially in the presence of inadequate anticoagulation. Biological valve dysfunction can occur around 8–10 years after implantation and close surveillance is required when this becomes evident.

Infective endocarditis

This is caused by microbial infection of a heart valve, the lining of a cardiac chamber or blood vessel, or a congenital anomaly. Both native and prosthetic valves can be affected. The most common causes of infective endocarditis are streptococci and staphylococci, but other organisms may also be involved.

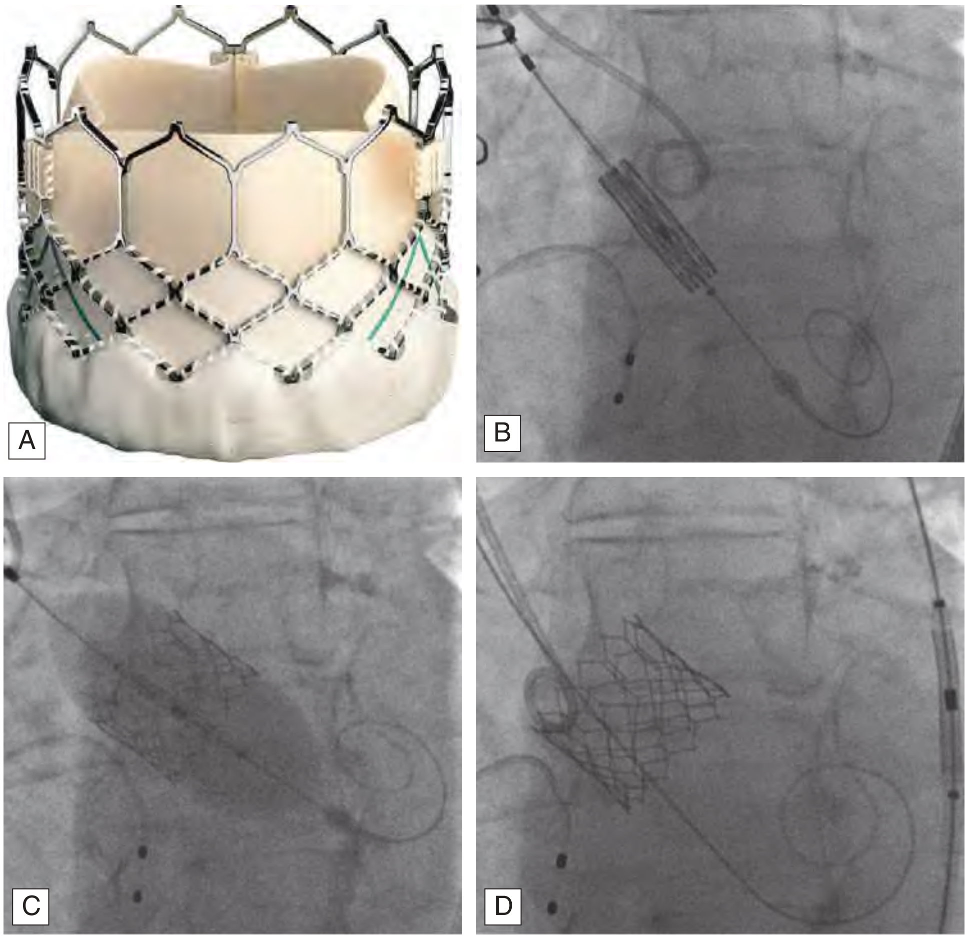

Fig. 16.85 **Transcatheter aortic valve implantation (TAVI).** Appearance of an expanded bioprosthetic valve **A**, which is positioned through a large femoral catheter in an unexpanded form **B**, before the valve is deployed by a balloon **C** during rapid ventricular pacing, to leave behind the fully expanded valve **D**.

16.93 Endocarditis in old age

- **Symptoms and signs**: may be non-specific, with delirium, weight loss, malaise and weakness, and the diagnosis may not be suspected.
- **Common causative organisms**: often enterococci (from the urinary tract) and *Streptococcus gallolyticus* subsp. *gallolyticus* (from a colonic source).
- **Morbidity and mortality**: much higher.

Epidemiology

The incidence of infective endocarditis is around 14 cases per 100 000 per annum, accounting for more than 66 000 deaths worldwide. More than 50% of patients are over 60 years of age (Box 16.93). In a large British study, the underlying condition was rheumatic heart disease in 24% of patients, congenital heart disease in 19%, and other cardiac abnormalities such as calcified aortic valve or floppy mitral valve in 25%. The remaining 32% were not thought to have a pre-existing cardiac abnormality. Bacterial endocarditis is a serious illness; the case fatality is approximately 20% even with treatment and is even higher in those with prosthetic valve endocarditis and those infected with antibiotic-resistant organisms.

Pathophysiology

Infective endocarditis typically occurs at sites of pre-existing endocardial damage, but infection with particularly virulent or aggressive organisms, such as *Staphylococcus aureus*, can cause endocarditis in a previously normal heart. Staphylococcal endocarditis of the tricuspid valve is a common complication of intravenous drug use. Many acquired and congenital cardiac lesions are vulnerable, particularly areas of endocardial damage caused by a high-pressure jet of blood, such as ventricular septal defect, mitral regurgitation and aortic regurgitation, many of which are haemodynamically insignificant. In contrast, the risk of endocarditis at the site of haemodynamically important but low-pressure lesions, such as a large atrial septal defect, is minimal.

In the setting of bacteraemia, infection tends to occur at sites of endothelial damage because they attract deposits of platelets and fibrin that are vulnerable to colonisation by blood-borne organisms. The avascular valve tissue and presence of fibrin and platelet aggregates help to protect proliferating organisms from host defence mechanisms. When the infection is established, vegetations composed of organisms, fibrin and platelets grow, detach and embolise and can become large enough to cause obstruction. Adjacent tissues are destroyed by infection and abscesses may form. Valve regurgitation may develop or increase if the affected valve is damaged by tissue distortion, cusp perforation or disruption of chordae. Extracardiac manifestations may occur due to emboli commonly causing stroke, myocardial infarction or abdominal organ infarction. Vasculitis, skin lesions and glomerulonephritis may occur either due to emboli or immune complex deposition. Mycotic aneurysms may develop in arteries at the site of infected emboli.

Microbiology

Over half of cases are caused by *Staphylococcus aureus* or oral streptococci. The viridans group of streptococci, such as *Streptococcus mitis* and *Strep. sanguis*, which are commensals in the oral cavity, can enter the blood stream on chewing or tooth-brushing, or at the time

(HACEK = *Haemophilus aphrophilus* – now known as *Aggregatibacter aphrophilus; Aggregatibacter actinomycetemcomitans; Cardiobacterium hominis; Eikenella corrodens;* and *Kingella kingae*)
Adapted from Moreillon P, Que YA. Infective endocarditis. Lancet 2004;363:139–149.

of dental treatment, and are common causes of subacute endocarditis (Box 16.94). Other organisms, including *Enterococcus faecalis*, *Enterococcus faecium* and *Streptococcus gallolyticus* subsp. *gallolyticus* (previously known as *Streptococcus bovis*), may enter the blood from the bowel or urinary tract. Patients who are found to have endocarditis caused by *Streptococcus gallolyticus* should undergo colonoscopy, since this organism is associated with large-bowel malignancy.

Staphylococcus aureus has now overtaken streptococci as the most common cause of acute endocarditis. It originates from skin infections, abscesses or vascular access sites such as intravenous and central lines, or from intravenous drug use. It is highly virulent and invasive, usually producing florid vegetations, rapid valve destruction and abscess formation. Other causes of acute endocarditis include *Streptococcus pneumoniae* and *Streptococcus pyogenes*.

Post-operative endocarditis after cardiac surgery may affect native or prosthetic heart valves or other prosthetic materials. The most common organisms are coagulase-negative staphylococci such as *Staphylococcus epidermidis*, which are part of the normal skin flora and are often found in wound infections. Coagulase-negative staphylococci cause native valve endocarditis in approximately 5% of cases and this possibility should always be considered before they are dismissed as blood culture contaminants. Another coagulase-negative staphylococcus, *Staphylococcus lugdunensis*, causes a rapidly destructive acute endocarditis that is associated with previously normal valves and multiple emboli. Unless accurately identified, it may also be overlooked as a contaminant.

In Q fever endocarditis due to *Coxiella burnetii*, the patient often has a history of contact with farm animals. The aortic valve is usually affected and there may also be hepatitis, pneumonia and purpura. Life-long antibiotic therapy may be required.

In about 3%–4% of cases, endocarditis may be caused by Gram-negative bacteria of the so-called HACEK group (*Haemophilus aphrophilus* – now known as *Aggregatibacter aphrophilus*; *Aggregatibacter actinomycetemcomitans*; *Cardiobacterium hominis*; *Eikenella corrodens*; and *Kingella kingae*). These are slow-growing, fastidious gram-negative organisms that are oropharyngeal commensals. The diagnosis may be revealed only after prolonged culture and the organisms may be resistant to penicillin.

Brucella endocarditis is associated with a history of contact with goats or cattle and often affects the aortic valve.

Blood culture–negative endocarditis may arise as a consequence of previous antibiotic administration or due to yeasts and fungi, such as *Candida* and *Aspergillus*, which may attack previously normal or prosthetic valves, particularly in immunocompromised patients or those with in-dwelling intravenous catheters. Abscesses and emboli are common, therapy is difficult, surgery is often required, and mortality is high. Concomitant bacterial infection may be present.

16.95 Diagnosis of infective endocarditis*

Major criteria

Positive blood culture
- Typical organism from two cultures
- Persistent positive blood cultures taken > 12 hrs apart
- Three or more positive cultures taken over > 1 hr

Endocardial involvement
- Positive echocardiographic findings of vegetations
- New valvular regurgitation

Minor criteria
- Predisposing valvular or cardiac abnormality
- Intravenous drug misuse
- Pyrexia ≥ 38°C
- Embolic phenomenon
- Vasculitic phenomenon
- Blood cultures suggestive: organism grown but not achieving major criteria
- Suggestive echocardiographic findings

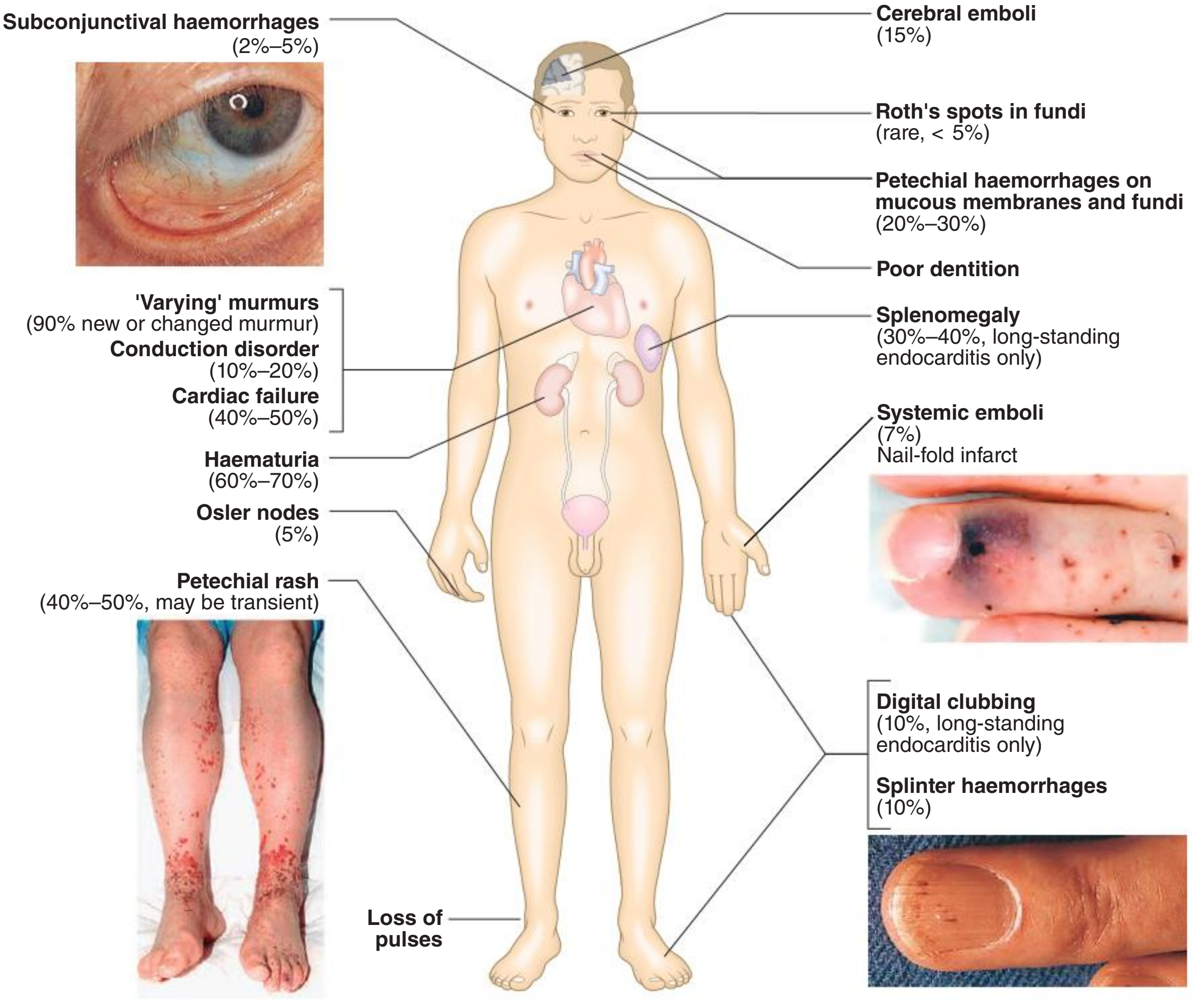
*Modified Duke criteria. Patients with two major, or one major and three minor, or five minor have definite endocarditis. Patients with one major and one minor, or three minor have possible endocarditis.

Clinical features

Endocarditis can take either an acute or a more insidious 'subacute' form; the latter often passes undetected initially. There is considerable overlap because the clinical pattern is influenced not only by the organism but also by the site of infection, prior antibiotic therapy and the presence of a valve or shunt prosthesis. The subacute form may abruptly develop acute life-threatening complications, such as valve disruption or emboli. The Duke criteria for diagnosis of infective endocarditis are shown in Box 16.95.

Subacute endocarditis

This should be suspected when a patient with congenital or valvular heart disease develops a persistent fever, complains of unusual tiredness, night sweats or weight loss, or develops new signs of valve dysfunction or heart failure. Less often, it presents as an embolic stroke or peripheral arterial embolism. Other features (Fig. 16.86) include purpura



Subconjunctival haemorrhages (2%–5%)
'Varying' murmurs (90% new or changed murmur)
Conduction disorder (10%–20%)
Cardiac failure (40%–50%)
Haematuria (60%–70%)
Osler nodes (5%)
Petechial rash (40%–50%, may be transient)
Loss of pulses
Cerebral emboli (15%)
Roth's spots in fundi (rare, < 5%)
Petechial haemorrhages on mucous membranes and fundi (20%–30%)
Poor dentition
Splenomegaly (30%–40%, long-standing endocarditis only)
Systemic emboli (7%)
Nail-fold infarct
Digital clubbing (10%, long-standing endocarditis only)
Splinter haemorrhages (10%)

Fig. 16.86 **Clinical features that may be present in endocarditis.** *Insets (Petechial rash, nail-fold infarct) From Newby D, Grubb N. Cardiology: an illustrated colour text. Edinburgh: Churchill Livingstone, Elsevier Ltd; 2005.*

and petechial haemorrhages in the skin and mucous membranes, and splinter haemorrhages under the fingernails or toenails. Osler nodes are painful, tender swellings at the fingertips that are probably the product of vasculitis; they are rare. Digital clubbing is a late sign. The spleen is frequently palpable; in *Coxiella* infections, the spleen and the liver may be considerably enlarged. Non-visible haematuria is common. The finding of any of these features in a patient with persistent fever, raised blood inflammatory markers, or malaise is an indication for re-examination to detect hitherto unrecognised heart disease.

Acute endocarditis

This presents as a severe febrile illness with prominent and changing heart murmurs, valve dysfunction and petechiae. Clinical stigmata of chronic endocarditis are usually absent. Embolic events are common, and cardiac or renal failure may develop rapidly. Abscesses may be detected on echocardiography. Partially treated acute endocarditis behaves like subacute endocarditis.

Post-operative endocarditis

This may present as an unexplained fever in a patient who has had heart valve surgery. The infection usually involves the valve ring and may resemble subacute or acute endocarditis, depending on the virulence of the organism. Morbidity and mortality are high and revision surgery is often required. Culprit bacteria are often coagulase-negative staphylococci introduced during the perioperative period.

Investigations

Blood culture (see Fig. 7.7) is the pivotal investigation to identify the organism and guide antibiotic therapy. Three to six sets of blood cultures should be taken prior to commencing therapy and should not wait for episodes of pyrexia. The first two specimens will detect bacteraemia in 90% of culture-positive cases. A meticulous aseptic technique is essential and in-dwelling lines should not be used to take cultures. Taking discrete sets of blood cultures from peripheral sites at intervals of 30 min reduces the risk of misdiagnosis due to contamination with skin commensals. Isolation of a typical organism in more than one culture provides strong evidence in favour of the diagnosis (see Box 16.95). Both aerobic and anaerobic cultures are required.

Echocardiography should be performed as soon as the diagnosis is suspected and is key for detecting and following the progress of vegetations, assessing valve damage and detecting abscess formation. Vegetations as small as 2–4 mm can be detected by transthoracic echocardiography, and even smaller ones (1–1.5 mm) can be visualised by transoesophageal echocardiography (TOE), which is particularly valuable for identifying abscess formation, imaging prosthetic heart valves or the initial transthoracic echo is negative or unremarkable. Vegetations may be difficult to distinguish in the presence of an abnormal valve; the sensitivity of transthoracic echo is approximately 65% but that of TOE is more than 90%. Failure to detect vegetations does not exclude the diagnosis.

Blood tests almost always reveal raised inflammatory markers. Elevation of CRP, ESR, a normocytic normochromic anaemia, and

Staphylococci – prosthetic valve				
Methicillin-sensitive	Flucloxacillin IV	2 g 4–6 times daily	–	6 weeks
	and gentamicin IV	1 mg/kg twice daily[2]	–	6 weeks
	and rifampicin orally	300–600 mg twice daily	–	6 weeks
Methicillin-resistant, vancomycin MIC ≤ 2 mg/L, rifampicin-sensitive	Vancomycin IV	1 g twice daily[3]	–	6 weeks
	and rifampicin orally	300–600 mg twice daily	–	6 weeks

[1] When conditions in Box 16.97 are met, 2 weeks of benzylpenicillin and gentamicin (1 mg/kg twice daily) may be sufficient. Ceftriaxone 2 g once daily IV/IM can be used instead of benzylpenicillin for those with non-severe penicillin allergy.

[2] Pre-dose gentamicin level should be ≤ 1 mg/L, post-dose 3–5 mg/L. Adjust dose according to levels and renal function.

[3] Pre-dose vancomycin level should be 15–20 mg/L. Adjust dose according to levels and renal function.

[4] Use 6 times daily if weight > 85 kg.

(IM = intramuscular; IV = intravenous; MIC = minimum inhibitory concentration)

Adapted from Gould FK, Denning DW, Elliott TS, et al. Guidelines for the diagnosis and antibiotic treatment of endocarditis in adults: a report of the working party of the British Society for Antimicrobial Chemotherapy. J Antimicrob Chemother 2012;67:269–289.

leucocytosis are common but not invariable. Surveillance CRP is more reliable than ESR in monitoring progress. Proteinuria may occur and non-visible haematuria is usually present.

The ECG may show the development of AV block (due to aortic root abscess formation) and occasionally infarction due to emboli. The chest X-ray may show evidence of cardiac failure and cardiomegaly.

Management

A multidisciplinary approach involving a physician, surgeon and microbiologist increases the chance of a successful outcome. Any source of infection should be removed as soon as possible; for example, a tooth with an apical abscess should be extracted, or an in-dwelling catheter or implantable device removed.

Empirical treatment depends on the mode of presentation, the suspected organism and the presence of a prosthetic valve or penicillin allergy. If the presentation is subacute, antibiotic treatment should ideally be withheld until the results of blood cultures are available. However, if empirical antibiotic treatment is considered necessary, amoxicillin (2 g IV 6 times daily) with ceftriaxone (4 g/day) or flucloxacillin (12 g/day) and gentamicin (3 mg/kg/day) should be considered. Cefazolin (6 g/day) or vancomycin (30 mg/kg/day) can be used in patients with penicillin allergy. Patients with suspected early prosthetic valve endocarditis should be treated with vancomycin and gentamicin at the above-mentioned doses, plus rifampicin orally in a dose of 900–1200 mg daily. Following identification of the causal organism, determination of the minimum inhibitory concentration (MIC) for the organism helps guide antibiotic therapy. Recommended regimens for some of the most common scenarios are shown in Box 16.96.

A 2-week treatment regimen may be sufficient for fully sensitive strains of streptococci, provided specific conditions are met (Box 16.97).

16.97 Conditions for the short-course treatment of endocarditis caused by fully sensitive streptococci

- Native valve infection
- Minimum inhibitory concentration (MIC) ≤ 0.125 mg/L
- No adverse prognostic factors (heart failure, aortic regurgitation, conduction defect)
- No evidence of thromboembolic disease
- No vegetations > 5 mm diameter
- Clinical response within 7 days

16.98 Indications for cardiac surgery in infective endocarditis*

- Heart failure due to valve damage
- Failure of antibiotic therapy (persistent/uncontrolled infection)
- Large vegetations on left-sided heart valves with echo appearance suggesting high risk of emboli
- Previous evidence of systemic emboli
- Abscess formation

*Patients with prosthetic valve endocarditis or fungal endocarditis often require cardiac surgery.

Cardiac surgery with debridement of infected material and valve replacement may be required in a substantial proportion of patients, particularly those with *Staphylococcus aureus* and fungal infections (Box 16.98). Antimicrobial therapy must be started before surgery.

Prevention

Antibiotic prophylaxis is not given routinely, but is recommended for high-risk patients undergoing oro-dental procedures. High-risk patients

16.99 Incidence and relative frequency of congenital cardiac malformations

Lesion	% of all congenital heart defects
Ventricular septal defect	30
Atrial septal defect	10
Persistent ductus arteriosus	10
Pulmonary stenosis	7
Coarctation of aorta	7

Others	20

susceptible to endocarditis include patients with previous endocarditis, congenital heart disease, prosthetic valves (surgical and transcatheter valves) and ventricular assist devices.

Congenital heart disease

Congenital heart disease can be the result of defects in the formation of the heart or great vessels or can arise because the anatomical changes that occur during transition between the fetus and the newborn child fail to proceed normally. Congenital heart disease usually presents in childhood, but some patients do not present until adult life. It has been estimated that the incidence of haemodynamically significant congenital cardiac abnormalities is about 0.8% of live births (Box 16.99). Defects that are well tolerated, such as atrial septal defect, may cause no symptoms until adult life or may be detected incidentally on routine examination or chest X-ray. Congenital defects that were previously fatal in childhood can now be corrected, or at least partially, so that survival to adult life is the norm. Such patients remain well for many years but subsequently re-present in later life with related problems, such as arrhythmia or heart failure (Box 16.100).

Pathophysiology

Understanding the fetal circulation helps clarify how some forms of congenital heart disease occur. Figure 16.87 shows the fetal circulation and the changes that normally occur immediately after birth. In the fetus there is little blood flow through the lungs, which are collapsed because they are not required for gas exchange. Instead, oxygenated blood from the placenta passes directly from the right atrium to the left side of the heart through the foramen ovale without having to flow through the lungs, and also from the pulmonary artery into the aorta via the ductus arteriosus.

During early embryonic life, the heart develops as a single tube that folds back on itself and then divides into two separate circulations. Failure of septation can cause some forms of atrial and ventricular septal defect, whereas failure of alignment of the great vessels with the ventricles contributes to transposition of the great arteries, tetralogy of Fallot and truncus arteriosus. Atrial septal defects occur because the foramen ovale fails to close at birth, as is normal. Similarly, a persistent ductus arteriosus will remain if it fails to close after birth. Failure of the aorta to develop at the point of the aortic isthmus and where the ductus arteriosus attaches can lead to coarctation of the aorta. Maternal infection and exposure to drugs or toxins are important causes of congenital heart disease. Maternal rubella infection is associated with persistent ductus arteriosus, pulmonary valvular and/or artery stenosis, and atrial septal defect. Maternal alcohol misuse is associated with septal defects, and maternal lupus erythematosus with congenital complete heart block. Genetic or chromosomal abnormalities, such as Down syndrome, may cause septal defects, and gene defects have also been identified as leading to specific abnormalities, such as Marfan syndrome and Turner syndrome (karyotype XO).

16.100 Presentation of congenital heart disease throughout life

Birth and neonatal period

- Cyanosis
- Heart failure

Infancy and childhood

- Cyanosis
- Heart failure
- Arrhythmia
- Murmur
- Failure to thrive

Adolescence and adulthood

- Heart failure
- Murmur
- Arrhythmia
- Eisenmenger syndrome
- Hypertension (coarctation)
- Complications of previous cardiac surgery:
  Arrhythmia related to scarring
  Heart failure secondary to scarring

Clinical features

Symptoms may be absent, or the child may be breathless or fail to attain normal growth and development. Some defects are not compatible with extrauterine life and lead to neonatal death. Clinical signs vary with the anatomical lesion. Murmurs, thrills or signs of cardiomegaly may be present. In coarctation of the aorta, radio-femoral delay may be noted (Fig. 16.88) and some female patients have the features of Turner syndrome (p. 716). Features of other congenital conditions, such as Marfan syndrome or Down syndrome, may also be apparent. Cerebrovascular events and cerebral abscesses may complicate severe cyanotic congenital disease.

Early diagnosis is important because many types of congenital heart disease are amenable to surgery, but this opportunity is lost if secondary changes, such as irreversible pulmonary hypertension, occur.

Central cyanosis and digital clubbing

Central cyanosis of cardiac origin occurs when desaturated blood enters the systemic circulation without passing through the lungs (right-to-left shunting). In the neonate, the most common cause is transposition of the great arteries, in which the aorta arises from the RV and the pulmonary artery from the LV in association with a ventricular septal defect. In older children, cyanosis is usually the consequence of a ventricular septal defect combined with severe pulmonary stenosis (as in tetralogy of Fallot) or with pulmonary vascular disease (Eisenmenger syndrome). Chronic cyanosis is associated with finger and toe clubbing.

Growth retardation and learning difficulties

These may occur with large left-to-right shunts at ventricular or great arterial level, and also with other defects, especially if they form part of a genetic syndrome. Major intellectual impairment is uncommon in children with isolated congenital heart disease, but minor learning difficulties can occur. Cerebral function can also be affected after cardiac surgery if cerebral perfusion is compromised.

Syncope

In the presence of increased pulmonary vascular resistance or severe left or right ventricular outflow obstruction, exercise may provoke syncope as systemic vascular resistance falls but pulmonary vascular resistance rises, worsening right-to-left shunting and cerebral oxygenation. Syncope can also occur because of associated arrhythmias.

Pulmonary hypertension

Persistently raised pulmonary flow with a left-to-right shunt causes increased pulmonary vascular resistance followed by pulmonary

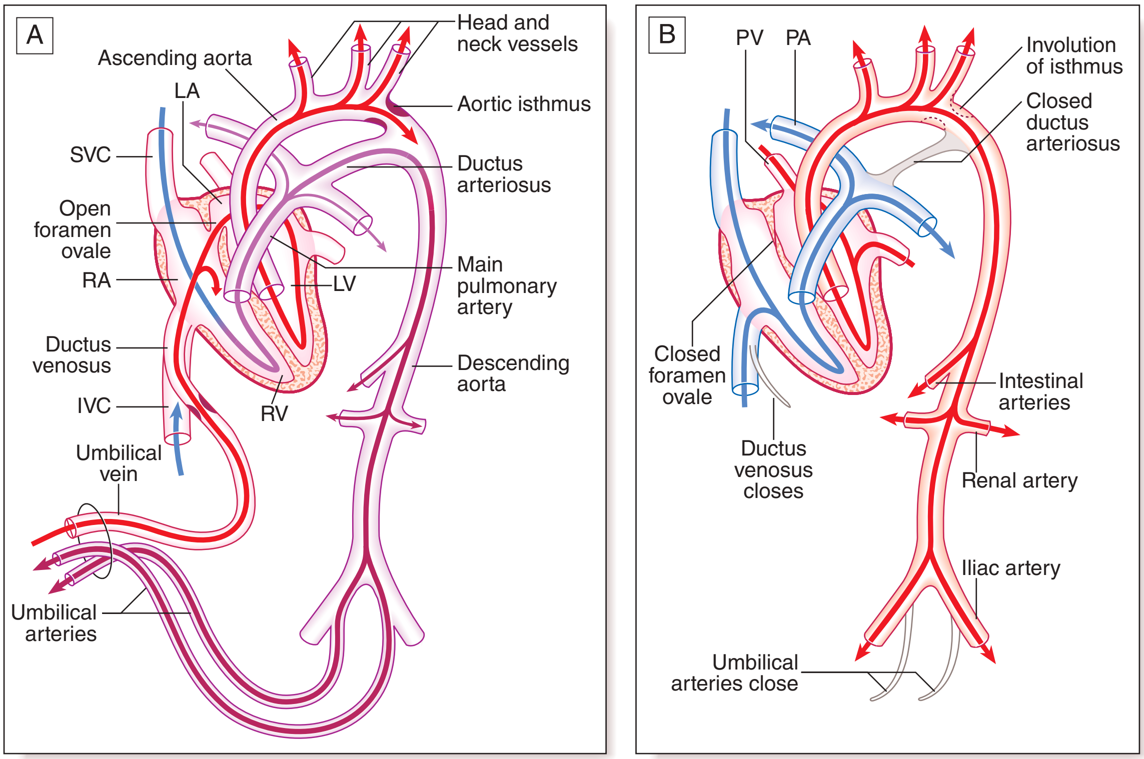

Fig. 16.87 Changes in the circulation at birth. **A** In the fetus, oxygenated blood comes through the umbilical vein where it enters the inferior vena cava (IVC) via the ductus venosus (red). The oxygenated blood streams from the right atrium (RA) through the open foramen ovale to the left atrium (LA) and via the left ventricle (LV) into the aorta. Venous blood from the superior vena cava (SVC, blue) crosses under the main blood stream into the RA and then, partly mixed with oxygenated blood (purple), into the right ventricle (RV) and pulmonary artery (PA). The pulmonary vasculature has a high resistance and so little blood passes to the lungs; most blood passes through the ductus arteriosus to the descending aorta. The aortic isthmus is a constriction in the aorta that lies in the aortic arch before the junction with the ductus arteriosus and limits the flow of oxygen-rich blood to the descending aorta. This configuration means that less oxygen-rich blood is supplied to organ systems that take up their function mainly after birth, e.g. the kidneys and intestinal tract. **B** At birth, the lungs expand with air and pulmonary vascular resistance falls, so that blood now flows to the lungs and back to the LA. The left atrial pressure rises above right atrial pressure and the flap valve of the foramen ovale closes. The umbilical arteries and the ductus venosus close. In the next few days, the ductus arteriosus closes under the influence of hormonal changes (particularly prostaglandins) and the aortic isthmus expands. (PV = pulmonary vein) *Adapted from Drews U. Colour atlas of embryology. Stuttgart: Georg Thieme; 1995.*

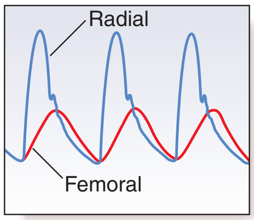

Fig. 16.88 Radio-femoral delay. The difference in pulse pressures is shown.

16.101 Pregnancy in women with congenital heart disease

- **Obstructive lesions**: poorly tolerated and associated with significant maternal morbidity and mortality.
- **Cyanotic conditions**: especially poorly tolerated. Specialised pre-conception counselling should explain the increased risks.
- **Surgically corrected disease**: patients often tolerate pregnancy well.
- **Children of patients with congenital heart disease**: 2%–5% will be born with cardiac abnormalities, especially if the mother is affected. The risk may be up to 20% in babies born of women with left-sided lesions.

hypertension. Progressive changes, including obliteration of distal arterioles, take place and are irreversible. At this stage, central cyanosis occurs and digital clubbing develops. The chest X-ray shows enlarged central pulmonary arteries and peripheral ‘pruning’ of the pulmonary vessels. The ECG and echocardiogram show features of right ventricular hypertrophy, and in advanced cases the RV will appear dilated.

Eisenmenger syndrome

In patients with severe and prolonged pulmonary hypertension the left-to-right shunt may reverse, resulting in right-to-left shunt and marked cyanosis. This is termed Eisenmenger syndrome. The cyanosis in Eisenmenger syndrome may be more apparent in the feet and toes than in the upper part of the body, resulting in so-called differential cyanosis. Eisenmenger syndrome is more common with large ventricular septal defects or persistent ductus arteriosus than with atrial septal defects, and is irreversible without heart and lung transplantation. Patients with Eisenmenger syndrome are at particular risk from abrupt changes in afterload that exacerbate right-to-left shunting, such as vasodilatation, anaesthesia and pregnancy. The long-term prognosis is poor with around 50% of young adults surviving 10 years from diagnosis.

Congenital heart disease in pregnancy

During pregnancy, there is a 50% increase in plasma volume, a 40% increase in whole blood volume and a similar increase in cardiac output, so problems may arise in women with congenital heart disease (Box 16.101). Many with palliated or untreated disease will tolerate pregnancy well, however. Pregnancy is particularly hazardous in the presence of conditions associated with cyanosis or severe pulmonary hypertension; maternal mortality in patients with Eisenmenger syndrome is more than 50%.

Persistent ductus arteriosus

Normally, the ductus arteriosus closes soon after birth but in this anomaly, it fails to do so. Persistence of the ductus is often associated with other abnormalities and is more common in females.

Pathophysiology

During fetal life, before the lungs begin to function, most of the blood from the pulmonary artery passes through the ductus arteriosus into the aorta (see Fig. 16.87). Persistence of the ductus causes a continuous shunt from the aorta to the pulmonary artery since pressure in the aorta is higher than that in the pulmonary artery throughout the cardiac cycle. The volume of the shunt depends on the size of the ductus but as much as 50% of the left ventricular output may be recirculated through the lungs, with a consequent increase in the work of the heart (Fig. 16.89). A large left-to-right shunt in infancy may cause a considerable rise in pulmonary artery pressure and sometimes this leads to progressive pulmonary vascular damage.

Clinical features

With small shunts there may be no symptoms for years, but when the ductus is large, growth and development may be retarded. Usually, there is no disability in infancy, but cardiac failure may eventually ensue, dyspnoea being the first symptom. A continuous 'machinery' murmur is heard with late systolic accentuation, maximal in the second left intercostal space below the clavicle (see Fig. 16.89). It is often accompanied by a thrill. Pulses are increased in volume.

Enlargement of the pulmonary artery may be detected radiologically. The ECG is usually normal. If pulmonary vascular resistance increases, pulmonary artery pressure may rise until it equals or exceeds aortic pressure. The shunt through the defect may then reverse, causing Eisenmenger syndrome. The murmur becomes quieter, may be confined to systole or may disappear.

Investigations

Echocardiography is the investigation of choice although the persistent ductus requires specific echocardiographic views, such as from the suprasternal notch, to reveal it. The ECG shows evidence of right ventricular hypertrophy.

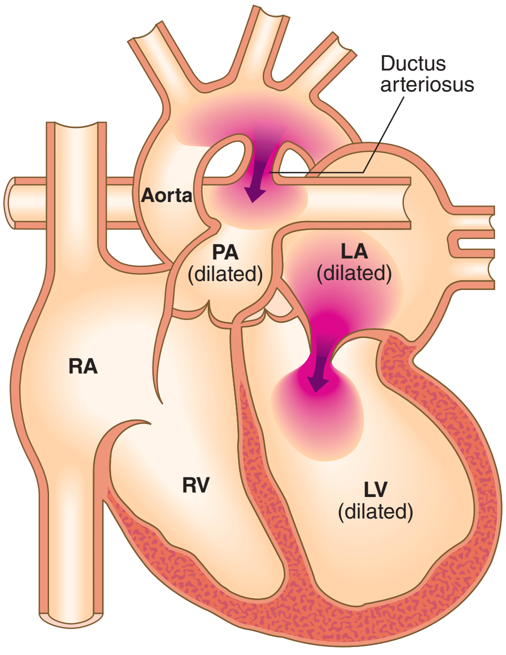

Fig. 16.89 **Persistent ductus arteriosus.** There is a connection between the aorta and the pulmonary artery with left-to-right shunting. (LA = left atrium; LV = left ventricle; PA = pulmonary artery; RA = right atrium; RV = right ventricle)

Management

A persistent ductus can be closed at cardiac catheterisation with an implantable occlusive device. Closure should be undertaken in infancy if the shunt is significant and pulmonary resistance not elevated, but this may be delayed until later childhood in those with smaller shunts, for whom closure remains advisable to reduce the risk of endocarditis. When the ductus is structurally intact, a prostaglandin synthetase inhibitor (indomethacin or ibuprofen) may be used in the first week of life to induce closure. However, in the presence of a congenital defect with impaired lung perfusion, such as occurs in severe pulmonary stenosis and left-to-right shunt through the ductus, it may be advisable to improve oxygenation by keeping the ductus open with prostaglandin treatment. Unfortunately, these treatments do not work if the ductus is intrinsically abnormal.

Coarctation of the aorta

This condition is twice as common in males and occurs in 1 in 4000 children. It is associated with other abnormalities, most frequently bicuspid aortic valve and 'berry' aneurysms of the cerebral circulation. Acquired coarctation of the aorta is rare but may follow trauma or occur as a complication of Takayasu disease.

Pathogenesis

Narrowing of the aorta occurs in the region where the ductus arteriosus joins the aorta, at the isthmus just below the origin of the left subclavian artery (see Fig. 16.87). This causes raised BP affecting vessels of the head and neck proximal to the coarctation, and reduced BP and impaired circulation distally.

Clinical features

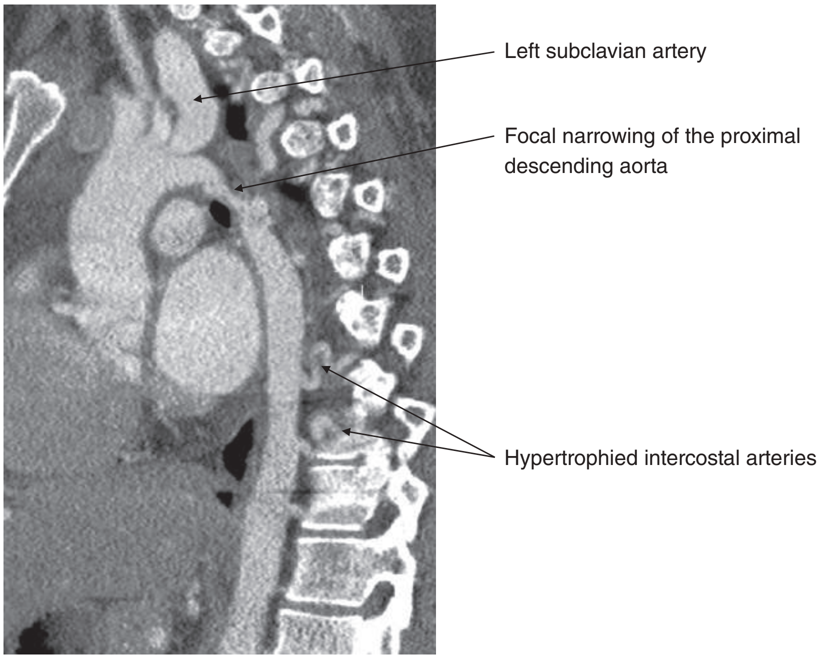
Aortic coarctation is an important cause of cardiac failure in the newborn but symptoms are often absent in older children or in adults. Headaches may occur from hypertension proximal to the coarctation, and occasionally weakness or cramps in the legs may result from decreased circulation in the lower part of the body. The BP is raised in the upper body but normal or low in the legs. The femoral pulses are weak and delayed in comparison with the radial pulse (see Fig. 16.88). A systolic murmur is usually heard posteriorly, over the coarctation. There may also be an ejection click and systolic murmur in the aortic area due to a bicuspid aortic valve. As a result of the aortic narrowing, collateral vessels form; they mainly involve the periscapular, internal mammary and intercostal arteries, and may result in localised bruits.

Investigations

Cross-sectional imaging, most commonly by CT, is the investigation of choice (Fig. 16.90). The chest X-ray in early childhood is often normal but later may show changes in the contour of the aorta (indentation of the descending aorta, '3 sign') and notching of the under-surfaces of the ribs from collaterals. The ECG may show evidence of left ventricular hypertrophy, which can be confirmed by echocardiography.

Management

In untreated cases, death may occur from left ventricular failure, dissection of the aorta or cerebral haemorrhage. Surgical correction is advisable in all but the mildest cases. If this is carried out sufficiently early in childhood, persistent hypertension can be avoided. Patients repaired in late childhood or adult life often remain hypertensive or develop recurrent hypertension later on. Recurrence of stenosis may occur as the child grows and this may be managed by balloon dilatation and sometimes stenting. The latter may be used as the primary treatment. Coexistent bicuspid aortic valve, which occurs in over 50% of cases, may lead to progressive aortic stenosis or regurgitation, and also requires long-term follow-up.



Left subclavian artery
Focal narrowing of the proximal descending aorta
Hypertrophied intercostal arteries

Fig. 16.90 **CT scan of coarctation of the aorta.** The aorta is severely narrowed just beyond the arch at the level of the proximal descending aorta. Collateral circulation has developed with evidence of enlarged intercostal arteries.

Atrial septal defect

Atrial septal defect is one of the most common congenital heart defects and occurs twice as frequently in females. Most are 'ostium secundum' defects, involving the fossa ovalis that, in utero, was the foramen ovale (see Fig. 16.87). 'Ostium primum' defects result from a defect in the atrioventricular septum and are associated with a 'cleft mitral valve' (split anterior leaflet).

Pathogenesis

Since the normal RV is more compliant than the LV, a patent foramen ovale is associated with shunting of blood from the LA to the RA, and then to the RV and pulmonary arteries (Fig. 16.91). As a result, there is gradual enlargement of the right side of the heart and of the pulmonary arteries. Pulmonary hypertension and shunt reversal sometimes complicate atrial septal defect but are less common and tend to occur later in life than with other types of left-to-right shunt.

Clinical features

Most children are asymptomatic for many years and the condition is often detected at routine examination or following a chest X-ray. Symptoms include dyspnoea, cardiac failure and arrhythmias, especially AF. The characteristic physical signs are the result of the volume overload of the RV:

- wide, fixed splitting of the second heart sound: wide because of delay in right ventricular ejection (increased stroke volume and RBBB), and fixed because the septal defect equalises left and right atrial pressures throughout the respiratory cycle
- a systolic flow murmur over the pulmonary valve.

In children with a large shunt, there may be a low-pitched mid-diastolic flow murmur at the lower left sternal edge.

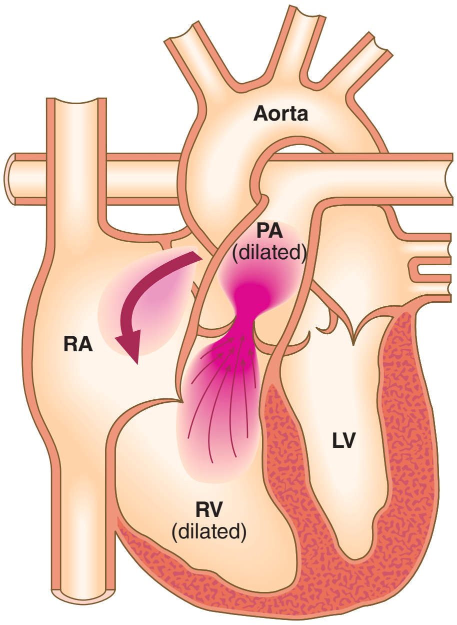


Fig. 16.91 **Atrial septal defect.** Blood flows across the atrial septum (arrow) from left to right. The murmur is produced by increased flow velocity across the pulmonary valve, as a result of left-to-right shunting and a large stroke volume. The density of shading is proportional to velocity of blood flow. (LV = left ventricle; PA = pulmonary artery; RA = right atrium; RV = right ventricle)

Investigations

Echocardiography is diagnostic. It directly demonstrates the defect and typically shows right ventricular dilatation, right ventricular hypertrophy and pulmonary artery dilatation. The precise size and location of the defect are best defined by TOE (Fig. 16.92). The chest X-ray typically shows enlargement of the heart and the pulmonary artery, as well as pulmonary plethora. The ECG usually demonstrates incomplete RBBB because right ventricular depolarisation is delayed as a result of ventricular dilatation (with a 'primum' defect, there is also left axis deviation).

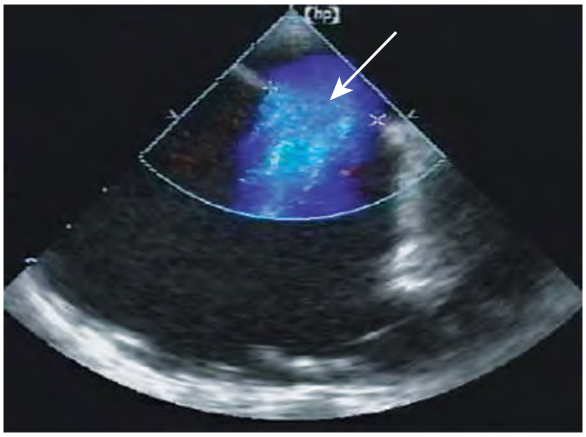

Fig. 16.92 Transoesophageal echocardiogram of an atrial septal defect. The defect is clearly seen (arrow) between the left atrium above and right atrium below. Doppler colour-flow imaging shows flow (blue) across the defect.

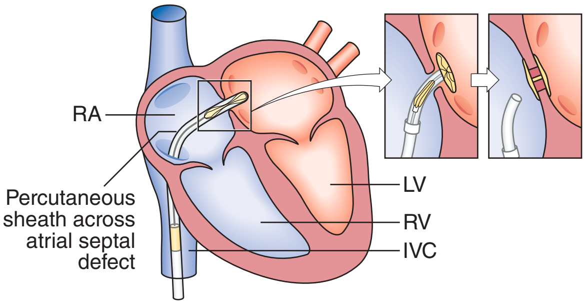

Fig. 16.93 Percutaneous closure of atrial septal defect. The closure device is delivered across the interatrial septum and a disc deployed on either side to seal the defect. (IVC = inferior vena cava; LV = left ventricle; RA = right atrium; RV = right ventricle)

Management

Atrial septal defects in which pulmonary flow is increased 50% above systemic flow (i.e. a flow ratio of 1.5:1) are often large enough to be clinically recognisable and should be closed surgically. Smaller defects may be managed conservatively and patients monitored periodically with echocardiography. Closure can also be accomplished at cardiac catheterisation using implantable closure devices (Fig. 16.93). The long-term prognosis thereafter is excellent, unless pulmonary hypertension has developed. Severe pulmonary hypertension and shunt reversal are both contraindications to surgery.

Ventricular septal defect

Ventricular septal defect is the most common congenital cardiac defect, occurring once in 500 live births. The defect may be isolated or part of complex congenital heart disease.

Pathogenesis

Congenital ventricular septal defect occurs as a result of incomplete septation of the ventricles. Embryologically, the interventricular septum has a membranous and a muscular portion, and the latter is further divided into inflow, trabecular and outflow portions. Most congenital defects are ‘perimembranous’, occurring at the junction of the membranous and muscular portions of the septum.

Clinical features

Flow from the high-pressure LV to the low-pressure RV during systole produces a pansystolic murmur, usually heard best at the left sternal border but radiating all over the precordium (Fig. 16.94). A small defect often produces a loud murmur (maladie de Roger) in the absence of other haemodynamic disturbance. Conversely, a large defect produces a quieter murmur, particularly if pressure in the RV is elevated. This may be found immediately after birth, while pulmonary vascular resistance remains high, or when the shunt is reversed in Eisenmenger syndrome. Congenital ventricular septal defect may present with cardiac failure in infants, as a murmur with only minor haemodynamic disturbance in older children or adults, or, rarely, as Eisenmenger syndrome. In some infants, the murmur becomes quieter or disappears due to spontaneous closure of the defect.

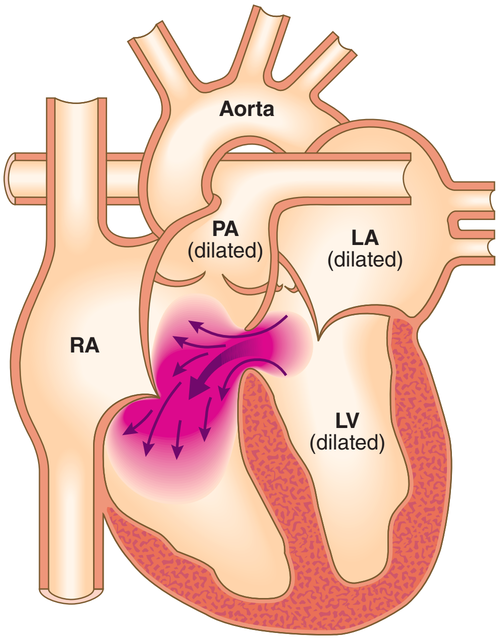

Fig. 16.94 Ventricular septal defect. In this example, a large left-to-right shunt (arrows) has resulted in chamber enlargement. (LA = left atrium; LV = left ventricle; PA = pulmonary artery; RA = right atrium)

If cardiac failure complicates a large defect, it is usually absent in the immediate postnatal period and becomes apparent only in the first 4–6 weeks of life. In addition to the murmur, there is prominent parasternal pulsation, tachypnoea and indrawing of the lower ribs on inspiration.

Investigations

Echocardiography should be performed since it helps to identify the small septal defects that are not haemodynamically significant and are likely to close spontaneously. Patients with larger defects should be monitored by serial echocardiography to check for signs of pulmonary hypertension. With larger defects, the chest X-ray shows pulmonary congestion, and the ECG shows bilateral ventricular hypertrophy.

Management

Small ventricular septal defects require no specific treatment. If there is cardiac failure in infancy, this should initially be treated with digoxin, diuretics and sometimes ACE inhibitors. Persisting cardiac failure is an indication for surgical repair of the defect. Percutaneous closure devices are suitable in specific circumstances, for example if there is a residual defect after surgical closure, or for certain muscular ventricular septal defects.

If serial ECG and echocardiography suggest that pulmonary hypertension is developing, surgical repair should be performed. Surgical closure is contraindicated in Eisenmenger syndrome, and heart–lung transplantation is the only effective treatment. The long-term prognosis is generally very good unless Eisenmenger syndrome develops, when death occurs in the second or third decade of life, but a few individuals survive to the fifth decade without transplantation.

Tetralogy of Fallot

This is a complex defect consisting of right ventricular outflow tract obstruction and right ventricular hypertrophy, a large ventricular septal defect and an overriding aorta that, when combined with the septal defect, allows blood to be pumped directly from the RV into the aorta. It occurs in about 1 in 2000 births and is the most common cause of cyanosis.

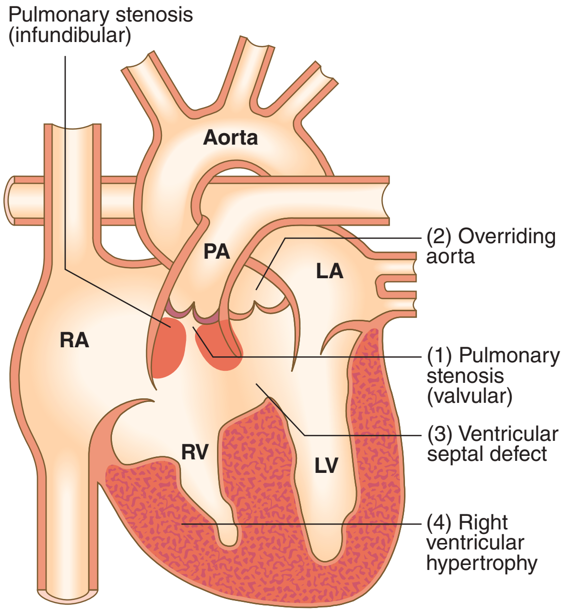
Pathogenesis

Tetralogy of Fallot occurs as the result of abnormal development of the bulbar septum that separates the ascending aorta from the pulmonary artery, and which normally aligns and fuses with the outflow part of the interventricular septum. The right ventricular outflow obstruction is most often subvalvular (muscular) but may be valvular, supravalvular or a combination of these (Fig. 16.95). The subvalvular component of the right ventricular outflow obstruction is dynamic and may increase suddenly with sympathetic stimulation. The ventricular septal defect is usually large and similar in aperture to the aortic orifice. The combination results in elevated right ventricular pressure and right-to-left shunting of cyanotic blood across the ventricular septal defect into the aorta.

Clinical features

Children are usually cyanosed, but this may not be the case in the neonate because it is only when right ventricular pressure rises to equal or exceed left ventricular pressure that a large right-to-left shunt develops. The affected child may suddenly become increasingly cyanosed, often after feeding or a crying attack, and may become apnoeic and unconscious. In older children, cyanotic spells are uncommon, but cyanosis becomes increasingly apparent, with stunting of growth, digital clubbing and polycythaemia. Some children characteristically obtain relief by squatting after exertion, which increases the afterload of the left heart and reduces the right-to-left shunting. This is called Fallot sign. The natural history before the development of surgical correction was variable but most patients died in infancy or childhood.

On examination, the most characteristic feature is the combination of cyanosis with a loud ejection systolic murmur in the pulmonary area (as for pulmonary stenosis). Cyanosis may be absent in the newborn or in patients with only mild right ventricular outflow obstruction, however. This is called acyanotic tetralogy of Fallot.



Pulmonary stenosis (infundibular)
Aorta
PA
LA
RA
RV
LV
(2) Overriding aorta
(1) Pulmonary stenosis (valvular)
(3) Ventricular septal defect
(4) Right ventricular hypertrophy

Fig. 16.95 Tetralogy of Fallot. The tetralogy comprises (1) pulmonary stenosis, (2) overriding of the ventricular septal defect by the aorta, (3) a ventricular septal defect and (4) right ventricular hypertrophy. (LA = left atrium; LV = left ventricle; PA = pulmonary artery; RA = right atrium; RV = right ventricle)

Investigations

Echocardiography is diagnostic and demonstrates that the aorta is not continuous with the anterior ventricular septum. The ECG shows right ventricular hypertrophy, and the chest X-ray shows an abnormally small pulmonary artery and a 'boot-shaped' heart.

Management

The definitive management is total correction of the defect by surgical relief of the pulmonary stenosis and closure of the ventricular septal defect. Primary surgical correction may be undertaken prior to the age of 5 years. If the pulmonary arteries are too hypoplastic for surgical repair, then palliation in the form of a Blalock–Taussig shunt may be performed, where an anastomosis is created between the pulmonary artery and subclavian artery. This improves pulmonary blood flow and pulmonary artery development and may facilitate later definitive correction.

The prognosis after total correction is good, especially if the operation is performed in childhood. Follow-up is needed to identify residual shunting, recurrent pulmonary stenosis and arrhythmias. An implantable defibrillator is sometimes recommended in adulthood.

Other causes of cyanotic congenital heart disease

Other types of cyanotic congenital heart disease are summarised in Box 16.102.

Grown-up congenital heart disease

There are increasing numbers of children who have had surgical correction of congenital defects and who may have further problems as adults. The transition period between paediatric and adult care needs to be managed in a carefully planned manner, addressing many diverse aspects of care (Box 16.103). Those who have undergone correction of coarctation of the aorta may develop hypertension in adult life. Those with transposition of the great arteries who have had a 'Mustard' repair, in which blood is redirected at atrial level leaving the RV connected to the

16.102 Other causes of cyanotic congenital heart disease

Defect	Features
Tricuspid atresia	Absent tricuspid orifice, hypoplastic RV, RA-to-LA shunt, ventricular septal defect shunt, other anomalies Surgical correction may be possible
Transposition of the great arteries	Aorta arises from the morphological RV, pulmonary artery from LV Shunt via atria, ductus and possibly ventricular septal defect Palliation by balloon atrial septostomy/enlargement Surgical correction possible
Pulmonary atresia	Pulmonary valve atretic and pulmonary artery hypoplastic RA-to-LA shunt, pulmonary flow via ductus Palliation by balloon atrial septostomy Surgical correction may be possible
Ebstein anomaly	Tricuspid valve is dysplastic and displaced into RV, RV 'atrialised' Tricuspid regurgitation and RA-to-LA shunt Wide spectrum of severity Arrhythmias Surgical repair possible but significant risk

(LA = left atrium; LV = left ventricle; RA = right atrium; RV = right ventricle)

16.103 Congenital heart disease in adolescence

- **Patients**: a heterogeneous population with residual disease and sequelae that vary according to the underlying lesion and in severity; each patient must be assessed individually.
- **Management plan**: should be agreed with the patient and include short- and long-term goals and timing of transition to adult care.
- **Risks of surgery**: non-cardiac surgery for associated congenital abnormalities carries increased risks and needs to be planned, with careful pre-operative assessment. Risks include thrombosis, embolism from synthetic shunts or patches and volume overload from fluid shifts. Operative approaches should address cosmetic concerns, such as site of implantation of abdominal generator.
- **Exercise**: patients with mild or repaired defects can undertake moderately vigorous exercise but those with complex defects, cyanosis, ventricular dysfunction or arrhythmias require specialist evaluation and individualised advice regarding exercise.
- **Genetics**: between 10% and 15% have a genetic basis and this should be assessed to understand the impact it may have for the patient's own future children. A family history, genetic evaluation of syndromic versus non-syndromic disorders and, sometimes, cytogenetics are required.
- **Education and employment**: may be adversely affected and occupational activity levels need to be assessed.
- **End of life**: some adolescents with complex disorders may misperceive and think they have been cured; transition to adult services may be the first time they receive information about mortality. Expectations on life expectancy need to be managed and adolescents are often willing to engage with this and play a role in decision-making.

aorta, may develop right ventricular failure in adult life. This is because the RV is unsuited for function at systemic pressures and may begin to dilate and fail when patients are in their twenties or thirties.

Those who have had surgery involving the atria may develop atrial arrhythmias, and those who have ventricular septal defect repair (and consequent ventricular scar) may develop ventricular arrhythmias. Antiarrhythmic drugs and an ICD may be required. Such patients require careful follow-up from adolescence throughout adult life, so that problems can be identified early and appropriate medical or surgical treatment instituted. The management of patients with grown-up congenital heart disease (GUCH) is complex and has developed as a cardiological subspecialty.

Diseases of the myocardium

The myocardium can be injured secondary to ischaemia in CAD and to pressure or volume overload in hypertension or valvular heart disease. The heart muscle can be directly affected by primary heart muscle diseases.

Myocarditis

This is an acute inflammatory condition that can have an infectious, toxic or autoimmune aetiology (Box 16.104). Myocarditis can complicate many infections in which inflammation may be due directly to infection of the myocardium or the effects of circulating toxins. Viral infections are the most common causes, such as Coxsackie (35 cases per 1000 infections), influenza A and B (25 cases per 1000 infections) and, more recently, SARS-CoV-2 infection. Myocarditis may occur several weeks after the initial viral symptoms, and susceptibility is increased by glucocorticoid treatment, immunosuppression, radiation, previous myocardial damage and exercise. Some bacterial and protozoal infections may be complicated by myocarditis; for example, approximately 5% of patients with Lyme disease *(Borrelia burgdorferi)* develop myopericarditis, which is often associated with AV block. Toxins such as alcohol and drugs such as cocaine, lithium and doxorubicin may directly injure the myocardium. Other drugs, including penicillins and sulphonamides, and poisons such as lead and carbon monoxide, may cause a hypersensitivity reaction and associated myocarditis. Rarely, SARS-CoV-2 vaccines can cause myocarditis and this is commoner in young men. Occasionally, autoimmune conditions, such as systemic lupus erythematosus and rheumatoid arthritis, are associated with myocarditis.

16.104 Some causes of myocarditis

Infections

Viral

- Coxsackie
- Adenovirus
- Influenza A
- Human immunodeficiency virus (HIV)
- Influenza B
- SARS-CoV-2
- Dengue virus

Bacterial

- *Borrelia burgdorferi* (Lyme disease)
- *Mycoplasma pneumoniae*

Protozoal

- *Trypanosoma cruzi* (Chagas disease)
- *Toxoplasma gondii*

Fungal

- *Aspergillus*

Parasitic

- *Shistosoma*

Drugs/Toxins

- Alcohol
- Anthracyclines
- Clozapine
- Cocaine
- Lithium
- Immune checkpoint inhibitors

Autoimmune

- Systemic lupus erythematosus
- Systemic sclerosis
- Rheumatoid arthritis
- Sarcoidosis
- Hypersensitivity reaction to penicillins, sulphonamides, lead, carbon monoxide

Clinical features

Myocarditis may present in one of four ways:

- *Fulminant myocarditis* follows a viral prodrome or influenza-like illness and results in severe heart failure or cardiogenic shock.
- *Acute myocarditis* presents over a longer period with heart failure; it can lead to dilated cardiomyopathy.
- *Chronic active myocarditis* is rare and associated with chronic myocardial inflammation.
- *Chronic persistent myocarditis* is characterised by focal myocardial infiltrates and can cause chest pain and arrhythmia without necessarily causing ventricular dysfunction.

Myocarditis is self-limiting in most patients and the immediate prognosis is good. Death may, however, occur due to a ventricular arrhythmia or rapidly progressive heart failure. Myocarditis has been reported as a cause of sudden and unexpected death in young athletes. Some forms of myocarditis may lead to chronic low-grade myocarditis or dilated cardiomyopathy (see below). For example, in Chagas disease, the patient frequently recovers from the acute infection but goes on to develop a chronic dilated cardiomyopathy 10 or 20 years later.

Investigations

The diagnosis of myocarditis is often made after other more common causes of cardiac dysfunction have been excluded. Echocardiography should be performed and may reveal left ventricular dysfunction that is sometimes regional (due to focal myocarditis). Cardiac MRI is also useful since it may show diagnostic patterns of myocardial inflammation or infiltration. The ECG is frequently abnormal, but the changes are non-specific. Blood should be taken to assess for cardiac troponin I or T, which can be used to monitor severity and progression of cardiac injury and myocarditis. Occasionally, endomyocardial biopsy may be required to confirm the diagnosis.

Management

Treatment of myocarditis is primarily supportive. Treatment for cardiac failure or arrhythmias should be given and patients should be advised to avoid intense physical exertion because there is some evidence that this can induce potentially fatal ventricular arrhythmias. There is no evidence of benefit from treatment with glucocorticoids and immunosuppressive agents.

Specific antimicrobial therapy may be used if a causative organism has been identified but this is rare. Patients who do not respond adequately to medical treatment may temporarily require circulatory support with a mechanical ventricular assist device. Rarely, cardiac transplantation may be required.

Cardiomyopathy

Cardiomyopathies are primary diseases of the myocardium, which are classified according to their effects on cardiac structure and function (Fig. 16.96). They can be inherited or be caused by infections or exposure to toxins. In some cases, no cause is identified.

Dilated cardiomyopathy

In North America and Europe, symptomatic dilated cardiomyopathy has an incidence of 20 per 100 000 and a prevalence of 38 per 100 000. Men are affected more than twice as often as women.

Pathogenesis

Cardiomyopathy is characterised by dilatation and impaired contraction of the LV and often the RV. Left ventricular mass is increased but wall thickness is normal or reduced (see Fig. 16.96). Dilatation of the valve rings can lead to functional mitral and tricuspid incompetence. Histological changes are variable but include myofibrillary loss, interstitial fibrosis and T-cell infiltrates. The term 'dilated cardiomyopathy' encompasses a heterogeneous group of conditions. Alcohol may be an important cause in some patients. At least 25% of cases are inherited as an autosomal dominant trait and a variety of single-gene mutations have been identified. Most of these mutations affect proteins in the cytoskeleton of the myocytes, such as dystrophin, lamin A and C, titan, emerin and metavinculin. Many are also associated with abnormalities of skeletal muscle. The X-linked inherited skeletal muscular dystrophies, such as Becker and Duchenne, are also associated with cardiomyopathy. Finally, a late autoimmune reaction to viral myocarditis is thought to be the cause in a substantial subgroup of patients with dilated cardiomyopathy; a similar mechanism is believed to be responsible for the myocardial involvement that occurs in up to 10% of patients with advanced human immunodeficiency virus (HIV) infection.

Clinical features

Patients either present with heart failure or are found to have the condition during routine investigation. Arrhythmia, thromboembolism and sudden death may occur at any stage, but these are more common in advanced disease; non-exertional chest pain is surprisingly common. The differential diagnosis includes ventricular dysfunction due to coronary artery disease, and a diagnosis of dilated cardiomyopathy should be made only when this has been excluded.

Investigations

Echocardiography will usually establish the diagnosis. Although ECG changes are common, they are non-specific, such as T-wave inversion or minor ST segment deviation. Cardiac MRI and CT coronary angiography can help distinguish between dilated cardiomyopathy and ventricular dysfunction due to coronary artery disease. Genetic testing is indicated if more than one family member is diagnosed with the condition.

Management

The focus of management is to control heart failure using the strategies described earlier in this chapter. Although some patients remain well for many years, the prognosis is variable and cardiac transplantation may be indicated. Patients with dilated cardiomyopathy and moderate or severe heart failure are at risk of sudden arrhythmic death and this can be reduced by rigorous medical therapy with β-blockers and either ACE inhibitors or ARBs. Some patients may be considered for implantation of a cardiac defibrillator and/or cardiac resynchronisation therapy.

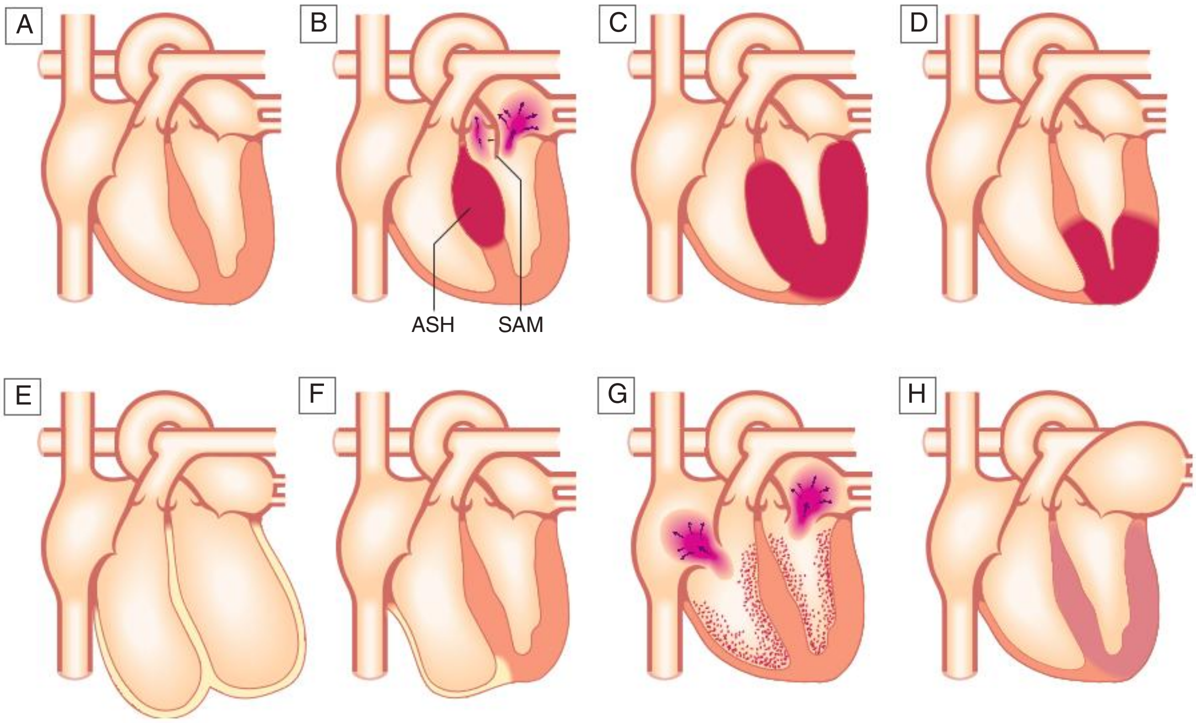


Fig. 16.96 Types of cardiomyopathy. **A** Normal heart. **B** Hypertrophic cardiomyopathy: asymmetric septal hypertrophy (ASH) with systolic anterior motion of the mitral valve (SAM), causing mitral reflux and dynamic left ventricular outflow tract obstruction. **C** Hypertrophic cardiomyopathy: concentric hypertrophy. **D** Hypertrophic cardiomyopathy: apical hypertrophy. **E** Dilated cardiomyopathy. **F** Arrhythmogenic right ventricular cardiomyopathy. **G** Obliterative cardiomyopathy. **H** Restrictive cardiomyopathy.

Hypertrophic cardiomyopathy

The prevalence of hypertrophic cardiomyopathy varies between populations but it affects around 1 in 500 people worldwide. It is characterised by inappropriate left ventricular hypertrophy with malalignment of the myocardial fibres and myocardial fibrosis. The hypertrophy may be generalised or confined largely to the interventricular septum (asymmetric septal hypertrophy, see Fig. 16.96) or other regions of the heart. A specific variant termed apical hypertrophic cardiomyopathy is common in the Far East.

Pathogenesis

Hypertrophic cardiomyopathy is a genetic disorder, usually with autosomal dominant transmission, a high degree of penetrance and variable expression. In most patients, it is due to a single-point mutation in one of the genes that encode sarcomeric contractile proteins. There are three common groups of mutation with different phenotypes. Beta-myosin heavy-chain mutations are associated with marked ventricular hypertrophy. In contrast, troponin mutations are associated with little, if any, hypertrophy but are characterised by marked myocardial fibre disarray, exercise-induced hypotension and a high risk of sudden death. Myosin-binding protein C mutations tend to present late in life and are often associated with hypertension and arrhythmia. In all subtypes, heart failure may develop because the stiff, non-compliant LV impedes diastolic filling. Septal hypertrophy may also cause dynamic left ventricular outflow tract obstruction (hypertrophic obstructive cardiomyopathy, HOCM) and mitral regurgitation due to abnormal systolic anterior motion of the anterior mitral valve leaflet.

Clinical features

Effort-related symptoms, such as angina, breathlessness, arrhythmia and sudden death, are the dominant clinical presentations. The symptoms and signs are similar to those of aortic stenosis, except that, in hypertrophic cardiomyopathy, the character of the arterial pulse is jerky (Box 16.105). The annual mortality from sudden death is 2%–3% among adults and 4%–6% in children and adolescents (Box 16.106). Sudden death typically occurs during or just after vigorous physical activity and is thought to be due to ventricular arrhythmias. Hypertrophic cardiomyopathy is the most common cause of sudden death in young athletes. In patients who do not suffer fatal arrhythmias, the natural history is variable but clinical deterioration is often slow.

Investigations

Echocardiography is the investigation of choice and is usually diagnostic. Sometimes the diagnosis is more difficult when another cause of left ventricular hypertrophy is present (such as hypertension or athletic training) but the degree of hypertrophy in hypertrophic cardiomyopathy is usually disproportionate, and the pattern is asymmetrical. The ECG is abnormal and shows features of left ventricular hypertrophy with a wide variety of often bizarre abnormalities, including deep T-wave inversion. Genetic testing can be performed and, in cases where a pathogenic mutation is identified, is helpful in screening relatives of affected individuals.

Management

Beta-blockers, rate-limiting calcium antagonists and disopyramide can help to relieve symptoms and prevent syncopal attacks. Mavacamten, a cardiac myosin inhibitor, also improves symptoms, but requires special monitoring as it can cause left ventricular systolic impairment. Arrhythmias often respond to treatment with amiodarone. No pharmacological treatment has been identified that can improve prognosis, however. Outflow tract obstruction can be improved by partial surgical resection (myectomy) or by iatrogenic infarction of the basal septum (septal ablation) using a catheter-delivered alcohol solution. An ICD should be considered in patients with clinical risk factors for sudden death (see Box 16.106). Digoxin and vasodilators may increase outflow tract obstruction and should be avoided.

16.105 Clinical features of hypertrophic cardiomyopathy

Symptoms

- Angina on effort
- Dyspnoea on effort
- Syncope on effort
- Sudden death

Signs

- Jerky pulse*
- Palpable left ventricular hypertrophy
- Double impulse at the apex (palpable fourth heart sound due to left atrial hypertrophy)
- Mid-systolic murmur at the base*
- Pansystolic murmur (due to mitral regurgitation) at the apex

*Signs of left ventricular outflow tract obstruction may be augmented by standing up (reduced venous return), inotropes and vasodilators.

16.106 Risk factors for sudden death in hypertrophic cardiomyopathy

- Young age at diagnosis
- A history of previous cardiac arrest or sustained ventricular tachycardia
- Recurrent syncope
- An adverse genotype and/or family history of sudden death at young age
- Exercise-induced hypotension
- Non-sustained ventricular tachycardia on ambulatory ECG monitoring
- Marked increase in left ventricular wall thickness
- High burden of myocardial fibrosis on MRI scan

Arrhythmogenic ventricular cardiomyopathy

Arrhythmogenic ventricular cardiomyopathy (AVC) predominantly affects the myocardium of the right ventricle. It is inherited in an autosomal dominant manner and has a prevalence of approximately 10 per 100 000. The genetic defect involves desmosomal protein genes, most commonly plakophilin 2 *(PKP-2)*, although current genetic testing protocols will not identify the culprit gene in many cases. It is characterised by replacement of patches of the right ventricular myocardium with fibrous and fatty tissue (see Fig. 16.96). In some cases, the LV is also involved, and this is associated with a poorer prognosis. The diagnosis is based on a complex set of criteria that takes account of the ECG, structural assessment, genetics and arrhythmias. The dominant clinical problems are ventricular arrhythmias, sudden death and right-sided cardiac failure. The ECG typically shows a slightly broadened QRS complex and inverted T waves in the right precordial leads. MRI is a helpful diagnostic tool and is used, along with the 12-lead ECG and ambulatory ECG monitoring, to screen the first-degree relatives of affected individuals. Management is based on treating right-sided cardiac failure with diuretics and cardiac arrhythmias with β-blockers or, in patients at high risk of sudden death, an implantable defibrillator can be offered.

Restrictive cardiomyopathy

In this rare condition, ventricular filling is impaired because the ventricles are ‘stiff’ (see Fig. 16.96). This leads to high atrial pressures with atrial hypertrophy, dilatation and, later, AF. Amyloidosis is the most common cause in the UK, although other forms of infiltration due to glycogen storage diseases, idiopathic perimyocyte fibrosis and a familial form of restrictive cardiomyopathy can also occur. The diagnosis can be difficult and requires assessment with Doppler echocardiography, CT or MRI, and endomyocardial biopsy. Treatment is symptomatic but the prognosis is usually poor and cardiac transplantation may be indicated.

Obliterative cardiomyopathy

This is a rare form of restrictive cardiomyopathy, involving the endocardium of one or both ventricles; it is characterised by thrombosis and

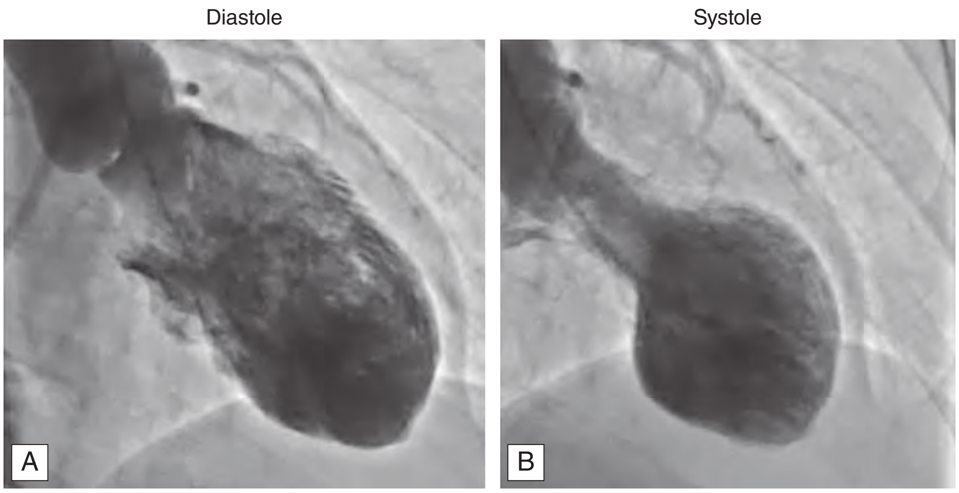

Fig. 16.97 Left ventriculograms in diastole A and systole B in a patient with Takotsubo cardiomyopathy. Note the ballooning of the left ventricular apex in systole which is characteristic of this condition (compare with Fig. 16.16).

fibrosis, with gradual obliteration of the ventricular cavities by fibrous tissue (see Fig. 16.96). The mitral and tricuspid valves become regurgitant. Heart failure and pulmonary and systemic embolism are prominent features. It can sometimes be associated with eosinophilia and can occur in eosinophilic leukaemia and eosinophilic granulomatosis with polyangiitis (formerly known as Churg–Strauss syndrome). In tropical countries, the disease may be responsible for up to 10% of cardiac deaths. Prognosis is poor, with a 50% mortality within 2 years of diagnosis. Anticoagulation and antiplatelet therapy are used to reduce the risk of embolism, and diuretics to treat heart failure. Surgery (tricuspid and/or mitral valve replacement with decortication of the endocardium) may be helpful in selected cases.

Takotsubo cardiomyopathy

Takotsubo cardiomyopathy (Takotsubo syndrome) is a form of acute left ventricular dysfunction characterised by dilatation of the left ventricular apex and adjacent myocardium, with associated left ventricular impairment. The mechanism is poorly understood. It is often associated with acute environmental or emotional stress (such as a bereavement) and presents with chest pain, breathlessness and sometimes cardiac failure. It occurs more frequently in women than in men and neurological disorders are present in 15%–20% of cases (e.g. prior cerebrovascular events, neurodegenerative disorders, migraine and epilepsy). The symptoms and ECG often mimic acute ST elevation acute coronary syndrome. The diagnosis is usually made at coronary angiography, when coronary artery disease is found to be absent or minimal. Echocardiography or left ventriculography then shows characteristic ‘apical ballooning’ of the LV. The dilated apex and narrow outflow of the LV resemble a Japanese octopus trap, or takotsubo (Fig. 16.97).

Left ventricular ejection fraction returns to normal within days to weeks. Although commonly thought to be a benign condition, it is associated with a recurrence rate of 10% and a mortality of 20% at 5 years. Beta-blockers have been shown to reduce the risk of recurrence and may reduce mortality in Takotsubo syndrome.

Secondary causes of cardiomyopathy

Many systemic conditions can produce a picture that is indistinguishable from dilated cardiomyopathy, including connective tissue disorders, sarcoidosis, haemochromatosis and alcoholic heart muscle disease (Box 16.107). In contrast, amyloidosis and eosinophilic heart disease produce symptoms and signs similar to those found in restrictive or obliterative cardiomyopathy, whereas the heart disease associated with Friedreich ataxia can mimic hypertrophic cardiomyopathy.

16.107 Specific diseases of heart muscle

Infections	
Viral	
Coxsackie A and B	HIV
Influenza	SARS-CoV-2
Bacterial	
Diphtheria	*Borrelia burgdorferi*
Protozoal	
Trypanosomiasis	*Toxoplasma gondii*
Endocrine and metabolic disorders	
Diabetes	Carcinoid syndrome
Hypo- and hyperthyroidism	Phaeochromocytoma
Acromegaly	Inherited storage diseases
Connective tissue diseases	
Systemic sclerosis	Polyarteritis nodosa
Systemic lupus erythematosus	
Infiltrative disorders	
Haemochromatosis	Sarcoidosis
Haemosiderosis	Amyloidosis
Toxins	
Doxorubicin	Cocaine
Alcohol	Irradiation
Neuromuscular disorders	
Dystrophia myotonica	Friedreich ataxia

Treatment and prognosis are determined by the underlying disorder. Abstention from alcohol may lead to a dramatic improvement in patients with alcoholic heart muscle disease.

Cardiac tumours

Primary cardiac tumours are rare (<0.2% of autopsies) but the heart and mediastinum may be the sites of metastases. Most primary tumours are benign (75%), and, of these, the majority are myxomas. The remainder are fibromas, lipomas, fibroelastomas and haemangiomas.

Atrial myxoma

Myxomas most commonly arise in the LA as single or multiple polypoid tumours, attached by a pedicle to the interatrial septum. They are usually gelatinous but may be solid and even calcified, with superimposed thrombus.

On examination, the first heart sound is usually loud, and there may be a murmur of mitral stenosis with a variable diastolic sound (tumour 'plop') due to prolapse of the mass through the mitral valve. The tumour can be detected incidentally on echocardiography, or following investigation of pyrexia, syncope, arrhythmias or emboli. Occasionally, the condition presents with malaise and features suggestive of a connective tissue disorder, including a raised ESR.

Treatment is by surgical excision. If the pedicle is removed, fewer than 5% of tumours recur.

Diseases of the pericardium

The normal pericardial sac contains about 50 mL of fluid, similar to lymph, which lubricates the surface of the heart. The pericardium limits distension of the heart, contributes to the haemodynamic interdependence of the ventricles, and acts as a barrier to infection. Nevertheless, congenital absence of the pericardium does not result in significant clinical or functional limitations.

Acute pericarditis

This is due to an acute inflammatory process affecting the pericardium, which may coexist with myocarditis.

Pathogenesis

A number of causes are recognised (Box 16.108), but in some cases the cause is unclear. All forms of pericarditis may produce a pericardial effusion that, depending on the aetiology, may be fibrinous, serous, haemorrhagic or purulent. A fibrinous exudate may eventually lead to varying degrees of adhesion formation, whereas serous pericarditis often produces a large effusion of turbid, straw-coloured fluid with a high protein content. A haemorrhagic effusion is often due to malignant disease, particularly carcinoma of the breast or bronchus, and lymphoma. Purulent pericarditis is rare and may occur as a complication of sepsis, by direct spread from an intrathoracic infection, or from a penetrating injury.

Clinical features

The typical presentation is with chest pain that is retrosternal, radiates to the shoulders and neck, and is typically aggravated by deep breathing, movement, a change of position, exercise and swallowing. A low-grade fever is common. A pericardial friction rub is a high-pitched, superficial scratching or crunching noise, produced by movement of the inflamed pericardium, and is diagnostic of pericarditis; it is usually heard in systole but may also be audible in diastole and frequently has a 'to-and-fro' quality.

i 16.108 Causes of acute pericarditis and pericardial effusion

Infection

- Viral
- Bacterial
- Tuberculosis

Inflammatory

- Rheumatoid arthritis
- Systemic lupus erythematosus
- Rheumatic fever

Other

- Post-myocardial infarction
- Uraemia
- Malignancy
- Trauma

Investigations

The diagnosis can often be made on the basis of clinical features and the ECG; the latter shows ST elevation with upward concavity (Fig. 16.98) over the affected area, which may be widespread. PR interval depression is a very specific indicator of acute pericarditis. Later, there may be T-wave inversion, particularly if there is a degree of myocarditis. Echocardiography may be normal or may reveal pericardial effusion, in which case regular echocardiographic monitoring is recommended.

Management

The pain usually responds to aspirin (600 mg 6 times daily) but a more potent anti-inflammatory agent, such as indomethacin (50 mg 3 times daily), may be required. Colchicine (0.5 mg twice daily, or once daily if weight less than 70 kg) is very effective at relieving symptoms and also prevents relapsing episodes if taken for 3 months from symptom onset. Glucocorticoids are no longer recommended for this condition. In viral pericarditis, recovery usually occurs within a few days or weeks but there may be recurrences (chronic relapsing pericarditis). Purulent pericarditis requires treatment with antimicrobial therapy, pericardiocentesis and, if necessary, surgical drainage.

Pericardial effusion

Pericardial effusion often accompanies pericarditis and can have several causes, as shown in Box 16.108.

Clinical features

With the onset of an effusion the heart sounds may become quieter, and a friction rub, if present, may diminish in intensity but is not always abolished. Larger effusions may be accompanied by a sensation of retrosternal oppression. While most effusions do not have significant

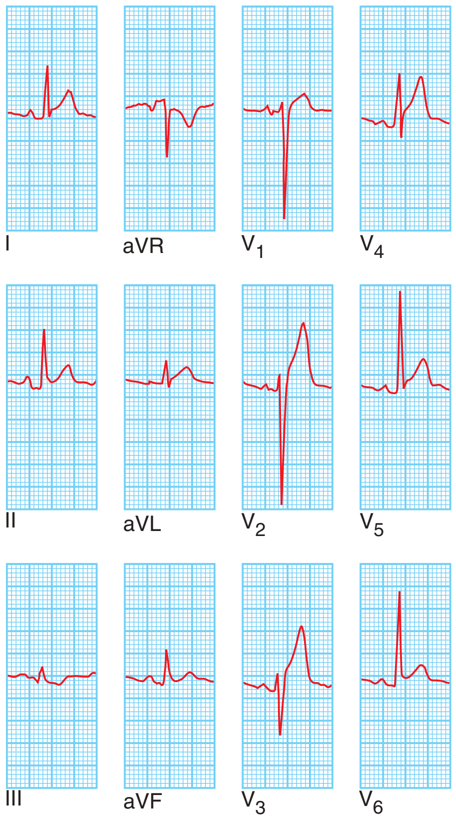

Fig. 16.98 ECG in viral pericarditis. Widespread ST elevation (leads I, II, aVL and V_1–V_6) is shown. The upward concave shape of the ST segments (see leads II and V_6) and the unusual distribution of changes (involving anterior and inferior leads) help to distinguish pericarditis from acute myocardial infarction.

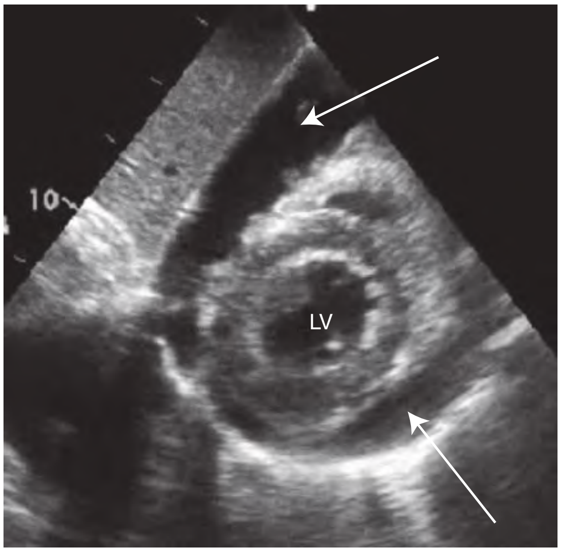

Fig. 16.99 **Pericardial effusion: echocardiogram (apical view).** Short-axis view of the heart showing a large circumferential pericardial effusion (arrows). (LV = left ventricle)

haemodynamic effects, large or rapidly developing effusions may cause cardiac tamponade. This term is used to describe acute heart failure due to compression of the heart and is described in detail below. Typical physical findings are a markedly raised JVP, hypotension, pulsus paradoxus and oliguria. Atypical presentations may occur when the effusion is loculated as a result of previous pericarditis or cardiac surgery.

Investigations

Echocardiography is the definitive investigation and is helpful in monitoring the size of the effusion and its effect on cardiac function (Fig. 16.99). The QRS voltages on the ECG are often reduced in the presence of a large effusion. The QRS complexes may alternate in amplitude due to a to-and-fro motion of the heart within the fluid-filled pericardial sac (electrical alternans). The chest X-ray may show an increase in the size of the cardiac silhouette and, when there is a large effusion, this has a globular appearance. Aspiration of the effusion may be required for diagnostic purposes and, if necessary, for treatment of large effusions, as described below.

Management

Patients with large effusions that are causing haemodynamic compromise or cardiac tamponade should undergo aspiration of the effusion. This involves inserting a needle under echocardiographic guidance medial to the cardiac apex or below the xiphoid process, directed upwards towards the left shoulder. The route of choice will depend on the experience of the operator, the shape of the patient and the position of the effusion. A pericardial drain may be placed to provide symptomatic relief. Complications of pericardiocentesis include arrhythmias, damage to a coronary artery and bleeding, with exacerbation of tamponade as a result of injury to the RV. When tamponade is due to cardiac rupture or aortic dissection, pericardial aspiration may precipitate further potentially fatal bleeding and, in these situations, emergency surgery is the treatment of choice. A viscous, loculated or recurrent effusion may also require formal surgical drainage.

Tuberculous pericarditis

Tuberculous pericarditis may complicate pulmonary tuberculosis but may also be the first manifestation of the infection. In Africa, a tuberculous pericardial effusion is a common feature of AIDS. The condition typically presents with chronic malaise, weight loss and a low-grade fever. An effusion usually develops, and the pericardium may become thick and unyielding, leading to pericardial constriction or tamponade. An associated pleural effusion is often present.

i **16.109 Clinical features of constrictive pericarditis**

- Fatigue
- Rapid, low-volume pulse
- Elevated JVP with a rapid *y* descent
- Loud early third heart sound or 'pericardial knock'
- Kussmaul sign
- Hepatomegaly
- Ascites
- Peripheral oedema
- Pulsus paradoxus

(JVP = jugular venous pressure)

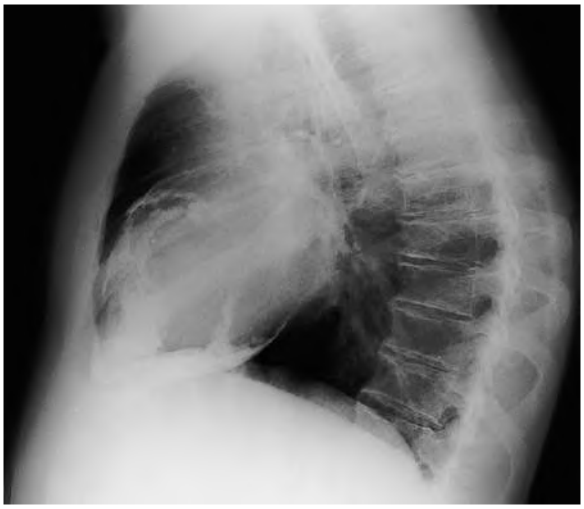

Fig. 16.100 **Lateral chest X-ray from a patient with severe heart failure due to chronic constrictive pericarditis.** There is heavy calcification of the pericardium.

The diagnosis may be confirmed by aspiration of the fluid and direct examination or culture for tubercle bacilli. Treatment requires specific antituberculous chemotherapy (p. 561). In addition, a course of prednisolone starting at an initial dose 60 mg per day, gradually tapering down over 3 months, improves outcome.

Chronic constrictive pericarditis

Constrictive pericarditis is due to progressive thickening, fibrosis and calcification of the pericardium. In effect, the heart is encased in a solid shell and cannot fill properly. The calcification may extend into the myocardium, so there may also be impaired myocardial contraction. The condition often follows an attack of tuberculous pericarditis but can also complicate haemopericardium, viral pericarditis, rheumatoid arthritis and purulent pericarditis. It is often impossible to identify the original insult.

Clinical features

The symptoms and signs of systemic venous congestion are the hallmarks of constrictive pericarditis. AF is common and there is often dramatic ascites and hepatomegaly. Kussmaul sign (a paradoxical rise in JVP during inspiration) may also be observed (Box 16.109). Breathlessness is not a prominent symptom because the lungs are seldom congested. The condition is sometimes overlooked but should be suspected in any patient with unexplained right heart failure and apparently normal heart size and function on echocardiography.

Investigations

A chest X-ray, which may show pericardial calcification (Fig. 16.100), and echocardiography often help to establish the diagnosis. CT scanning is useful for imaging the pericardial calcification. Constrictive pericarditis is often difficult to distinguish from restrictive cardiomyopathy and in such cases complex echo–Doppler studies and cardiac catheterisation may be required.

i 16.110 Clinical features of cardiac tamponade

- Dyspnoea
- Collapse
- Tachycardia
- Hypotension
- Gross elevation of the JVP
- Soft heart sounds with an early third heart sound
- Pulsus paradoxus (a large fall in BP during inspiration, when the pulse may be impalpable)
- Kussmaul sign (rare)

(JVP = jugular venous pressure)

Management

The resulting diastolic heart failure is treated using loop diuretics and aldosterone antagonists, such as spironolactone. Surgical resection of the diseased pericardium can lead to a dramatic improvement but carries a high morbidity, especially if performed late in the disease course, as the pericardium becomes heavily bound to the myocardium.

Cardiac tamponade

This term is used to describe acute heart failure due to compression of the heart as the result of a large pericardial effusion. Tamponade may complicate any form of pericarditis but can be caused by malignant disease, by blood in the pericardial space following trauma, or by rupture of the free wall of the myocardium following MI.

Clinical features

Patients with tamponade are unwell, with hypotension, tachycardia and a markedly raised JVP. Other clinical features are summarised in Box 16.110.

Investigations

The pivotal investigation is echocardiography, which can confirm the diagnosis and also helps to identify the optimum site for aspiration of the fluid. The ECG may show features of the underlying disease, such as pericarditis or acute MI. When there is a large pericardial effusion, the ECG complexes are small and there may be electrical alternans: a changing axis with alternate beats caused by the heart swinging from side to side in the pericardial fluid. A chest X-ray shows an enlarged globular heart but can look normal.

Management

Cardiac tamponade is a medical emergency. When the diagnosis is confirmed, percutaneous pericardiocentesis should be performed as soon as possible, which usually results in a dramatic improvement. In some cases, surgical drainage may be required.

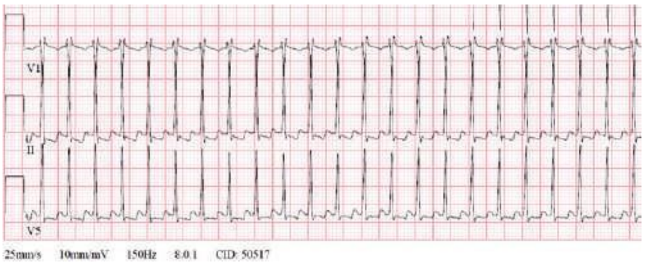
Multiple Choice Questions

16.1. A 24-year-old woman presents at the emergency department with an episode of sudden-onset rapid regular palpitation of one hour's duration. She has no previous cardiovascular history. On examination, heart rate is 180 beats/min and regular, blood pressure 104/68 mmHg. Examination is otherwise unremarkable. The ECG shows a regular, narrow QRS tachycardia (see figure).



Which of the following is the most appropriate initial management for this rhythm?

A. Intravenous adenosine
B. Oral β-blocker
C. Valsalva manoeuvre with or without leg raising
D. Bilateral carotid sinus pressure
E. Intravenous atropine

Answer: C.

The diagnosis is supraventricular tachycardia (SVT), based on the sudden onset, the regular nature of the tachycardia, and the absence of obvious P waves on the ECG. SVT is usually caused by a re-entrant mechanism involving the atrioventricular node (p. 452). Treatments that cause transient AV nodal block interrupt the tachycardia and restore sinus rhythm. Intravenous adenosine is usually effective but is not normally given until after vagal manoeuvres have been tried. The Valsalva manoeuvre is often effective and can be enhanced by leg raising after breath-holding is released (the 'REVERT' manoeuvre). Carotid sinus pressure may also be effective but should never be applied to both carotid arteries simultaneously. Atropine is an anticholinergic drug which is used to treat symptomatic bradycardia, not tachycardia.

16.2. A 77-year-old diabetic woman presents to her general practitioner because of fatigue and breathlessness. She is found to have an irregular pulse at 74 beats/min. An ECG confirms atrial fibrillation with good heart rate control. An echocardiogram is performed showing left atrial enlargement but no other abnormality. What is the most appropriate strategy to reduce this patient's risk of a future stroke?

A. Oral aspirin, 75 mg once daily
B. Oral clopidogrel, 75 mg once daily
C. Immediate DC cardioversion
D. Oral digoxin
E. Oral anticoagulation with warfarin or a direct oral anticoagulant

Answer: E.

This woman has atrial fibrillation and a relatively high CHA_2DS_2-VASc score of 4 points (1 point each for gender and diabetes mellitus, and 2 points for age greater than 75 years). She has an annual stroke risk of around 4%, which would be reduced to 1% with oral anticoagulation using a direct oral anticoagulant such as apixaban or edoxaban, or with warfarin (target International Normalised Ratio 2–3). Oral antiplatelet drugs such as aspirin or clopidogrel are ineffective for stroke prevention in atrial fibrillation. Immediate cardioversion would increase stroke risk because a prior period of oral anticoagulation is required to make the procedure safe. Digoxin is used for heart rate control but has no impact on stroke risk. (For more on stroke prevention in atrial fibrillation see page 450.)

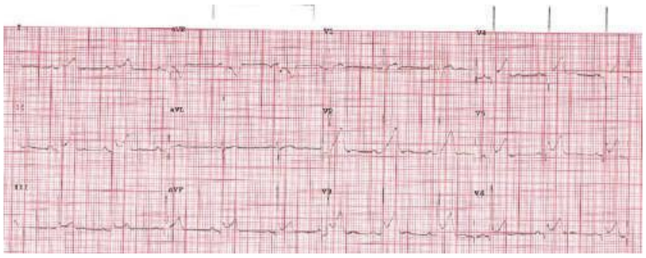
16.3. A fit 25-year-old man presents to the emergency department with an episode of syncope while running a half-marathon. He had a few seconds' warning with lightheadedness, was syncopal for around 15 seconds, and made a rapid recovery. His father had died suddenly age 54 years with no cause determined. On examination the patient appeared well, pulse 50 and regular, BP 110/62 mmHg. Precordial examination revealed a forceful apical impulse and an ejection systolic murmur loudest in the aortic area. What is the most likely diagnosis?

A. Hypertrophic obstructive cardiomyopathy
B. Aortic stenosis
C. Mitral regurgitation
D. Long QT syndrome
E. Dilated cardiomyopathy

Answer: A.

This patient presents with symptoms and signs of hypertrophic obstructive cardiomyopathy. Syncope is a common symptom and is caused either by left ventricular outflow tract obstruction during exercise, or by ventricular arrhythmia. The patient presents with typical cardiac syncope – a short prodrome, brief syncope and a rapid recovery. The family history of sudden death raises suspicion of an inherited cardiac condition. While aortic stenosis is a possibility, it is not likely in such a young patient and is rarely inherited. Hypertrophic cardiomyopathy is inherited with an autosomal dominant pattern and the murmur is caused by left ventricular outflow obstruction. Mitral regurgitation does cause a systolic murmur but it is usually pansystolic, and there is no association with syncope. Long QT syndrome can cause sudden death and is inherited, but is not associated with any structural abnormality or murmur. Dilated cardiomyopathy is sometimes inherited but does not commonly cause syncope or a murmur.

16.4. A 30-year-old woman presents with a 2-week history of fever and malaise, and develops sharp left-sided chest pain, worse on inspiration and on lying flat. The pain radiates to her left shoulder. On examination pulse is 100 beats/min and regular, blood pressure 104/66 mmHg. The jugular venous pulse is not elevated. The apex beat is not displaced and feels normal. First and second are both present, with a harsh to-and-fro sound audible in systole and diastole. An echocardiogram shows a small pericardial effusion and no other abnormality. The 12-lead ECG is shown in the figure.



Which of the following treatments is most appropriate?

A. Oral ibuprofen, 400 mg three times daily
B. Oral prednisolone, initially 40 mg daily and reducing dose over 2 weeks
C. Pericardiocentesis
D. Oral colchicine 500 µg twice daily for 3 months
E. Percutaneous coronary intervention

Answer: D.

The diagnosis is acute pericarditis, probably of viral aetiology because of the prodromal symptoms. Examination reveals a pericardial rub, and the ECG shows widespread saddle-shaped ST segment elevation without reciprocal ST segment depression. The most effective treatment for symptoms and to prevent recurrence is colchicine. Non-steroidal anti-inflammatory drugs such as ibuprofen may also help acute symptoms, but oral corticosteroids are not effective. Pericardiocentesis would only be indicated if there was a large pericardial effusion and compromise (hypotension, pulsus paradoxus, elevated jugular venous pulse, oliguria). Percutaneous coronary intervention is not appropriate as the pattern of ST segment elevation suggests pericarditis and not ST elevation myocardial infarction.

16.5. A 67-year-old man presents to the emergency department with severe central chest pain of sudden onset and some shortness of breath. He is sweaty and clammy with marked dysphoria and autonomic arousal. His blood pressure from a sphygmomanometer is 200/110 mmHg in his right arm, jugular venous pressure is not elevated and he has a tachycardia but no heart murmurs. He has a temperature of 37.1°C and a respiratory rate of 20/min with oxygen saturations of 95% on air. A 12-lead electrocardiogram shows voltage criteria for left ventricular hypertrophy, and there is lateral ST-segment depression. Chest X-ray shows a left-sided pleural effusion and a slightly wide upper mediastinum. What is the most likely diagnosis?

A. Acute myocardial infarction
B. Pneumonia
C. Pulmonary thromboembolism
D. Acute aortic dissection
E. Malignant hypertension

Answer: D.

The diagnosis is acute aortic dissection. This is commonly unrecognised and a missed diagnosis. Patients often present like a patient with an acute myocardial infarction with severe pain and autonomic arousal. Classically, the pain is interscapular, especially if the dissection arises from, or extends into, the descending aorta. If the dissection involves the left subclavian artery, the left arm blood pressure is much lower than the right arm. Occasionally, a dissection of the ascending aorta can compromise the coronary arteries and cause acute myocardial infarction. Retrograde propagation of the dissection can cause haemopericardium and death. A pleural effusion is common due to the inflammation of the aorta, although rupture is also possible, which is usually a terminal event. A widened mediastinum is typical as the aorta enlarges with the dissection. Early recognition and confirmation with CT or MRI is essential as life-saving emergency surgery is indicated for those with type A dissection or with impending rupture or visceral compromise. Medical therapy is targeted at controlling the blood pressure in an attempt to inhibit propagation and expansion of the dissection.

16.6. A 62-year-old woman was referred for a cardiology review for symptoms of breathlessness (NYHA class II). Since an anterior myocardial infarction 15 years ago, she had been taking aspirin, atorvastatin, bisoprolol, furosemide, eplerenone and ramipril. Clinical assessment revealed severe left ventricular systolic dysfunction with a left ventricular ejection fraction of 28%, anterior Q waves on the ECG and a QRS duration of 98 msecs. Exam revealed heart rate of 70 bpm, blood pressure 108/74, normal heart sounds and mild fluid congestion. What changes to her treatment give her the best chance of improving her symptoms, cardiac function and prognosis?

A. Switch ramipril to sacubitril/valsartan, add dapagliflozin, implant cardiac resynchronisation therapy (CRT) pacemaker
B. Switch ramipril to sacubitril/valsartan, add dapagliflozin, titrate furosemide to residual oedema
C. Add dapagliflozin, stop bisoprolol, implant CRT pacemaker
D. Switch ramipril to sacubitril/valsartan, implant CRT pacemaker
E. Switch ramipril to sacubitril/valsartan, increase furosemide

Answer: B.

Medical therapy for chronic heart failure with reduced ejection fraction (HFrEF) has improved in the last decade since this woman's myocardial infarction. Sacubitril/valsartan improves outcomes for these patients. A further class of drugs has shown benefit in heart failure; sodium-glucose co-transporter 2 inhibitors such as dapagliflozin have been shown to be beneficial in heart failure patients.

Cardiac resynchronisation therapy (CRT) pacemakers can improve symptoms, cardiac function and prognosis in patients with HFrEF who have left bundle branch block (LBBB) on the ECG. This patient does not have LBBB but has a narrow QRS duration. CRT pacemaker will not be beneficial for this patient. Implanting a defibrillator (ICD) is not offered as an option here but could be considered to help protect from life-threatening ventricular arrhythmias in the future if cardiac function does not improve with medication, but an ICD will not improve symptoms.

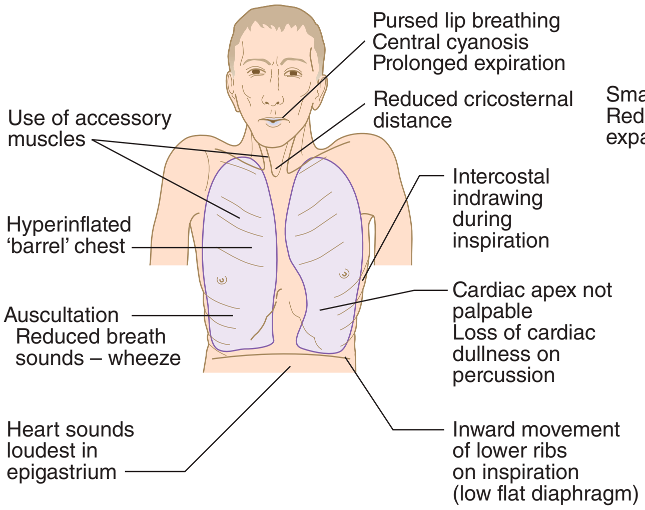
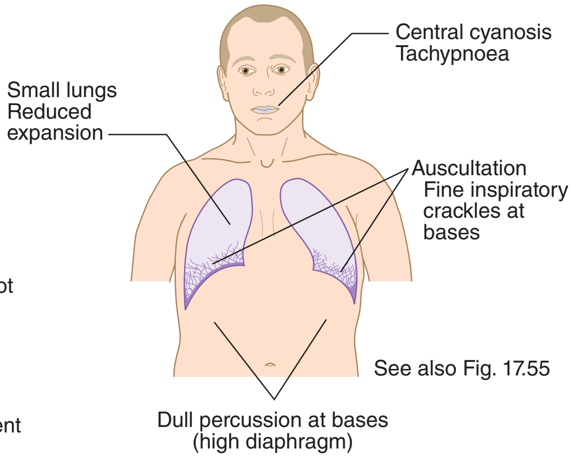
Chronic obstructive pulmonary disease



Pursed lip breathing
Central cyanosis
Prolonged expiration
Reduced cricosternal distance
Use of accessory muscles
Intercostal indrawing during inspiration
Hyperinflated 'barrel' chest
Cardiac apex not palpable
Loss of cardiac dullness on percussion
Auscultation
Reduced breath sounds – wheeze
Heart sounds loudest in epigastrium
Inward movement of lower ribs on inspiration (low flat diaphragm)

Also: raised jugular venous pressure (JVP), peripheral oedema from salt and water retention and/or cor pulmonale

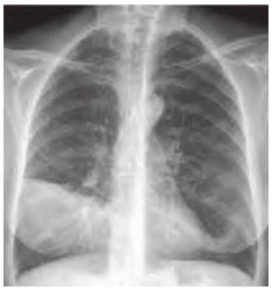
Pulmonary fibrosis



Central cyanosis
Tachypnoea
Small lungs
Reduced expansion
Auscultation
Fine inspiratory crackles at bases
See also Fig. 17.55
Dull percussion at bases (high diaphragm)

Also: finger clubbing common in idiopathic pulmonary fibrosis; raised JVP and peripheral oedema if cor pulmonale

Right middle lobe pneumonia



Obscures R heart border on X-ray

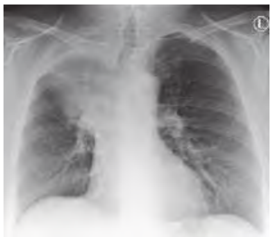
Inspection
- Tachypnoea
- Central cyanosis (if severe)

Palpation
- ↓Expansion on R

Percussion
- Dull R mid-zone and axilla

Auscultation
- Bronchial breath sounds and ↑vocal resonance over consolidation and whispering pectoriloquy
- Pleural rub if pleurisy

Right upper lobe collapse



X-ray
- Deviated trachea (to R)
- Elevated horizontal fissure
- ↓Volume R hemithorax
- Central (hilar) mass may be seen

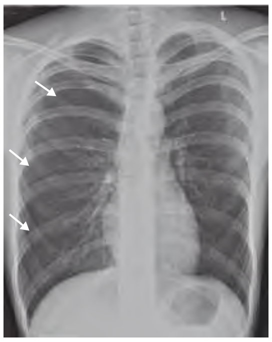
Inspection
- ↓Volume R upper zone

Palpation
- Trachea deviated to R
- ↓Expansion R upper zone

Percussion
- Dull R upper zone

Auscultation
- ↓Breath sounds with central obstruction

Right pneumothorax



Inspection
- Tachypnoea (pain, deflation reflex)

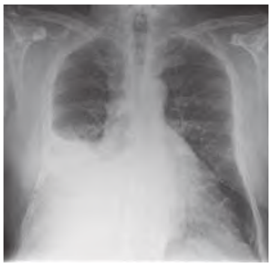
Palpation
- ↓Expansion R side

Percussion
- Resonant or hyper-resonant on R

Auscultation
- Absent breath sounds on R

Tension pneumothorax also causes
- Deviation of trachea to opposite side
- Tachycardia and hypotension

Large right pleural effusion



Inspection
- Tachypnoea

Palpation
- ↓Expansion on R
- Trachea and apex may be moved to L

Percussion
- Stony dull
- R mid- and lower zones

Auscultation
- Absent breath sounds and vocal resonance R base
- Bronchial breathing or crackles above effusion

Respiratory infections such as tuberculosis, pneumonia and virus infections such as influenza and COVID-19 represent a major burden of morbidity and mortality globally. The increasing prevalence of allergy, asthma and chronic obstructive pulmonary disease (COPD) contributes to the burden of chronic disease in the community. By 2030, the World Health Organization (WHO) predicts that the number of cigarette smokers worldwide will reduce to 1.2 billion; however, the ongoing tobacco exposure ensures a continuing burden of tobacco-related respiratory conditions.

Respiratory disease covers many pathologies, including infectious, inflammatory, neoplastic and degenerative processes. The practice of respiratory medicine thus requires collaboration with a range of disciplines. Recent advances have improved the lives of many patients with obstructive lung disease, cystic fibrosis, obstructive sleep apnoea and pulmonary hypertension, but the outlook remains poor for respiratory cancers and for some of the interstitial lung diseases.

Functional anatomy and physiology

The lungs occupy the upper two-thirds of the bony thorax, bounded medially by the spine, the heart and the mediastinum and inferiorly by the diaphragm. During breathing, free movement of the lung surface relative to the chest wall is facilitated by sliding contact between the parietal and visceral pleura, which cover the inner surface of the chest wall and the lung, respectively, and are normally closely apposed. Inspiration involves downward contraction of the diaphragm (innervated by the phrenic nerves originating from C3, 4 and 5) and upward, outward movement of the ribs, caused by contraction of the external intercostal muscles (innervated by intercostal nerves originating from the thoracic spinal cord). Expiration is largely passive, driven by elastic recoil of the lungs.

The conducting airways from the nose to the alveoli connect the external environment with the alveolar surface. As air is inhaled through the upper airways it is filtered in the nose, heated to body temperature and fully saturated with water vapour; partial recovery of this heat and moisture occurs on expiration. Total airway cross-section is smallest in the glottis and trachea, making the central airway particularly vulnerable to obstruction. Normal breath sounds originate mainly from the rapid turbulent airflow in the larynx, trachea and main bronchi.

The multitude of small airways within the lung parenchyma has a very large combined cross-sectional area (over 300 cm^2 in the third-generation respiratory bronchioles), resulting in very slow flow rates. Airflow is virtually silent here and gas transport occurs largely by diffusion in the final generations. Major bronchial and pulmonary divisions are shown in Figure 17.1.

The acinus (Fig. 17.2) is the gas exchange unit of the lung and comprises branching respiratory bronchioles and clusters of alveoli. Here the air makes close contact with the blood in the pulmonary capillaries (gas-to-blood distance $< 0.4\,\mu\text{m}$), and oxygen uptake and CO_2 excretion occur. The alveoli are lined with flattened epithelial cells (type I pneumocytes) and a few, more cuboidal, type II pneumocytes. The latter produce surfactant, which is a phospholipid mixture that reduces surface tension and thereby counteracts the tendency of alveoli to collapse. Type II pneumocytes can divide to reconstitute type I pneumocytes after lung injury.

Lung mechanics

Healthy alveolar walls contain a fine network of elastin and collagen fibres (see Fig. 17.2). The volume of the lungs at the end of a tidal ('normal')

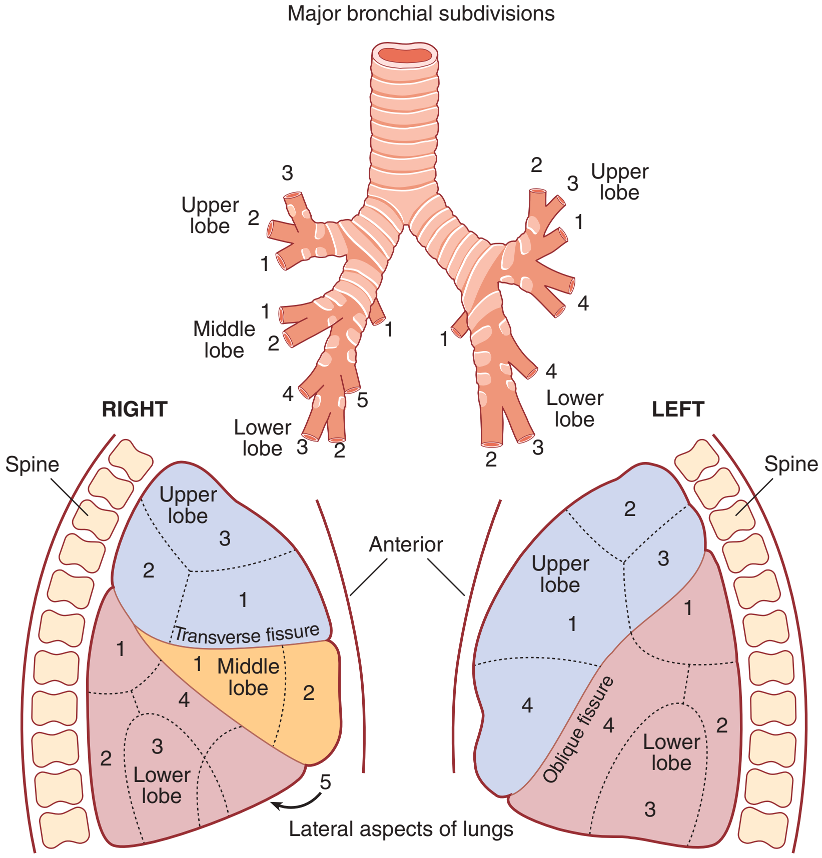

Fig. 17.1 The major bronchial divisions and the fissures, lobes and segments of the lungs. The angle of the oblique fissure means that the left upper lobe is largely anterior to the lower lobe. On the right, the transverse fissure separates the upper from the anteriorly placed middle lobe, which is matched by the lingular segment on the left side. The site of a lobe determines whether physical signs are mainly anterior or posterior. Each lobe is composed of two or more bronchopulmonary segments that are supplied by the main branches of each lobar bronchus. *Bronchopulmonary segments*: **Right** *Upper lobe*: (1) Anterior, (2) Posterior, (3) Apical. *Middle lobe*: (1) Lateral, (2) Medial. *Lower lobe*: (1) Apical, (2) Posterior basal, (3) Lateral basal, (4) Anterior basal, (5) Medial basal. **Left** *Upper lobe*: (1) Anterior, (2) Apical, (3) Posterior, (4) Lingular. *Lower lobe*: (1) Apical, (2) Posterior basal, (3) Lateral basal, (4) Anterior basal.

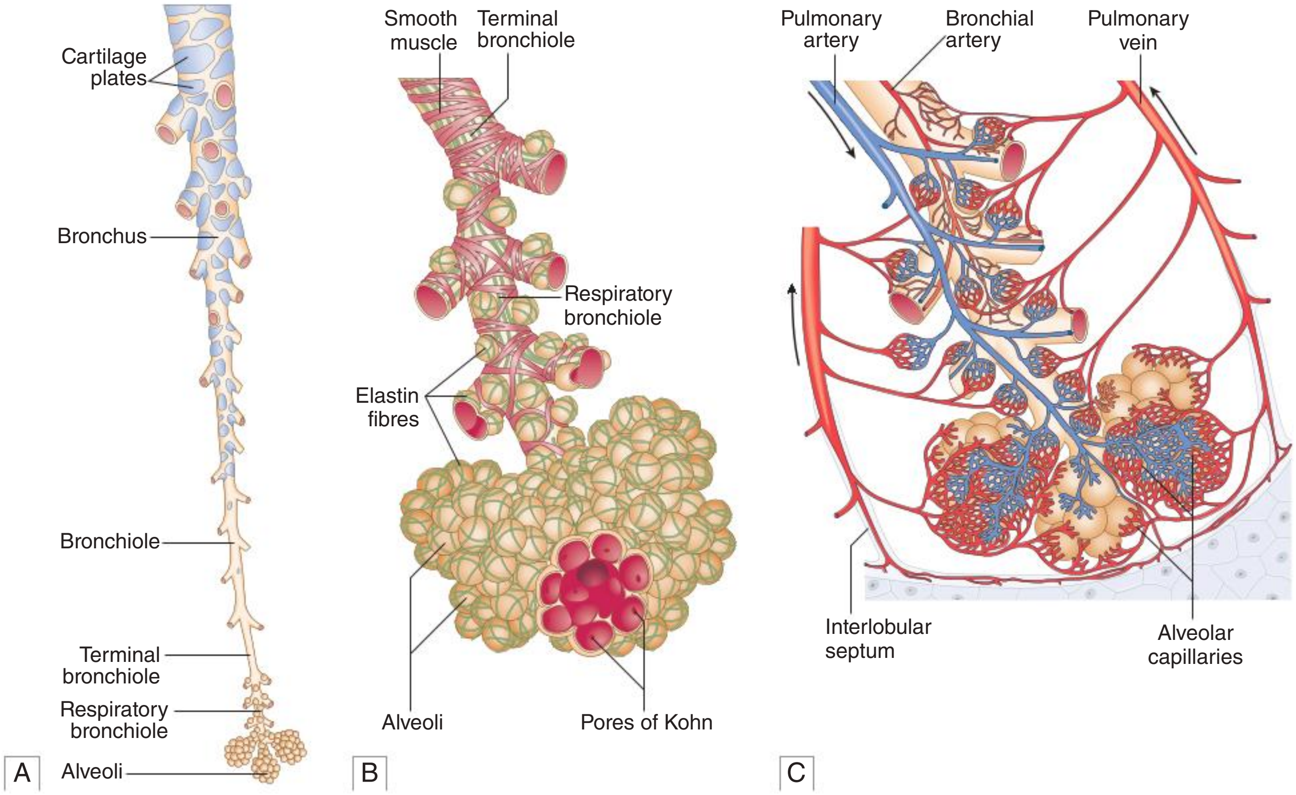

Fig. 17.2 Functional anatomy of the lung. **A** The tapering, branching bronchus is armoured against compression by plates of cartilage. The more distal bronchioles are collapsible but held patent by surrounding elastic tissue. **B** The unit of lung supplied by a terminal bronchiole is called an acinus. The bronchiolar wall contains smooth muscle and elastin fibres. The latter also run through the alveolar walls. Gas exchange occurs in the alveoli, which are connected to each other by the pores of Kohn. **C** Vascular anatomy of an acinus. Both the pulmonary artery (carrying desaturated blood) and the bronchial artery (systemic supply to airway tissue) run along the bronchus. The venous drainage to the left atrium follows the interlobular septa. *From www.Netter.com: Illustrations 155 (bronchus, acinus) and 191 (circulation), Elsevier.*

breath out is called the functional residual capacity (FRC). At this volume, the inward elastic recoil of the lungs (resulting from elastin fibres and surface tension in the alveolar lining fluid) is balanced by the resistance of the chest wall to inward distortion from its resting shape, causing negative pressure in the pleural space. Elastin fibres allow the lung to be easily distended at physiological lung volumes, but collagen fibres cause increasing stiffness as full inflation is approached, so that, in health, the maximum inspiratory volume is limited by the lung (rather than the chest wall). The weight of lung tissue compresses the dependent regions and distends the uppermost parts, so a greater portion of an inhaled breath passes to the basal regions, which also receive the greatest blood flow as a result of gravity. Elastin fibres in alveolar walls maintain small airway patency by radial traction on the airway walls. Even in health, however, these small airways narrow during expiration because they are surrounded by alveoli at higher pressure but are prevented from collapsing by radial elastic traction. The volume that can be exhaled is thus limited purely by the capacity of the expiratory muscles to distort the chest wall inwards. In emphysema, loss of alveolar walls leaves the small airways unsupported, and their collapse on expiration causes air trapping and limits expiration at a high end-expiratory volume.

Control of breathing

The respiratory motor neurons in the posterior medulla oblongata are the origin of the respiratory cycle. Their activity is modulated by multiple external inputs in health and in disease (see Fig. 17.9).

- Central chemoreceptors in the ventrolateral medulla sense the pH of the cerebrospinal fluid (CSF) and are indirectly stimulated by a rise in arterial PCO_2.
- The carotid bodies sense hypoxaemia but are mainly activated by arterial PO_2 values below 8 kPa (60 mmHg). They are also sensitised to hypoxia by raised arterial PCO_2.
- Muscle spindles in the respiratory muscles sense changes in mechanical load.
- Vagal sensory fibres in the lung may be stimulated by stretch, inhaled toxins or disease processes in the interstitium.
- Cortical (volitional) and limbic (emotional) influences can override the automatic control of breathing.

Ventilation/perfusion matching and the pulmonary circulation

The regional distribution of ventilation and perfusion must be matched for optimal gas exchange within the lungs. At segmental and sub-segmental level, hypoxia constricts pulmonary arterioles and airway CO_2 dilates bronchi, helping to maintain good regional matching of ventilation and perfusion. Lung disease may create regions of relative under-ventilation or under-perfusion, which disturb this regional matching, causing respiratory failure. In addition to causing ventilation–perfusion mismatch, diseases like emphysema or fibrosis that destroy capillaries or thicken the alveolar capillary membrane can impair gas diffusion directly.

The pulmonary circulation in health operates at low pressure (approximately 24/9 mmHg) and can accommodate large increases in flow with minimal rise in pressure, as occurs during exercise. Pulmonary hypertension occurs when vessels are destroyed by emphysema, obstructed by thrombus, involved in interstitial inflammation or thickened by pulmonary vascular disease. The right ventricle responds by hypertrophy, with right axis deviation and P pulmonale (tall, peaked p waves) on the electrocardiogram (ECG), and clinical features of right heart failure; the term 'cor pulmonale' is often used for these findings.

Changes in respiratory function associated with old age are shown in Box 17.1.

17.1 Respiratory function in old age

- **Reserve capacity**: a significant reduction in function can occur with ageing with only minimal effect on normal breathing, but the ability to combat acute disease is reduced.
- **Decline in FEV$_1$**: the FEV$_1$/FVC (forced expiratory volume/forced vital capacity) ratio falls by around 0.2% per year from 70% at the age of 40–45 years, due to a decline in elastic recoil in the small airways with age. Smoking accelerates this decline threefold on average. Symptoms usually occur only when FEV$_1$ drops below 50% of predicted.
- **Increasing ventilation–perfusion mismatch**: the reduction in elastic recoil causes a tendency for the small airways to collapse during expiration, particularly in dependent areas of the lungs, thus reducing ventilation.
- **Reduced ventilatory responses to hypoxia and hypercapnia**: older people may be less tachypnoeic for any given fall in PaO_2 or rise in $PaCO_2$.
- **Impaired defences against infection**: due to reduced numbers of glandular epithelial cells, which lead to a reduction in protective mucus.
- **Decline in maximum oxygen uptake**: due to a combination of impairments in muscle, and the respiratory and cardiovascular systems. This leads to a reduction in cardiorespiratory reserve and exercise capacity.
- **Loss of chest wall compliance**: due to reduced intervertebral disc spaces and ossification of the costal cartilages; respiratory muscle strength and endurance also decline. These changes become important only in the presence of other respiratory disease.

Lung defences

Upper airway defences

Large airborne particles are trapped by nasal hairs, and smaller particles settling on the mucosa are cleared towards the oropharynx by the columnar ciliated epithelium that covers the turbinates and septum (Fig. 17.3). During cough, expiratory muscle effort against a closed glottis results in high intrathoracic pressure, which is then released explosively. The flexible posterior tracheal wall is pushed inwards by the high surrounding pressure, which reduces tracheal cross-section and maximises the airspeed to achieve effective expectoration. The larynx also acts as a sphincter, closing to protect the airway during swallowing and vomiting.

Lower airway defences

The structure and function of the lower airways are maintained by close cooperation between the innate and adaptive immune responses. Traditionally, the healthy lower respiratory tract was considered to be sterile. However, molecular analysis has established that the lower respiratory tract has a diverse resident microbial population (the lung microbiome). Understanding interactions between the immune system and the lung microbiome, and its role in health and disease, is in its infancy.

The innate immune response in the lungs is characterised by a number of non-specific defence mechanisms. Inhaled particulate matter is trapped in airway mucus and cleared by the mucociliary escalator. Tobacco smoke increases mucus secretion but reduces mucociliary clearance and predisposes towards lower respiratory tract infections, including pneumonia. Defective mucociliary transport is also a feature of rare diseases including cystic fibrosis, and primary ciliary dyskinesia, which are characterised by repeated sino-pulmonary infections and bronchiectasis.

Airway secretions contain an array of antimicrobial peptides (AMPs) such as defensins and lysozyme, immunoglobulin A (IgA), antiproteinases and antioxidants. Many assist with the opsonisation and killing of bacteria and the regulation of the proteolytic enzymes secreted by inflammatory cells. In particular, α_1-antitrypsin regulates neutrophil elastase, and deficiency of this may be associated with premature emphysema.

Macrophages engulf microbes, organic dusts and other particulate matter. They cannot digest inorganic agents such as asbestos or silica, which cause their death and lead to the release of powerful proteolytic enzymes that damage the lung. Neutrophil numbers in the airway are low but the pulmonary circulation contains a marginated pool that may be recruited rapidly in response to bacterial infection.

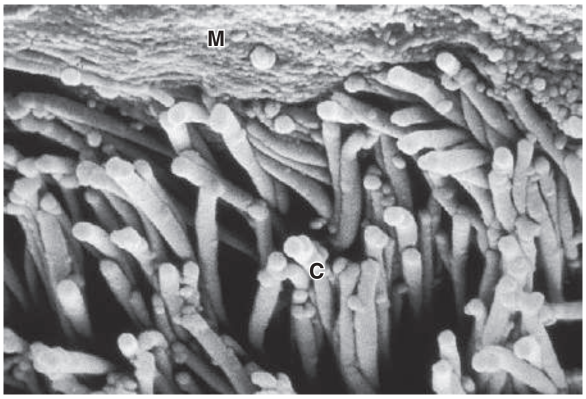

Fig. 17.3 The mucociliary escalator. Scanning electron micrograph of the respiratory epithelium showing large numbers of cilia (C) overlaid by the mucus 'raft' (M).

Adaptive immunity is characterised by a specific response and immunological memory. Lung dendritic cells facilitate antigen presentation to T and B lymphocytes.

Investigation of respiratory disease

A detailed history, thorough examination and basic haematological and biochemical tests usually indicate the likely diagnosis and differential. A number of other investigations are normally required to confirm the diagnosis and/or monitor disease activity.

Imaging

Chest X-ray

The chest X-ray (CXR) is an initial investigation performed on the majority of patients suspected of having respiratory disease. A posteroanterior (PA) CXR film provides information on the lung fields, heart, mediastinum, vascular structures and thoracic cage (Fig. 17.4). A lateral CXR film may provide additional information, particularly if pathology is suspected behind the heart or deep in the diaphragmatic sulci. An approach to interpreting the CXR is given in Box 17.2, and common abnormalities are listed in Box 17.3.

Increased shadowing may represent accumulation of fluid, lobar collapse or consolidation. Uncomplicated consolidation should not change the position of the mediastinum and the presence of an air bronchogram means that proximal bronchi are patent. Collapse (implying obstruction of the lobar bronchus) is accompanied by loss of volume and displacement of the mediastinum towards the affected side (Fig. 17.5).

The presence of ring shadows (thickened bronchi seen end-on), tramline shadows (thickened bronchi side-on) or tubular shadows (bronchi filled with secretions) suggests bronchiectasis. The presence of pleural fluid is suggested by a dense basal shadow, which, in the erect patient, ascends towards the axilla. In a large pulmonary embolism, relative oligaemia may cause a lung field to appear abnormally dark.

Computed tomography

Computed tomography (CT) provides detailed images of the pulmonary parenchyma, mediastinum, pleura and bony structures. The displayed range of densities can be adjusted to highlight different structures such as the lung parenchyma, the mediastinal vascular structures or bone. Cross-sectional formatting allows recognition of the axial distribution of the disease, while coronal reformation displays the craniocaudal distribution. In cases of suspected lung cancer, CT is central to both diagnosis and staging and facilitates percutaneous needle biopsy. The extent and appearance of pleural thickening can be identified on CT (see Fig. 17.64) and reliably differentiates pleural and pericardial fat from

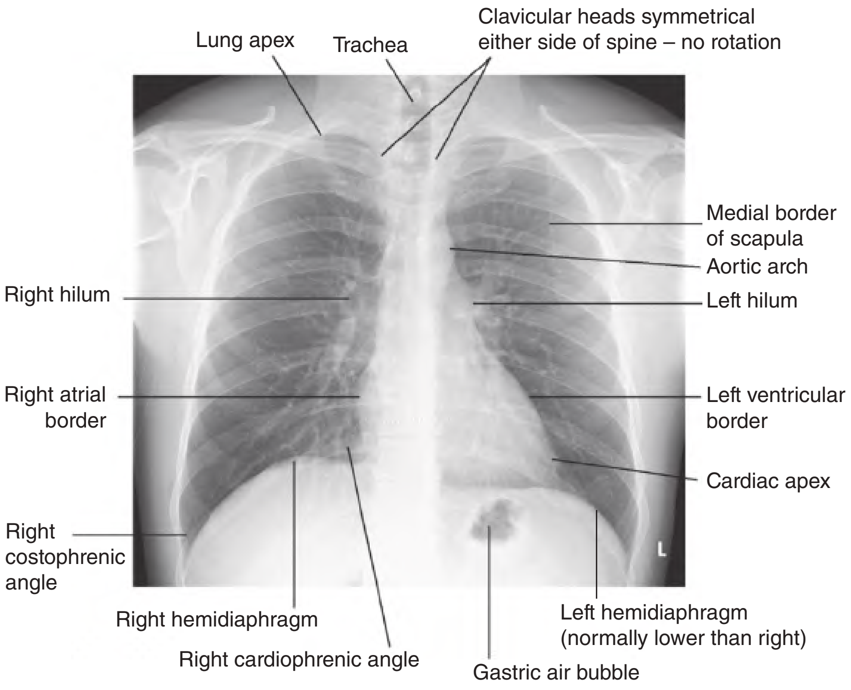

Fig. 17.4 The normal chest X-ray. The lung markings consist of branching and tapering lines radiating out from the hila. Where airways and vessels turn towards the film, they can appear as open or filled circles (see upper pole of right hilum). The scapulae may overlie the lung fields; trace the edge of bony structures to avoid mistaking them for pleural or pulmonary shadows. To check for hyperinflation, count the ribs; if more than 10 are visible posteriorly above the diaphragm, the lungs are hyperinflated. *From Innes JA. Davidson's essentials of medicine. Edinburgh: Churchill Livingstone, Elsevier Ltd; 2009.*

17.2 Features to look for when interpreting a chest X-ray

Name, date, orientation	Films are posteroanterior (PA) unless marked AP to denote that they are anteroposterior
Lung fields	Check for equal translucency Check horizontal fissure from right hilum to sixth rib at the anterior axillary line Check for masses, consolidation and cavitation
Lung apices	Check behind the clavicles for masses, consolidation or cavitation
Trachea	Check that trachea is central between the clavicular heads Check for paratracheal masses and goitre
Heart	Check that the heart has a normal shape Cardiothoracic ratio (should be less than half the intrathoracic diameter) Check for retrocardiac masses
Hila	Left should be higher than right Shape (should be concave laterally; if convex, consider mass or lymphadenopathy) Check for equal hilar density
Diaphragm	Right should be higher than left Hyperinflation (no more than 10 ribs should be visible posteriorly above the diaphragm)
Costophrenic angles	Should be acute and well-defined; pleural fluid if not
Soft tissues	Check breast shadows in females Check chest wall for masses or subcutaneous emphysema
Bones	Check ribs, vertebrae, scapulae and clavicles Check if fractures are visible at bone margins and for signs of osteolysis

17.3 Common abnormalities on chest X-ray

Pulmonary and pleural shadowing

- Consolidation: infection, infarction, inflammation and, rarely, bronchoalveolar cell carcinoma
- Lobar collapse: mucus plugging, tumour, compression by lymph nodes
- Solitary nodule
- Multiple nodules: miliary tuberculosis (TB), dust inhalation, metastatic malignancy, healed varicella pneumonia, rheumatoid disease
- Ring shadows, tramlines and tubular shadows: bronchiectasis
- Cavitating lesions: tumour, abscess, infarct, pneumonia *(Staphylococcus/ Klebsiella)*, granulomatosis with polyangiitis (GPA)
- Reticular, nodular and reticulonodular shadows: diffuse parenchymal lung disease, infection
- Pleural abnormalities: fluid, plaques, tumour

Increased translucency

- Bullae
- Pneumothorax
- Oligaemia

Hilar abnormalities

- Unilateral hilar enlargement: TB, lung cancer, lymphoma
- Bilateral hilar enlargement: sarcoidosis, lymphoma, TB, silicosis

Other abnormalities

- Hiatus hernia
- Surgical emphysema

pathology. High-resolution thin-section CT (HRCT) scanning provides detailed images of the pulmonary parenchyma and is superior to CXR for assessment of diffuse parenchymal lung disease (see Fig. 17.55), identifying airway thickening, bronchiectasis (see Fig. 17.29) and emphysema (see Fig. 17.27). The relative contribution of competing pathologies to a patient with breathlessness may be assessed. Prone imaging may be used to differentiate the gravity-induced posterobasal attenuation seen in supine scans. Computed tomography pulmonary angiography (CTPA) has become the investigation of choice in the diagnosis of pulmonary thromboembolism (see Fig. 17.67), when it may either confirm the suspected embolism or highlight an alternative diagnosis. It has largely replaced the radioisotope-based ventilation–perfusion ($\dot{V}/\dot{Q}$) scan for this purpose. It may assist in identifying cavitation and other features of infection (such as air crescent and halo signs in

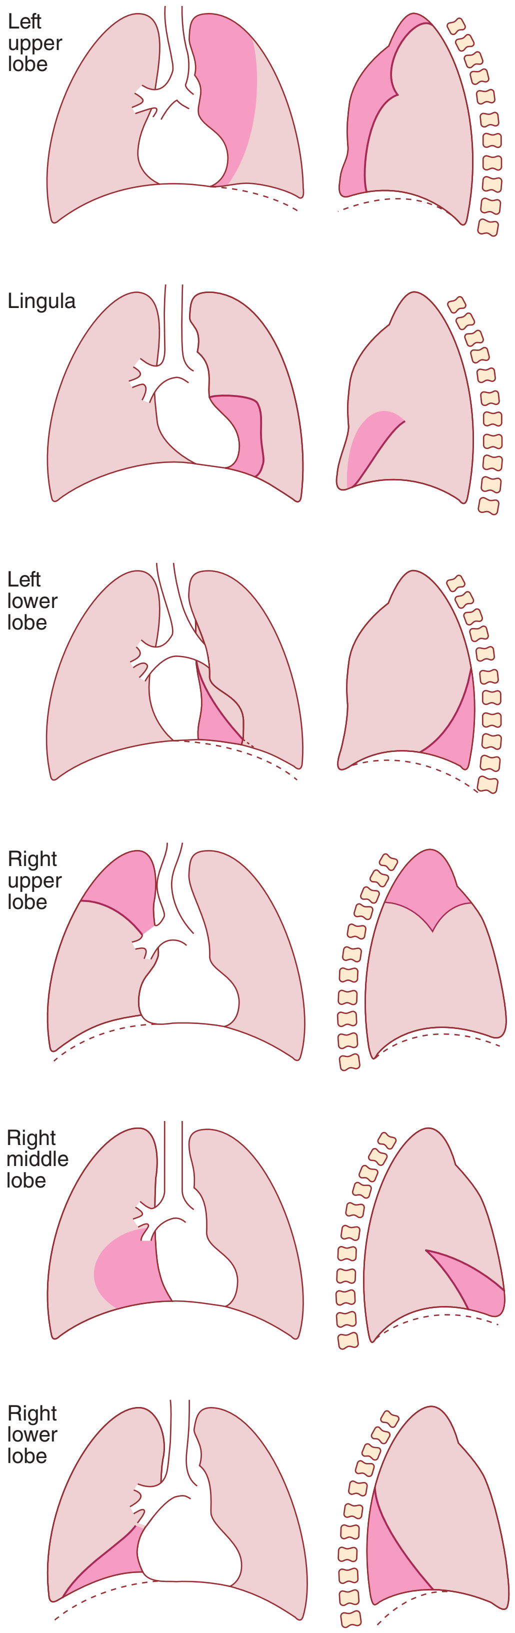

Fig. 17.5 Radiological features of lobar collapse caused by bronchial obstruction. The dotted line in the drawings represents the normal position of the diaphragm. The dark pink area represents the extent of shadowing seen on the CXR.

aspergillosis). Finally, it may be used to monitor disease progression in established disease and more recently has been established for lung cancer screening in high-risk populations using a low radiation dose technique.

Positron emission tomography

Positron emission tomography (PET) scanners employ the radiotracer ^{18}F-fluorodeoxyglucose (FDG) to quantify the rate of glucose metabolism by cells. The FDG is rapidly taken up by metabolically active tissue, where it is phosphorylated and retained within the cell. The assessment of FDG uptake may be qualitative (visual analysis) or semi-quantitative, using the standardised uptake value (SUV) (Fig. 17.6). It is also useful in the staging of mediastinal lymph nodes and distal metastatic disease in patients with lung cancer and in the investigation of pulmonary nodules. Combining PET and CT (PET-CT) enhances localisation and characterisation of metabolically active deposits (see Fig. 17.6). Imaging with FDG PET may also differentiate benign from malignant pleural disease and can be used to assess the extent of extrapulmonary disease in sarcoidosis. However, FDG uptake by a lesion is affected by a large number of parameters, including equipment used, the physics, and biological factors such as amount of body fat and brown fat uptake and the blood glucose level.

Magnetic resonance imaging

Conventional magnetic resonance imaging (MRI) of the lung parenchyma is seldom useful, although the technique is being used increasingly in distinguishing benign from malignant pleural disease and in delineating invasion of the chest wall or diaphragm by tumour.

The use of hyperpolarised helium-3 (^{3}He) MRI is a developing method of assessing the distribution of ventilation within the lung.

Ultrasound

Transthoracic ultrasound is a point-of-care investigation used to assess the pleural space (see Fig. 17.15). In the hands of an experienced operator, it can distinguish pleural fluid from pleural thickening and identify a pneumothorax. Ultrasound can directly visualise the diaphragm and solid organs such as the liver, spleen and kidneys, and is recommended to be used to safely guide pleural aspiration, biopsy and intercostal chest drain insertion. It is also used to guide needle biopsy of superficial lymph node or chest wall masses and provides useful information on the shape and movement of the diaphragm.

Endoscopic examination

Laryngoscopy

The larynx may be inspected directly with a fibreoptic laryngoscope in cases of suspected intermittent laryngeal obstruction (ILO), when paradoxical movement of the vocal cords may mimic asthma. Left-sided lung tumours may involve the left recurrent laryngeal nerve, paralysing the left vocal cord and leading to a hoarse voice and a ‘bovine’ cough. Continuous laryngoscopy during exercise tests allows the identification of exercise-induced ILO.

Bronchoscopy

The trachea and the first 3–4 generations of bronchi may be inspected using a flexible fibreoptic bronchoscope. This is usually performed under local anaesthesia with sedation, on an outpatient basis. Abnormal tissue in the bronchial lumen or wall can be biopsied, and bronchial brushings, washings or aspirates can be taken for cytological or microbiological examination. Small biopsy specimens of lung tissue, taken by forceps passed through the bronchial wall (transbronchial biopsies), may be helpful in the diagnosis of bronchocentric disorders such as sarcoidosis and diffuse malignancy but are generally too small to be of diagnostic value in other diffuse parenchymal pulmonary disease.

Rigid bronchoscopy requires general anaesthesia and is reserved for specific situations, such as massive haemoptysis or removal of a foreign body (see Fig. 10.2) and can facilitate endobronchial laser therapy and stenting for bronchial obstruction such as that caused by stenosis or tumours.

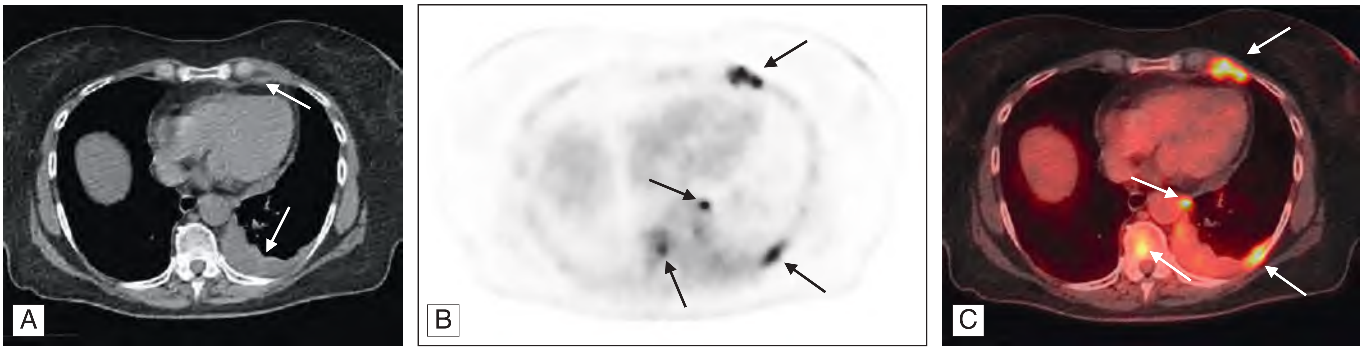

Fig. 17.6 Positron emission tomography and computed tomography in a patient with lung cancer. **A** The CT scan shows a left posterior pleural effusion and minimal pleural thickening anteriorly (white arrows). **B** The FDG PET scan reveals two focal areas of FDG pleural uptake adjacent to the effusion as well as FDG uptake within the area of pleural thickening on the left and in the vertebral body, consistent with metastases (black arrows). **C** Combining the CT and PET images allows precise correlation to determine the anatomical location of the areas of FDG uptake (white arrows). A bone metastasis in the vertebral body is also demonstrated. (CT = computed tomography; FDG = ^{18}F-fluorodeoxyglucose; PET = positron emission tomography)

Endobronchial ultrasound

Endobronchial ultrasound (EBUS) allows directed needle aspiration from peribronchial nodes and is used increasingly to stage lung cancer. It may also be useful in non-malignant conditions, such as mediastinal lymphadenopathy caused by tuberculosis or sarcoidosis. Lymph nodes down to the main carina can also be sampled using a mediastinoscope passed through a small incision at the suprasternal notch under general anaesthetic. Lymph nodes in the lower mediastinum may be biopsied via the oesophagus using an oesophageal endoscope equipped with an ultrasound transducer and biopsy needle (endoscopic ultrasound).

Thoracoscopy

Thoracoscopy, which involves the insertion of an endoscope through the chest wall, facilitates biopsy under direct vision and is the gold standard for the evaluation of the pleural surfaces, characterisation of complex pleural effusion, and identification of exudate and haemorrhage. It is also used for accurate staging of apical tumours.

Microbiological investigations

Sputum, pleural fluid, throat swabs, blood and bronchial washings and aspirates can be examined using microscopy, culture and sensitivity for bacteria and fungi. The use of hypertonic saline to induce expectoration of sputum may avoid the need for more invasive procedures such as bronchoscopy. Molecular tests, such as nucleic acid amplification tests (NAATs), are being used increasingly as first-line diagnostic tests for respiratory viruses (including influenza and coronaviruses such as SARS-CoV-2) as well as bacterial pathogens, such as *Legionella* and *Mycoplasma*, for which they have largely replaced paired serology and antigen-based tests. NAATs are also gaining an increased role as first-line diagnostic tests for tuberculosis and for rapid identification of antimicrobial drug resistance.

Immunological and serological tests

The presence of atopy can be detected by demonstrating an elevated level of immunoglobulin E (IgE), and the measurement of IgE directed against specific antigens. This can be useful to support the diagnosis of allergic asthma and in identifying triggers. Many autoimmune diseases present with pulmonary involvement, and autoantibodies may be identified in patients with rheumatoid disease and connective tissue diseases. Serum precipitins (antibodies that form visible lines of precipitated glycoprotein when they encounter their specific antigen in an agarose gel) can be used to identify a reaction to fungi such as *Aspergillus* or to antigens involved in hypersensitivity pneumonitis, such as farmer's lung or bird fancier's lung. The presence of pneumococcal antigen in sputum, blood or urine may be of diagnostic importance in pneumonia.

Respiratory viruses can be detected in nose/throat swabs by immunofluorescence, and *Legionella* infection may diagnosed by detection of a *Legionella* antigen in urine. Beta-1,3-D-glucan detection (in blood) is a marker of fungal infection (Ch. 14), and *Aspergillus* galactomannan (in blood and bronchial lavage fluid) is used to diagnose invasive aspergillosis. Interferon-gamma release assays are useful in the detection of latent tuberculosis.

Cytology and histopathology

Cytological examination of exfoliated cells in pleural fluid or bronchial brushings and washings, or of fine needle aspirates from lymph nodes or pulmonary lesions, can support a diagnosis of malignancy. A larger tissue biopsy is often necessary, however, as this allows immunohistochemistry and genetic testing to characterise the tumour and guide targeted therapies. Histopathology may also allow identification of microorganisms using conventional staining or NAATs. Differential cell counts in bronchial lavage fluid may help to distinguish pulmonary changes due to sarcoidosis, idiopathic pulmonary fibrosis or hypersensitivity pneumonitis.

Respiratory function testing

Respiratory function tests are used to aid diagnosis, quantify functional impairment and monitor treatment or progression of disease. Airway narrowing, lung volume and gas exchange capacity are quantified and compared with normal values adjusted for age, sex, height and ethnic origin. In diseases characterised by airway narrowing, such as asthma, bronchitis and emphysema, maximum expiratory flow is limited by dynamic compression of small intrathoracic airways, some of which may close completely during expiration, limiting the volume that can be expired (obstructive defect). This causes hyperinflation of the chest, which can become extreme if elastic recoil is also lost due to parenchymal destruction, as in emphysema. In contrast, diseases that cause interstitial inflammation and/or fibrosis lead to progressive loss of lung volume (restrictive defect) with normal expiratory flow rates. Typical laboratory traces are illustrated in Figure 17.7.

Measurement of airway obstruction

Airway narrowing is assessed by asking patients to breathe in fully, then blow out as hard and fast as they can into a peak flow meter or a spirometer. Peak flow meters are useful for home monitoring of peak expiratory flow (PEF) in the detection and monitoring of asthma, but results are effort-dependent. More accurate and reproducible measures are obtained by maximum forced expiration into a spirometer. The forced expired volume in 1 second (FEV_1) is the volume exhaled in the first second, and the forced vital capacity (FVC) is the total volume exhaled. Airflow obstruction is defined as a FEV_1/FVC ratio of less than 70% or a Z-score below the lower limit of normal. In this

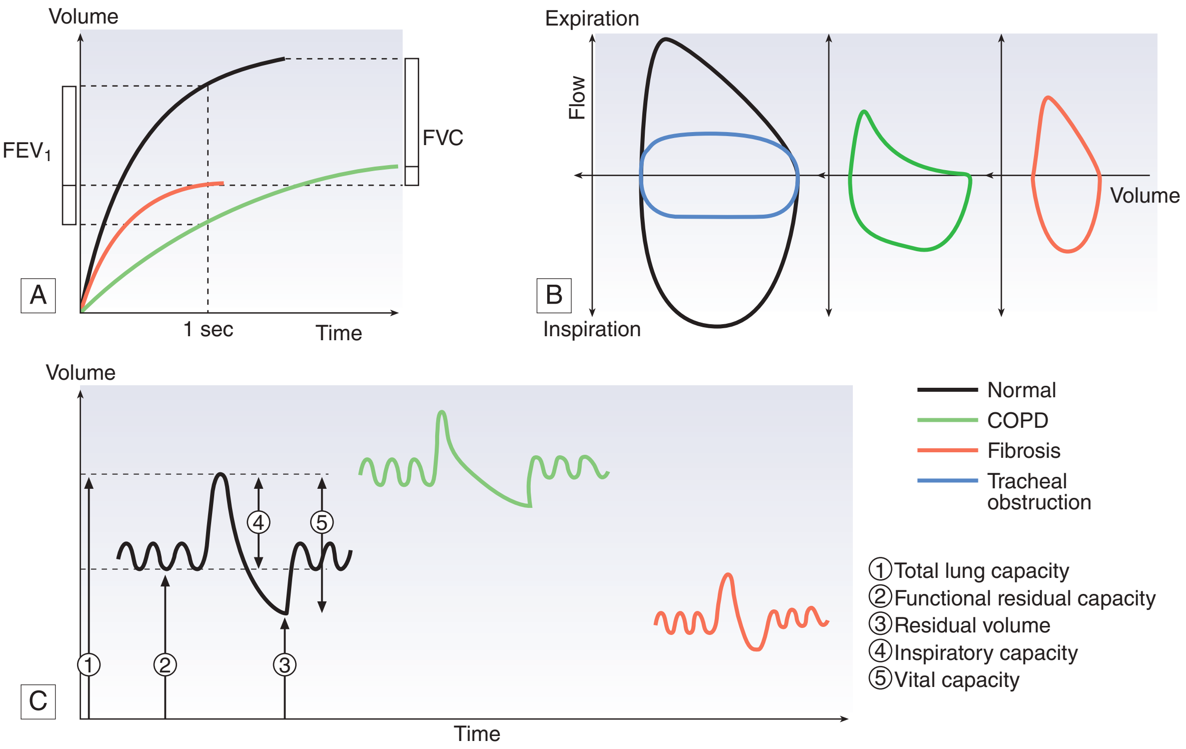

Fig. 17.7 Respiratory function tests in health and disease. **A** Volume/time traces from forced expiration in health, chronic obstructive pulmonary disease (COPD) and fibrosis. COPD causes slow, prolonged and limited exhalation. In fibrosis, forced expiration results in rapid expulsion of a reduced forced vital capacity (FVC). Forced expiratory volume (FEV_1) is reduced in both diseases but disproportionately so, compared to FVC, in COPD. **B** The same data plotted as flow/volume loops. In COPD, collapse of intrathoracic airways limits flow, particularly during mid- and late expiration. The blue trace illustrates large airway obstruction, which particularly limits peak flow rates. **C** Lung volume measurement. Volume/time graphs during quiet breathing with a single maximal breath in and out. COPD causes hyperinflation with increased residual volume. Fibrosis causes a proportional reduction in all lung volumes.

situation, spirometry should be repeated following inhaled short-acting β_2-adrenoceptor agonists such as salbutamol. An increase of > 12% and > 200 mL in FEV_1 or FVC indicates significant reversibility. A large improvement in FEV_1 (> 400 mL) or variability in peak flow over time are features of asthma.

Large airway narrowing, such as tracheal stenosis or compression by a retrosternal goitre (see Fig. 20.12), can be distinguished from small airway narrowing through plotting spirometry data as flow/volume loops. These display flow in relation to lung volume (rather than time) during maximum expiration and inspiration, and the pattern of flow reveals the site of airflow obstruction (see Fig. 17.7B).

Lung volumes

Spirometry can measure only the volume of gas that can be exhaled; it cannot measure the gas remaining in the lungs after a maximal expiration. All the gas in the lungs can be measured by rebreathing an inert non-absorbed gas (usually helium) and recording how much the test gas is diluted by lung gas at equilibrium. This measures the volume of intrathoracic gas that mixes freely with tidal breaths. Alternatively, lung volume may be measured by body plethysmography which determines the pressure/volume relationship of the thorax. This method measures total intrathoracic gas volume, including poorly ventilated areas such as bullae. The terms used to describe lung volume are shown in Figure 17.7C.

Transfer factor

To measure the capacity of the lungs to exchange gas, patients inhale a test mixture of 0.3% carbon monoxide, which is taken up avidly by haemoglobin in pulmonary capillaries. After a short breath-hold, the rate of disappearance of CO into the circulation is calculated from a sample of expirate and expressed as the TL_{CO} or carbon monoxide transfer factor. Helium is also included in the test breath to allow calculation of the volume of lung examined by the test breath. Transfer factor expressed per unit lung volume is termed K_{CO}. Common respiratory function abnormalities are summarised in Box 17.4.

17.4 Patterns of respiratory function test abnormalities in different diseases

	Asthma	Chronic bronchitis	Emphysema	Pulmonary fibrosis
FEV_1	↓↓	↓↓	↓↓	↓
FVC	↓	↓	↓	↓↓
FEV_1/FVC	↓	↓	↓	→/↑
TL_{CO}	→	→	↓↓	↓↓
K_{CO}	→/↑	→	↓	→/↓
TLC	→/↑	↑	↑↑	↓
RV	→/↑	↑	↑↑	↓

(RV = residual volume; TLC = total lung capacity; see text for other abbreviations)

Arterial blood gases and oximetry

The measurement of hydrogen ion concentration, PaO_2 and $PaCO_2$, and derived bicarbonate concentration in an arterial blood gas (ABG) sample is essential for assessing the degree and type of respiratory failure and for measuring acid–base status. This is discussed in detail on pages 535 and 672 (see Box 17.16). Interpretation of these results is facilitated by ABG diagrams (Fig. 17.8), which indicate whether any acidosis or alkalosis is due to acute or chronic respiratory derangements of $PaCO_2$ or to metabolic causes.

Pulse oximeters provide a continuous estimation of arterial oxygen saturation (SaO_2, or SpO_2 if measured by pulse oximetry) (p. 213), thus allowing a real-time assessment of a patient's response to oxygen therapy.

Exercise tests

Resting measurements may be unhelpful in early disease or in patients complaining only of exercise-induced symptoms. Spirometry testing before and after exercise can help to reveal exercise-induced asthma.

Walk tests include the self-paced 6-minute walk and the externally paced incremental 'shuttle' test, where patients walk at increasing pace between two cones 10 m apart. These provide simple, repeatable assessments of disability and response to treatment. Cardiopulmonary bicycle exercise testing, with measurement of metabolic gas exchange, ventilation and ECG changes, is useful for quantifying exercise limitation and detecting occult cardiovascular or respiratory limitation in a breathless patient.

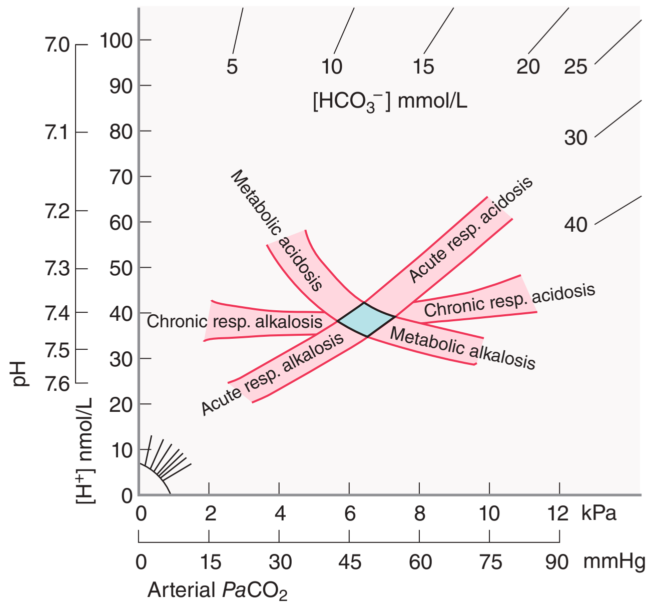

Fig. 17.8 Changes in blood [H+], $Pa\text{CO}_2$ and plasma [HCO_3–] in acid–base disorders. The blue rectangle indicates normal limits for [H^+] and $Pa\text{CO}_2$. The pink bands represent 95% confidence limits of single disturbances in human blood. To determine the likely cause of an acid–base disorder, plot the values of [H^+] and $Pa\text{CO}_2$ from an arterial blood gas measurement. The diagram indicates whether any acidosis or alkalosis results primarily from a respiratory disorder of $Pa\text{CO}_2$ or from a metabolic derangement. *Modified from Flenley D. Lancet 1971;1:1921, with permission from Elsevier.*

Presenting problems in respiratory disease

Cough

Cough is the most frequent symptom of respiratory disease and is caused by stimulation of sensory nerves in the mucosa of the pharynx, larynx, trachea and bronchi. Acute sensitisation of the normal cough reflex occurs in a number of conditions and it is typically induced by changes in air temperature or exposure to irritants, such as cigarette smoke or perfumes. Distinguishing characteristics of various causes of cough are detailed in Box 17.5.

The explosive quality of a normal cough is lost in patients with respiratory muscle paralysis or vocal cord palsy. Paralysis of a single vocal cord gives rise to a prolonged, low-pitched, inefficient 'bovine' cough accompanied by hoarseness. Coexistence of an inspiratory noise (stridor) indicates partial obstruction of a major airway. Causes include laryngeal oedema, tracheal tumour, scarring, compression or an inhaled foreign body. This requires urgent investigation and treatment. Sputum production is common in patients with acute or chronic cough, and its nature and appearance can provide clues to the aetiology.

Aetiology

Acute transient cough is most commonly caused by viral tracheo-bronchial infection, post-nasal drip resulting from rhinitis or sinusitis, aspiration of a foreign body, or throat-clearing secondary to laryngitis or pharyngitis. When cough occurs in the context of more serious diseases, such as pneumonia, aspiration, congestive heart failure or pulmonary embolism, it is usually easy to diagnose from other clinical features.

i 17.5 Distinguishing features of different causes of cough

Origin	Common causes	Clinical features
Pharynx	Post-nasal drip	History of chronic rhinitis
Larynx	Laryngitis, tumour, whooping cough, croup	Voice or swallowing altered, harsh or painful cough Paroxysms of cough, often associated with stridor
Trachea	Tracheitis	Raw retrosternal pain with cough
Bronchi	Bronchitis (acute) and chronic obstructive pulmonary disease (COPD)	Dry or productive, worse in mornings
	Asthma	Usually dry, worse at night
	Eosinophilic bronchitis	Features similar to asthma but airway hyper-reactivity absent
	Lung cancer	Persistent (often with haemoptysis)
Lung parenchyma	Tuberculosis	Productive (often with haemoptysis)
	Pneumonia	Dry initially, productive later Atypical pneumonias, including COVID-19, often present with a dry cough
	Bronchiectasis	Productive, changes in posture induce sputum production
	Pulmonary oedema	Often at night (may be productive of pink, frothy sputum)
	Interstitial fibrosis	Dry and distressing
Drug side-effect	Angiotensin-converting enzyme (ACE) inhibitors	Dry cough
Aspiration	Gastro-oesophageal disease	History of acid reflux, heartburn, hiatus hernia Obesity

Adapted from Munro JF, Campbell IW. Macleod's clinical examination, 10th ed. Edinburgh: Churchill Livingstone, Elsevier Ltd; 2000.

Patients with chronic cough present more of a challenge and should be assessed with history, physical examination, CXR and lung function studies.

Adults with chronic cough and a history of tobacco exposure should be considered for CT scanning if their CXR is abnormal, or if it is normal and there are other symptoms that might suggest lung cancer, such as haemoptysis.

In the context of normal respiratory examination and investigations, extra-thoracic causes of cough need to be considered, such as post-nasal drip secondary to nasal or sinus disease, gastro-oesophageal reflux disease or cough hypersensitivity. Use of angiotensin-converting enzyme (ACE) inhibitors can result in a chronic dry cough, taking up to 6 months to resolve following cessation. *Bordetella pertussis* infection in adults can result in cough lasting up to 3 months.

The presence of fine inspiratory crackles and a dry cough should prompt investigation for the possibility of an interstitial lung disease.

Breathlessness

Breathlessness or dyspnoea is defined as the feeling of an uncomfortable need to breathe. It is unusual among sensations, as it has no defined receptors, no localised representation in the brain, and multiple causes both in health – such as occurs physiologically during strenuous exercise – and in diseases of the lungs, heart or muscles.

Pathophysiology

Stimuli to breathing resulting from disease processes are shown in Figure 17.9. Respiratory diseases can stimulate breathing and dyspnoea by:

- stimulating intrapulmonary sensory nerves (pneumothorax, interstitial inflammation and pulmonary embolus)
- increasing the mechanical load on the respiratory muscles (airflow obstruction or pulmonary fibrosis)
- causing hypoxia, hypercapnia or acidosis, which stimulate chemoreceptors.

In cardiac failure, pulmonary congestion reduces lung compliance and can also obstruct the small airways. Reduced cardiac output also limits oxygen supply to the skeletal muscles during exercise, causing early lactic acidaemia and further stimulating breathing by activating chemoreceptors in the central nervous system (CNS).

Breathlessness and the effects of treatment can be quantified using a symptom scale. Patients tend to report breathlessness in proportion to the sum of the above stimuli to breathing. Individual patients differ greatly in the intensity of breathlessness reported for a given set of circumstances, but breathlessness scores during exercise within individuals are reproducible and can be used to monitor the effects of therapy.

Differential diagnosis

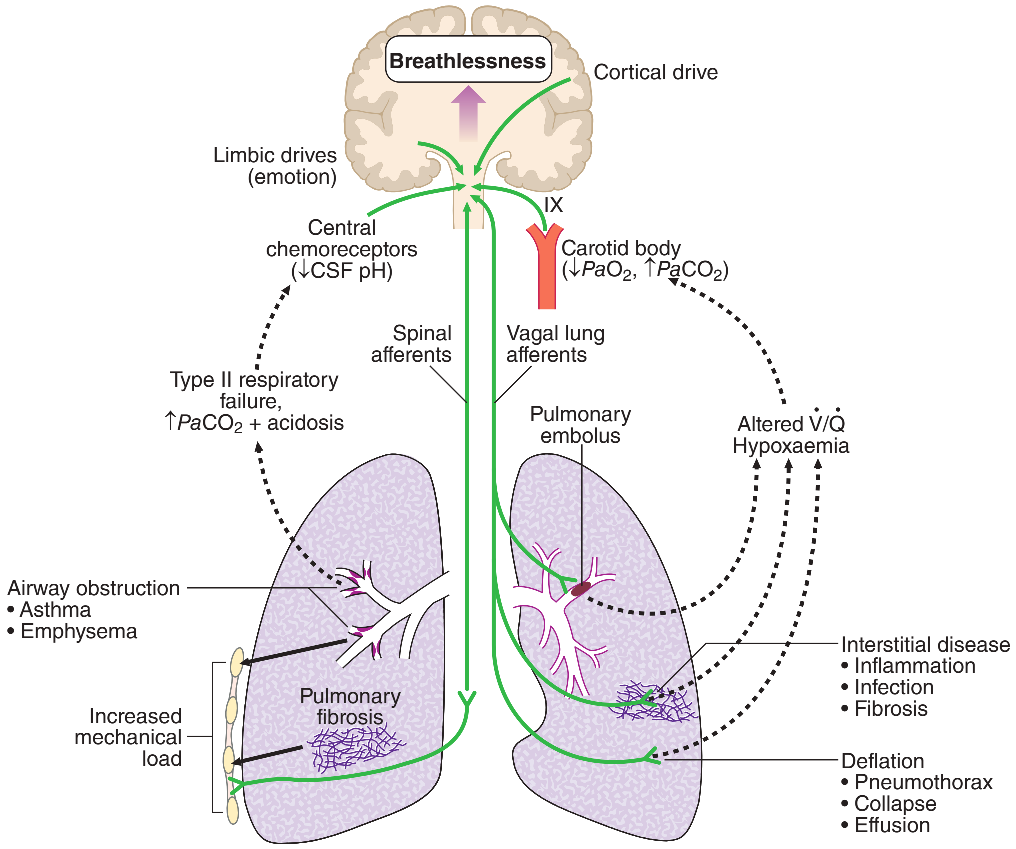
Patients may present either with chronic exertional breathlessness or as an emergency with acute breathlessness, with prominent symptoms even at rest. The causes are classified in Box 17.6.

Chronic exertional breathlessness

The cause of breathlessness is often apparent from the clinical history. Key questions are detailed below.

How is your breathing at rest and overnight?

In COPD, there is a fixed, structural limit to maximum ventilation and a tendency for progressive hyperinflation during exercise. Breathlessness is apparent mainly when walking, and patients usually report minimal symptoms at rest and overnight. In contrast, patients with significant asthma are often woken from their sleep by breathlessness with chest tightness and wheeze.



Breathlessness
Cortical drive
Limbic drives (emotion)
IX
Central chemoreceptors (↓CSF pH)
Carotid body (↓PaO_2, ↑$PaCO_2$)
Spinal afferents
Vagal lung afferents
Type II respiratory failure, ↑$PaCO_2$ + acidosis
Pulmonary embolus
Altered $\dot{V}/\dot{Q}$ Hypoxaemia
Airway obstruction
• Asthma
• Emphysema
Interstitial disease
• Inflammation
• Infection
• Fibrosis
Pulmonary fibrosis
Increased mechanical load
Deflation
• Pneumothorax
• Collapse
• Effusion

Fig. 17.9 Respiratory stimuli contributing to breathlessness. Mechanisms by which disease can stimulate the respiratory motor neurons in the medulla. Breathlessness is usually felt in proportion to the sum of these stimuli. Further explanation is given on page 217. (CSF = cerebrospinal fluid; IX = glossopharyngeal nerve; $\dot{V}/\dot{Q}$ = ventilation/perfusion ratio)

17.6 Causes of breathlessness

System	Acute dyspnoea	Chronic exertional dyspnoea
Cardiovascular	Acute pulmonary oedema*	Chronic heart failure* Myocardial ischaemia (angina equivalent)
Respiratory	Acute severe asthma* Acute exacerbation of COPD* Pneumothorax* Bacterial and viral pneumonias* Pulmonary embolus* Acute respiratory distress syndrome Inhaled foreign body (especially in children) Lobar collapse Laryngeal oedema (anaphylaxis)	COPD* Chronic asthma* Lung cancer Interstitial lung disease (sarcoidosis, fibrosing alveolitis, extrinsic allergic alveolitis, pneumoconiosis) Chronic pulmonary thromboembolism Lymphangitis carcinomatosis (may cause intolerable breathlessness) Large pleural effusion(s)
Others	Metabolic acidosis (diabetic ketoacidosis, lactic acidosis, uraemia, aspirin overdose, ethylene glycol poisoning) Psychogenic hyperventilation (anxiety- or panic-related)	Severe anaemia Obesity Deconditioning

*Denotes a common cause.
(COPD = chronic obstructive pulmonary disease)

Orthopnoea is common in COPD, as well as in heart disease, because airflow obstruction is made worse by cranial displacement of the diaphragm by the abdominal contents when recumbent, so many patients choose to sleep propped up. Orthopnoea it is not a useful differentiating symptom unless there is a clear history of previous angina or infarction to suggest cardiac disease.

How much can you do on a good day?

Noting 'breathless on exertion' is not enough; the approximate distance the patient can walk on the level should be documented, along with capacity to climb inclines or stairs. Variability within and between days is a hallmark of asthma; in mild asthma, the patient may be free of symptoms and signs when well. Gradual, progressive loss of exercise capacity over months and years, with consistent disability over days, is typical of COPD. When asthma is suspected, the degree of variability can be detected by home peak flow monitoring.

Relentless, progressive breathlessness that is also present at rest, often accompanied by a dry cough, suggests interstitial lung disease. Impaired left ventricular function can also cause chronic exertional breathlessness, cough and wheeze. A history of angina, hypertension or myocardial infarction raises the possibility of a cardiac cause. This may be confirmed by a displaced apex beat, a raised jugular venous pressure (JVP) and cardiac murmurs (although these signs can occur in severe hypoxic lung disease with fluid retention). The CXR may show cardiomegaly, and an ECG and echocardiogram may provide evidence of left ventricular disease. Measurement of an ABG may help, as, in the absence of an intracardiac shunt or pulmonary oedema, the PaO_2 in cardiac disease is normal and the $PaCO_2$ is low or normal.

Did you have breathing problems in childhood or at school?

When present, a history of childhood wheeze increases the likelihood of asthma, although this history may be absent in late-onset asthma. A history of other atopic disease also increases the likelihood of asthma.

Do you have other symptoms along with your breathlessness?

Digital or perioral paraesthesiae and a feeling that 'I cannot get a deep enough breath in' are typical features of breathing pattern disorder, but this cannot be diagnosed until other potential causes have been excluded. Breathing pattern disorders rarely disturb sleep, can occur at rest and may be provoked by anxiety or stress. Additional symptoms include lightheadedness, central chest discomfort and occasionally carpopedal spasm due to acute respiratory alkalosis. These alarming symptoms may provoke further anxiety and exacerbate hyperventilation. The Nijmegen questionnaire (see further information) can be used to score some of the typical symptoms of breathing pattern disorders (Box 17.7). Arterial blood gases show normal (or high) PO_2, low PCO_2 and alkalosis.

17.7 Features suggesting psychogenic hyperventilation

- 'Inability to take a deep breath'
- Frequent sighing/erratic ventilation at rest
- Short breath-holding time in the absence of severe respiratory disease
- Difficulty in performing and/or inconsistent spirometry measures
- High score (over 26) on Nijmegen questionnaire
- Induction of symptoms during submaximal hyperventilation
- Resting end-tidal $CO_2 < 4.5\%$
- Associated digital and/or perioral paraesthesiae

Pleuritic chest pain in a patient with chronic breathlessness, particularly if it occurs in more than one site over time, should raise suspicion of thromboembolic disease, which can occasionally present as chronic breathlessness with no other specific features and should always be considered before a diagnosis of breathing pattern disorder is made.

Morning headache is an important symptom in patients with breathlessness, as it may signal the onset of carbon dioxide retention and chronic respiratory failure. This is particularly significant in patients with musculoskeletal or neuromuscular disease impairing respiratory function, such as kyphoscoliosis, muscular dystrophy or motor neuron disease.

Acute severe breathlessness

This is one of the most common and dramatic medical emergencies. Although respiratory causes are common, it can result from cardiac disease, metabolic disease or poisoning causing acidosis, or from psychogenic causes. The approach to patients with acute severe breathlessness is covered on page 217.

Chest pain

Chest pain can result from cardiac, respiratory, oesophageal or musculoskeletal disorders. The approach to this common symptom is covered on page 215.

Finger clubbing

Finger clubbing describes painless swelling of the soft tissues of the terminal phalanges, causing increased longitudinal and lateral convexity of the nail (Fig. 17.10). Upward displacement of the proximal nail margin causes the anteroposterior diameter of the finger at that point to exceed that at the distal interphalangeal joint. It also removes the normal hyponychial angle between the proximal part of the nail and the adjoining skin. Clubbing usually affects the fingers symmetrically and commonly also involves the

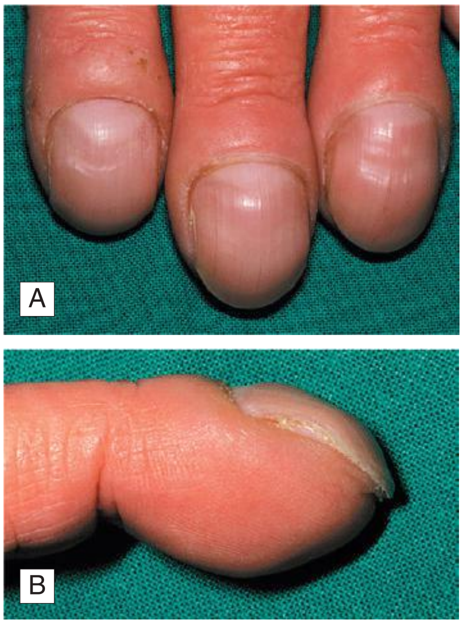


Fig. 17.10 Finger clubbing. **A** Anterior view. **B** Lateral view. *From Douglas G, Nicol F, Robertson C. Macleod's clinical examination. 13th ed. Edinburgh: Churchill Livingstone, Elsevier Ltd; 2013.*

toes but can be unilateral if caused by a proximal vascular condition such as an arteriovenous shunt for dialysis. Although clubbing is usually idiopathic, it can be associated with suppurative or malignant lung conditions (Box 17.8). Clubbing may recede if the underlying condition resolves, for example after successful lung transplantation for cystic fibrosis.

Haemoptysis

Coughing up blood is an alarming symptom, and patients nearly always seek medical advice. Care should be taken to establish that it is true haemoptysis and not haematemesis, or gum or nose bleeding. Haemoptysis must always be assumed to have a serious cause until this is excluded (Box 17.9).

Many episodes of haemoptysis remain unexplained, even after full investigation, and are likely to be due to simple bronchial infection. A history of repeated small haemoptysis, or blood-streaking of sputum, is highly suggestive of lung cancer. Fever, night sweats and weight loss suggest tuberculosis. Pneumococcal pneumonia often causes 'rusty'-coloured sputum but can cause frank haemoptysis, as can all suppurative respiratory infections. Lung abscess, bronchiectasis and intracavitary mycetoma can cause catastrophic bronchial haemorrhage. Finally, pulmonary thromboembolism is a common cause of haemoptysis and should always be considered.

Physical examination may reveal additional clues. Finger clubbing suggests lung cancer or bronchiectasis; other signs of malignancy, such as cachexia, hepatomegaly and lymphadenopathy, may also be observed. Fever, pleural rub and signs of consolidation occur in pneumonia or pulmonary infarction; a minority of patients with pulmonary infarction also have unilateral leg swelling or pain suggestive of deep venous thrombosis. Rashes, haematuria and digital infarcts point to an underlying systemic disease such as a vasculitis, which may cause haemoptysis.

Management

In severe acute haemoptysis the patient should be nursed upright (or on the side of the bleeding, if this is known), given high-flow oxygen and resuscitated as required. Bronchoscopy in the acute phase is difficult and often merely shows blood throughout the bronchial tree. Infusions of the antifibrinolytic agent tranexamic acid or the vasopressin receptor agonist terlipressin may help to limit bleeding, but evidence of efficacy is limited. If radiology shows an obvious central cause, then rigid bronchoscopy under general anaesthesia may allow intervention to stop bleeding; however, the source often cannot be visualised. Intubation with a divided endotracheal tube may allow protected ventilation of the unaffected lung to stabilise the patient. Bronchial arteriography and embolisation (Fig. 17.11), or even emergency surgery, can be life-saving in the acute situation.

17.8 Differential diagnosis of finger clubbing

Congenital or familial (5%–10%)

Acquired

Thoracic (~80%)

- Chronic suppurative conditions:
  - Pulmonary tuberculosis
  - Bronchiectasis
  - Lung abscess
  - Empyema
  - Cystic fibrosis
- Tumours:
  - Lung cancer
  - Mesothelioma
  - Fibroma
- Pulmonary fibrosis

Cardiovascular

- Cyanotic congenital heart disease
- Infective endocarditis
- Arteriovenous shunts and aneurysms

Gastrointestinal

- Cirrhosis
- Inflammatory bowel disease
- Coeliac disease

Others

- Thyrotoxicosis (thyroid acropachy)
- Primary hypertrophic osteoarthropathy

17.9 Causes of haemoptysis

Bronchial disease

- Cancer*
- Bronchiectasis*
- Acute bronchitis*
- Bronchial adenoma
- Foreign body

Parenchymal disease

- Tuberculosis*
- Suppurative pneumonia
- Parasites (e.g. hydatid disease, flukes)
- Lung abscess
- Trauma
- Actinomycosis
- Mycetoma

Pulmonary vascular disease

- Pulmonary infarction*
- Goodpasture syndrome
- ANCA-associated vasculitis
- Idiopathic pulmonary haemosiderosis

Cardiovascular disease

- Acute left ventricular failure*
- Mitral stenosis
- Aortic aneurysm

Blood disorders

- Leukaemia
- Haemophilia
- Anticoagulants

---

*Denotes a common cause.

In the vast majority of cases, however, the haemoptysis itself is not life-threatening, and the following series of investigations should be performed:

- CXR – this may provide evidence of a localised lesion such as tumour, pneumonia, mycetoma or tuberculosis.
- Full blood count (FBC) and clotting screen – this may show anaemia or evidence of a bleeding disorder.
- CTPA – this may show underlying pulmonary thromboembolic disease or alternative causes not seen on the CXR, such as pulmonary arteriovenous malformation and small or hidden tumours.
- Bronchoscopic biopsy (after acute bleeding has settled) if the CT scan suggests an abnormality that needs biopsy.

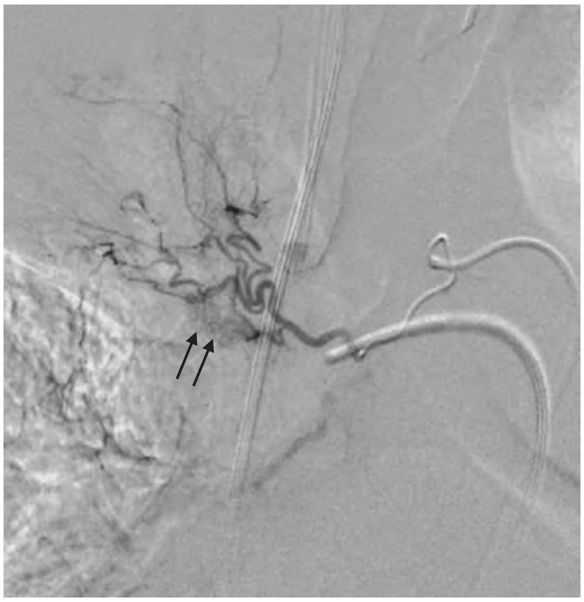

Fig. 17.11 Bronchial artery angiography. Right bronchial artery arteriogram in a patient with major haemoptysis secondary to vasculitis, demonstrating increased vascularity and a contrast blush (arrows) in the right upper lobe, in keeping with active bleeding. The bleeding vessel was successfully embolised.

Incidental pulmonary nodule

A pulmonary nodule may be defined as a well or poorly circumscribed, approximately rounded structure that appears on imaging as a focal opacity less than 3 cm in diameter that is surrounded by aerated lung. The term 'incidental pulmonary nodule' is used to describe the finding of a pulmonary nodule on CT scanning where the imaging has been performed for a reason other than to detect a nodule. Detecting of such nodules has become increasingly common with the increased use of CT scanning (Fig. 17.12). Such nodules must not be ignored until a treatable condition has been excluded or stability has been demonstrated for at least 2 years.

The list of potential causes of pulmonary nodules is extensive, and most are benign (Box 17.10). Features on a CT scan consistent with a benign lesion include being less than 5 mm in diameter or less than 80 mm^3 in volume; diffuse, central, laminated or popcorn calcification; or the presence of macroscopic fat. In addition, perifissural lymph nodes and subpleural nodules with a lentiform or triangular shape do not require any further investigation.

In cases where a benign lesion cannot be confidently assumed, further assessment depends on both the appearance of the nodule and the clinical context (Box 17.11). These assessments may be aided by the use of computer-assisted prediction algorithms (Fig. 17.13A).

A variety of diagnostic approaches may be considered, including bronchoscopy, percutaneous needle biopsy, FDG PET, interval CT scanning or surgical resection of the lesion. Pulmonary nodules are invariably beyond the vision of the bronchoscope and, with the notable exception of chronic pulmonary infections such as tuberculosis, the yield from blind washings is low. If the nodule is favourably located and of sufficient size, percutaneous needle biopsy under ultrasound or CT guidance may be employed. The procedural risk of pneumothorax is approximately 15% and around 7% require intercostal drainage, so this should be contemplated only in individuals with an FEV1 of more than 35% of predicted. Haemorrhage into the lung or pleural space, air embolism and tumour seeding are rare but recognised complications.

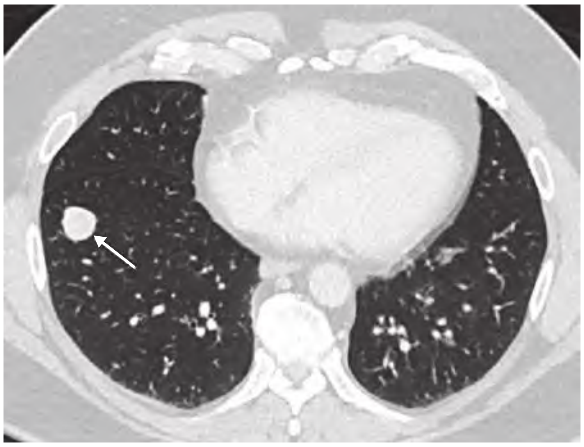

Fig. 17.12 Thoracic CT scan showing a solitary pulmonary nodule identified within the lower lobe of the right lung (arrow).

i 17.10 Causes of pulmonary nodules

Common causes

- Lung cancer
- Single metastasis
- Localised pneumonia
- Lung abscess
- Tuberculoma
- Pulmonary infarct

Uncommon causes

- Benign tumour
- Lymphoma
- Arteriovenous malformation
- Hydatid cyst
- Bronchogenic cyst
- Rheumatoid nodule
- Granulomatosis with polyangiitis (GPA)
- Pulmonary sequestration
- Pulmonary haematoma
- 'Pseudotumour' – fluid collection in a fissure
- Aspergilloma (usually surrounded by air crescent)
- *Cryptococcus*
- *Aspergillus* nodule

Imaging with PET-CT can provide useful information about nodules of 1 cm in diameter or more. The presence of high metabolic activity is strongly suggestive of malignancy, while an inactive 'cold' nodule suggests benign disease. However, high FDG uptake is a marker of glucose metabolism, not malignancy, and PET-CT has significant limitations in regions with high endemic rates of infectious or granulomatous disease. False-negative results may occur with neuroendocrine tumours and minimally invasive lepidic adenocarcinoma. Detection of neuroendocrine tumours may be improved by the use of ^{68}Ga-DOTATOC in place of FDG.

If the nodule is small and inaccessible, interval CT scanning may be employed. A repeat CT scan with volumetric analysis at 3 months will reliably detect growth in larger nodules and may also demonstrate resolution. Further interval scans may be arranged depending on the clinical context (Fig. 17.13B). Particular care must be taken with sub-solid nodules, particularly if further imaging demonstrates the development of a new solid component, as these may represent a pre-malignant or an early invasive form of adenocarcinoma.

Nodules with a high clinical suspicion for malignancy despite benign or indeterminate biopsies may merit proceeding straight to surgical resection, as this represents the best chance of curative therapy for lung cancer. It is important for the logic underlying this approach to be discussed with the patient, mentioning the consideration of having a frozen section taken of the lesion intraoperatively and the possibility that a benign lesion may be resected if there is a doubt about the diagnosis.

Where the probability of cancer is low, the potential risk of further scanning must be considered. Subsequent scans often detect further nodules, increase the risk of false-positive findings and lead to unnecessary patient anxiety while exposing the individual to increased radiation.

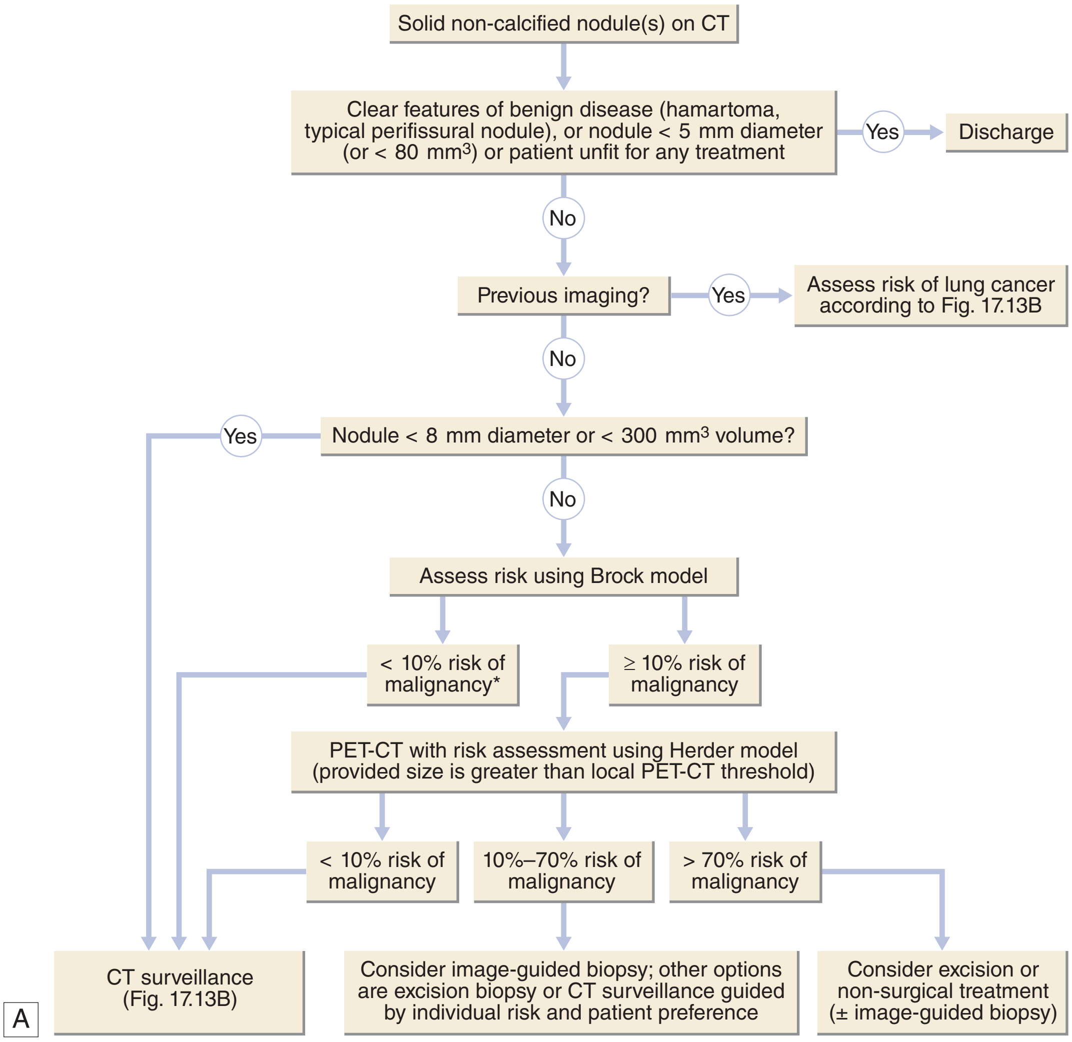
Pleural effusion

The accumulation of serous fluid within the pleural space is termed pleural effusion. Accumulations of pus, blood and chyle are termed empyema,

17.11 Clinical and radiographic features distinguishing benign from malignant nodules*

Feature	Risk of malignancy	Feature	Risk of malignancy
Characteristics of nodule		**Characteristics of patient**	
Size	Nearly all > 3 cm but fewer than 1% < 4 mm are malignant	Age	Increases with age and is uncommon below age of 40
Margin	Usually smooth in benign lesions Spiculated suggests malignancy	Smoking history	Increases in proportion to duration and amount smoked
Calcification or fat	Laminated or central deposition of calcification suggests granuloma 'Popcorn' pattern suggests hamartoma Fat may suggest hamartoma or lipoid granuloma	Other	Increased by history of lung cancer in first-degree relative and by exposure to asbestos, silica, uranium and radon
Location	70% of lung cancers occur in upper lobes Benign lesions are equally distributed throughout upper and lower lobes		

*Linear or sheet-like lung opacities are unlikely to represent neoplasms and do not require follow-up. Some nodular opacities may be sufficiently typical of scarring for follow-up not to be warranted.
Adapted from MacMahon H, Austin JH, Gamsu G, et al. Guidelines for management of small pulmonary nodules detected on CT scans: a statement from the Fleischner Society. Radiology 2005;237:395–400.



Solid non-calcified nodule(s) on CT
Clear features of benign disease (hamartoma, typical perifissural nodule), or nodule < 5 mm diameter (or < 80 mm³) or patient unfit for any treatment

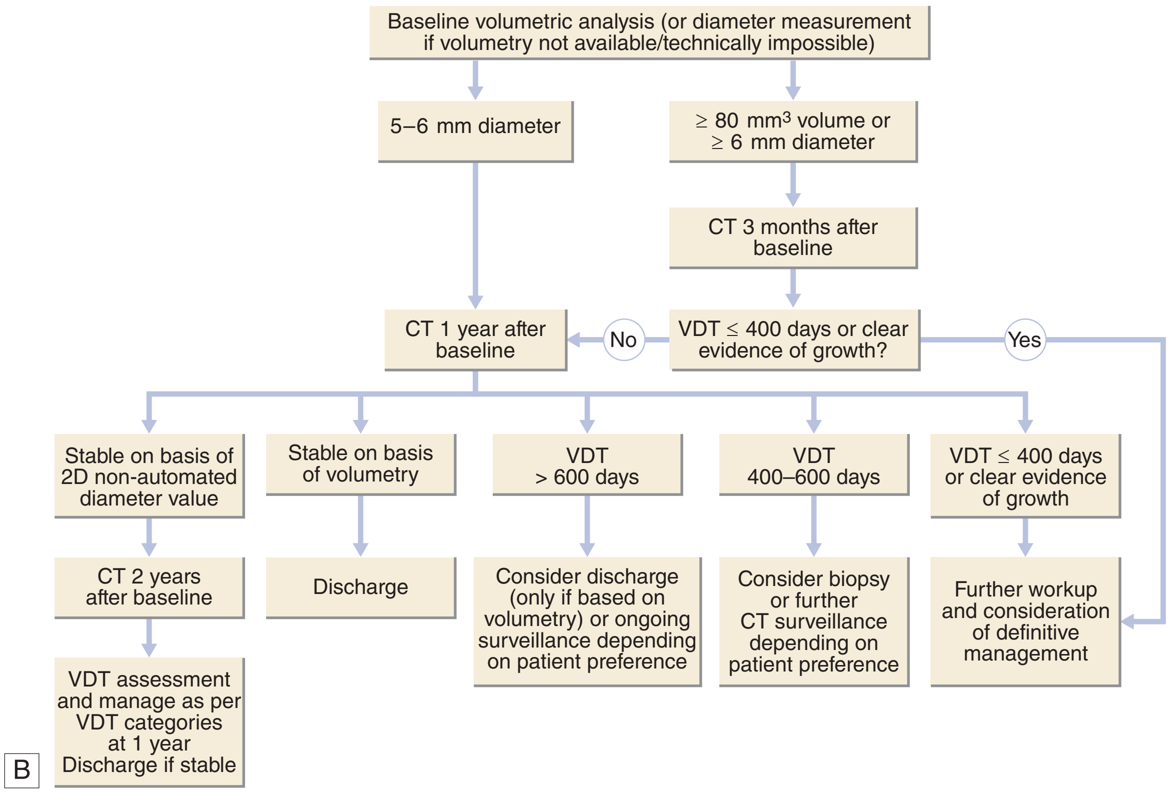
Consider excision or non-surgical treatment (± image-guided biopsy)

Fig. 17.13 Recommendations on the assessment of a solid pulmonary nodule. A Initial approach to solid pulmonary nodules. The Brock model is an online calculator that can also be downloaded as an app (https://brocku.ca/lung-cancer-risk-calculator). The model integrates data on age, sex, family history of cancer, the presence of emphysema, nodule size, nodule type, nodule position, nodule count and speculation, and calculates the probability that a nodule will become malignant within a 2- to 4-year follow-up period. The Herder model uses a similar approach (see further information). *Consider positron emission tomography–computed tomography (PET-CT) for larger nodules in young patients with low risk by Brock score, as this score was developed in a screening cohort (50–75 years) and so performance in younger patients is unproven.



Baseline volumetric analysis (or diameter measurement if volumetry not available/technically impossible)
5–6 mm diameter
≥ 80 mm³ volume or ≥ 6 mm diameter
CT 3 months after baseline
CT 1 year after baseline
No
VDT ≤ 400 days or clear evidence of growth?
Yes
Stable on basis of 2D non-automated diameter value
Stable on basis of volumetry
VDT > 600 days
VDT 400–600 days
VDT ≤ 400 days or clear evidence of growth
CT 2 years after baseline
Discharge
Consider discharge (only if based on volumetry) or ongoing surveillance depending on patient preference
Consider biopsy or further CT surveillance depending on patient preference
Further workup and consideration of definitive management
VDT assessment and manage as per VDT categories at 1 year Discharge if stable
B

haemothorax and chylothorax, respectively. In general, pleural fluid accumulates because of either increased hydrostatic pressure or decreased osmotic pressure ('transudative' effusion, as seen in cardiac, liver or renal failure), or from increased microvascular pressure due to disease of the pleura or injury in the adjacent lung ('exudative' effusion). The causes of the majority of pleural effusions (Boxes 17.12 and 17.13) can be identified by a thorough history, examination and relevant investigations.

Clinical assessment

Symptoms (pain on inspiration and coughing) and signs of pleurisy, such as a pleural rub, often precede the development of an effusion, especially in patients with underlying pneumonia, pulmonary infarction or connective tissue disease. When breathlessness is the only symptom, however, the onset may be insidious, depending on the size and rate of accumulation. The physical signs are detailed on page 519.

Investigations

Radiological investigations

The classical appearance of pleural fluid on the erect PA CXR is of a curved shadow at the lung base, blunting the costophrenic angle and ascending towards the axilla. Fluid appears to track up the lateral chest wall. In fact, fluid surrounds the whole lung at this level but casts a radiological shadow only where the X-ray beam passes tangentially across the fluid against the lateral chest wall. Around 200 mL of fluid is required in order for it to be detectable on a PA CXR. Previous scarring or adhesions in the pleural space can cause localised effusions. Pleural fluid localised below the lower lobe (sub-pulmonary effusion) simulates an elevated hemidiaphragm. Pleural fluid localised within an oblique fissure may produce a rounded opacity that may be mistaken for a tumour.

Ultrasound is more accurate than plain CXR for determining the presence of fluid. A clear hypoechoic space is consistent with a transudate and the presence of moving, floating densities suggests an exudate. The presence of septation most likely indicates an evolving empyema or resolving haemothorax. CT scanning is indicated where there is concern for malignant disease or loculation is suspected.

17.12 Causes of pleural effusion

Common causes

- Pneumonia ('parapneumonic effusion')
- Tuberculosis
- Pulmonary infarction*
- Malignant disease
- Cardiac failure*
- Subdiaphragmatic disorders (subphrenic abscess, and pancreatic disease)

Uncommon causes

- Hypoproteinaemia* (nephrotic syndrome, liver failure, malnutrition)
- Connective tissue diseases* (particularly systemic lupus erythematosus and rheumatoid arthritis)
- Post-myocardial infarction syndrome
- Acute rheumatic fever
- Meigs syndrome (ovarian tumour plus pleural effusion)
- Myxoedema*
- Uraemia*
- Asbestos-related benign pleural effusion

*May cause bilateral effusions.

Pleural aspiration and biopsy

In some conditions, such as left ventricular failure, it is not necessary to sample fluid unless atypical features are present; in these circumstances, treatment should be administered and the effusion re-evaluated. In most other circumstances, however, diagnostic sampling is required. Simple aspiration provides information on the colour and texture of fluid and these alone may immediately suggest an empyema or chylothorax. The presence of blood is consistent with pulmonary infarction or malignancy but may result from a traumatic tap. Biochemical analysis allows classification into transudate or exudate (Box 17.14). Cytological examination can characterise

17.13 Pleural effusion: main causes and clinical features

Cause	Appearance of fluid	Type of fluid	Predominant cells in fluid	Other diagnostic features
Tuberculosis	Serous, usually amber-coloured	Exudate	Lymphocytes (occasionally polymorphs)	Positive tuberculin test Isolation of *Mycobacterium tuberculosis* from pleural fluid (20%) Positive pleural biopsy (80%) Raised adenosine deaminase
Malignant disease	Serous, often blood-stained	Exudate	Serosal cells and lymphocytes Often clumps of malignant cells	Positive pleural biopsy (40%) Evidence of malignancy elsewhere
Cardiac failure	Serous, straw-coloured	Transudate	Few serosal cells	Other signs of cardiac failure Response to diuretics
Pulmonary infarction	Serous or blood-stained	Exudate (rarely transudate)	Red blood cells Eosinophils	Evidence of pulmonary infarction Obvious source of embolism Factors predisposing to venous thrombosis
Rheumatoid arthritis	Serous Turbid if chronic	Exudate	Lymphocytes (occasionally polymorphs)	Positive: rheumatoid factor and anti-cyclic citrullinated peptide (anti-CCP) antibodies Cholesterol in chronic effusion; very low glucose in pleural fluid
Systemic lupus erythematosus (SLE)	Serous	Exudate	Lymphocytes and serosal cells	Other signs of SLE Antinuclear factor and anti-double stranded DNA positive
Acute pancreatitis	Serous or blood-stained	Exudate	No cells predominate	Higher amylase in pleural fluid than in serum
Obstruction of thoracic duct	Milky	Chyle	None	Chylomicrons

17.14 Light's criteria for distinguishing pleural transudate from exudate

Exudate is likely if one or more of the following criteria are met:

- Pleural fluid protein:serum protein ratio > 0.5
- Pleural fluid LDH:serum LDH ratio > 0.6
- Pleural fluid LDH > two-thirds of the upper limit of normal serum LDH

(LDH = lactate dehydrogenase)

the presence of inflammatory or malignant cells. Microbiological staining can detect bacteria and mycobacteria. If a diagnosis of tuberculosis is being considered, adenosine deaminase (ADA) should be measured (see p. 559). A low pH suggests infection but may also occur in rheumatoid arthritis, ruptured oesophagus or advanced malignancy. Ultrasound- or CT-guided pleural biopsy provides tissue for pathological and microbiological analysis. Where necessary, video-assisted thoracoscopy allows visualisation of the pleura and direct guidance of a biopsy.

Management

Therapeutic aspiration may be required to palliate breathlessness, but removing more than 1.5 L at a time is associated with a small risk of re-expansion pulmonary oedema. An effusion should never be completely drained before establishing a diagnosis, as biopsy may be precluded until further fluid accumulates. Treatment of an underlying cause such as heart failure, pneumonia, pulmonary embolism or subphrenic abscess will often be followed by resolution of the effusion. The management of pleural effusion in pneumonia, tuberculosis and malignancy is dealt with below.

Empyema

An empyema is a collection of pus within the pleural space. Microscopically, neutrophil leucocytes are present in large numbers, and bacteria may be identified on Gram stain. An empyema may involve the whole pleural space or only part of it ('loculated' or 'encysted' empyema) and is usually unilateral. It is usually secondary to infection in a neighbouring structure, usually the lung, most commonly due to the bacterial pneumonia or tuberculosis. Over 40% of patients with community-acquired pneumonia develop an associated pleural effusion ('parapneumonic' effusion) and about 15% of these become secondarily infected. Other causes are infection of a haemothorax following trauma or surgery, oesophageal rupture and rupture of a subphrenic abscess through the diaphragm.

Macroscopically, the pleural surfaces are covered with an inflammatory exudate. The pus can be under considerable pressure. Inadequate treatment can result in rupture into a bronchus, causing a bronchopleural fistula and pyopneumothorax, or tracking through the chest wall forming a subcutaneous abscess or sinus ('empyema necessitans').

Clinical assessment

An empyema should be suspected in patients with pulmonary infection if there is severe pleuritic chest pain or persisting or recurrent pyrexia despite appropriate antimicrobial treatment. In other cases, the primary infection may be so mild that it passes unrecognised and the first definite clinical features are due to the empyema itself. Once an empyema has developed, systemic features are prominent (Box 17.15).

Investigations

The appearances on CXR may be indistinguishable from those of pleural effusion, although pleural adhesions may confine the empyema to form a 'D'-shaped shadow against the inside of the chest wall (Fig. 17.14). When air is present as well as pus (pyopneumothorax), a horizontal 'fluid level' marks the air/liquid interface. Ultrasound can show the position of the fluid, the extent of pleural thickening and whether fluid is in a single collection or multiloculated, containing fibrin and debris (Fig. 17.15). Imaging with CT provides information on the pleura, underlying lung parenchyma and patency of the major bronchi. Ultrasound or CT can be used to identify the optimal site for aspiration, which is best performed using a wide-bore needle. If the fluid is thick and turbid pus, empyema is confirmed. Other features suggesting empyema are a fluid glucose of less than 3.3 mmol/L (60 mg/dL), lactate dehydrogenase (LDH) of more than 1000 IU/L or a fluid pH of less than 7.2. However, pH measurement should be avoided if pus is thick, as it damages blood gas analysers. Bacterial culture may be negative if antibiotics have already been given.

i 17.15 Clinical features of empyema

Systemic features

- Pyrexia, usually high and remittent
- Rigors, sweating, malaise and weight loss
- Polymorphonuclear leucocytosis, high C-reactive protein

Local features

- Pleural pain; breathlessness; cough and sputum, usually because of underlying lung disease; copious purulent sputum if empyema ruptures into a bronchus (bronchopleural fistula)
- Clinical signs of pleural effusion

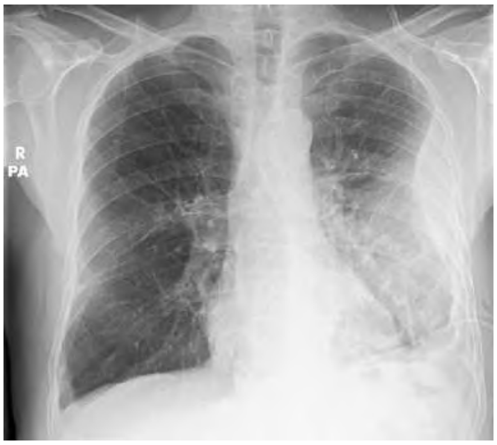

Fig. 17.14 Chest X-ray appearances of empyema. The 'D'-shaped shadow in the left mid-zone is consistent with an empyema. In this case, an intercostal chest drain has been inserted but the loculated collection of pus remains.

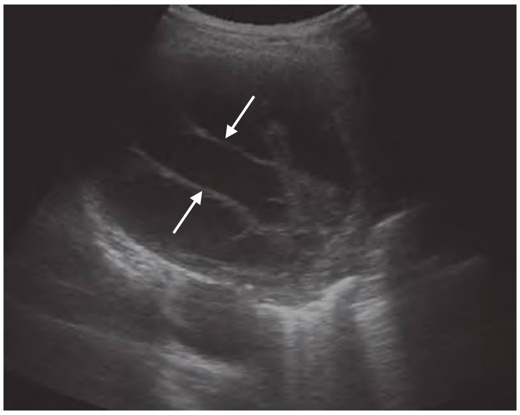

Fig. 17.15 Pleural ultrasound showing septation (arrows) in the pleural fluid. Septations are thin, strand-like structures that can be seen within infected or malignant pleural fluid. *Courtesy of Dr P. Sivasothy, Department of Respiratory Medicine, Addenbrooke's Hospital, Cambridge.*

The distinction between tuberculous and non-tuberculous disease can be difficult and may require pleural biopsy, histology and microbiological tests.

Management

An empyema will heal only if infection is eradicated and the empyema space is obliterated, allowing apposition of the visceral and parietal pleural layers. This can only occur if all the pus is removed from the pleural space. When the pus is sufficiently thin, this is most easily achieved by the insertion of a wide-bore intercostal tube into the most dependent part of the empyema space. If the initial aspirate reveals turbid fluid or frank pus, or if loculations are seen on ultrasound, the tube should be put on suction (–5 to –10 cmH$_2$O) and flushed regularly with 20 mL normal saline. Antibiotics should not be started until they are deemed clinically necessary, and ideally not until a sample has been taken and the causative organism identified. If an organism is identified, the narrowest spectrum antibiotic that will cover that organism should be used. If not, empirical antibiotic treatment with intravenous co-amoxiclav 1.2 g 3 times daily or cefuroxime 1.5 g twice daily plus metronidazole 500 mg 3 times daily should be used. Antibiotics should be continued until the infection has resolved and inflammatory markers have normalised, usually after about 2–4 weeks. There is no consensus on the optimum duration of intravenous vs. oral antibiotics. The use of intrapleural fibrinolytics in combination with DNase may be of benefit in selected situations.

An empyema can be successfully treated with a combination of antibiotics and pleural drainage, but delays can result in a failure of these therapies and a need for surgical intervention to clear the empyema cavity of pus and break down any adhesions. Surgical 'decortication' of the lung may also be required if gross thickening of the visceral pleura is preventing re-expansion of the lung. Surgery is also necessary if a bronchopleural fistula or empyema necessitans develops.

Respiratory failure

The term 'respiratory failure' is used when pulmonary gas exchange fails to maintain normal arterial oxygen and carbon dioxide levels. Its classification into types I and II is defined by the absence or presence of hypercapnia (raised $PaCO_2$).

Pathophysiology

When disease impairs ventilation of part of a lung, such as in asthma or pneumonia, perfusion of that region results in hypoxic and CO$_2$-laden blood entering the pulmonary veins. Increased ventilation of neighbouring regions of normal lung can increase CO$_2$ excretion, correcting arterial CO$_2$ to normal, but cannot augment oxygen uptake because the haemoglobin flowing through these normal regions is already fully saturated. Admixture of blood from the under-ventilated and normal regions thus results in hypoxia with normocapnia, which is called 'type I respiratory failure'. Diseases causing this include all those that impair ventilation locally with sparing of other regions (Box 17.16).

Arterial hypoxia with hypercapnia (type II respiratory failure) is seen in conditions that cause generalised, severe ventilation–perfusion mismatch, leaving insufficient normal lung to correct $PaCO_2$, or any disease that reduces total ventilation. The latter includes not just diseases of the lung but also disorders affecting any part of the neuromuscular mechanism of ventilation (see Box 17.16). Acute type II respiratory failure is an emergency requiring immediate intervention. It is useful to distinguish between patients with high ventilatory drive (rapid respiratory rate and accessory muscle recruitment) who cannot move sufficient air, and those with reduced or inadequate respiratory effort.

Management of acute respiratory failure

Prompt diagnosis and management of the underlying cause is crucial. In type I respiratory failure, oxygen should be administered and titrated to maintain a normal arterial oxygen saturation (SaO_2), which will usually relieve hypoxia by increasing the alveolar PO_2 in poorly ventilated lung units. Occasionally, however, mechanical ventilation may be needed to relieve hypoxia in severe pneumonia.

If inspiratory stridor is present, then an upper or large airway issue should be considered. This can include acute upper airway obstruction, foreign body inhalation or laryngeal obstruction (angioedema, carcinoma or vocal cord paralysis). Depending on the cause, the Heimlich manoeuvre, immediate intubation or emergency tracheostomy may be required.

More commonly, the problem is within the lungs, with severe generalised bronchial obstruction from COPD or asthma, acute respiratory distress syndrome (ARDS) or tension pneumothorax. Oxygen should be administered to maintain the SaO_2 within the target range of 94%–98%, or 88%–92% for those patients at risk of type II respiratory failure,

17.16 Interpretation of blood gas abnormalities in respiratory failure

	Type I		Type II	
	Hypoxia (PaO_2 < 8.0 kPa (60 mmHg))		Hypoxia (PaO_2 < 8.0 kPa (60 mmHg))	
	Normal or low $PaCO_2$ (≤ 6 kPa (45 mmHg))		Raised $PaCO_2$ (> 6 kPa (45 mmHg))	
	Acute	**Chronic**	**Acute**	**Chronic**
H^+	↔	↔	↑	↔ or ↑
Bicarbonate	↔	↔	↔	↑
Causes	Acute asthma Pulmonary oedema Pneumonia Lobar collapse Pneumothorax Pulmonary embolus ARDS	COPD Lung fibrosis Lymphangitic carcinomatosis Right-to-left shunts	Acute severe asthma Acute exacerbation of COPD Upper airway obstruction Acute neuropathies/paralysis Narcotic drugs Primary alveolar hypoventilation Flail chest injury	COPD Sleep apnoea Kyphoscoliosis Myopathies/muscular dystrophy Ankylosing spondylitis

(ARDS = acute respiratory distress syndrome; COPD = chronic obstructive pulmonary disease)

pending a rapid examination of the respiratory system and measurement of arterial blood gases. Patients with the trachea deviated away from a silent and hyper-resonant hemithorax are likely to have tension pneumothorax, and air should be aspirated from the pleural space and a chest drain inserted as soon as possible. Patients with generalised wheeze, scanty breath sounds bilaterally or a history of asthma or COPD should be treated with salbutamol 2.5 mg nebulised with oxygen, repeated until bronchospasm is relieved. Failure to respond to initial treatment, declining conscious level and worsening respiratory acidosis (pH < 7.35), $PaCO_2$ > 6.6 kPa) on blood gases are all indications that supported ventilation is required.

A small proportion of patients with severe chronic lung disease and type II respiratory failure develop abnormal tolerance to raised $PaCO_2$ and may become dependent on hypoxic drive to breathe. In these patients only, lower concentrations of oxygen (24%–28% by Venturi mask) should be used to avoid precipitating worsening respiratory depression (see below). In all cases, regular monitoring of arterial blood gases is important to assess progress.

Patients with acute type II respiratory failure may be suffering from sedative poisoning, CO_2 narcosis or a primary failure of neurological drive as the result of an intracerebral haemorrhage or head injury. History from a witness may be invaluable in defining the underlying cause. Reversal of opiate overdose with opiate antagonists like naloxone is usually successful but should not delay intubation and supported mechanical ventilation if necessary.

Chronic and acute on chronic type II respiratory failure

The most common cause of chronic type II respiratory failure is severe COPD. Although $PaCO_2$ may be persistently raised, there is no persisting acidaemia because the kidneys retain bicarbonate, maintaining arterial pH in the normal range. This compensated pattern, which may also occur in chronic neuromuscular disease, kyphoscoliosis or other end-stage respiratory diseases, is maintained until there is an acute illness (see Box 17.16), such as an exacerbation of COPD, which can precipitate an episode of acute on chronic respiratory failure, with acidaemia and initial respiratory distress followed by drowsiness and eventually coma. These patients have lost their chemosensitivity to elevated $PaCO_2$, and so they may paradoxically depend on hypoxia for respiratory drive and are at risk of respiratory depression if given high concentrations of oxygen. This can occur during ambulance transfers or in emergency departments. Moreover, in contrast to acute severe asthma, some patients with acute on chronic type II respiratory failure due to COPD may not appear distressed, despite being critically ill with severe hypoxaemia, hypercapnia and acidaemia. While the physical signs of CO_2 retention (delirium, flapping tremor, bounding pulses and so on) can be helpful if present, they may not be, so measurement of arterial blood gases is mandatory in the assessment of initial severity and response to treatment.

Management

The principal aims of treatment in acute on chronic type II respiratory failure are to achieve a safe PaO_2 (> 7.0 kPa (52 mmHg)) without increasing $PaCO_2$ and acidosis, while identifying and treating the precipitating condition. In these patients, it is not necessary to achieve a normal PaO_2; even a small increase will greatly improve tissue oxygen delivery, since their PaO_2 values are often on the steep part of the oxygen dissociation curve (see Fig. 10.12). The risks of worsening hypercapnia and coma must be balanced against those of severe hypoxaemia, which include potentially fatal arrhythmias and hypoxic brain damage. Immediate treatment is shown in Box 17.17. Patients who are conscious and have adequate respiratory drive may benefit from non-invasive ventilation (NIV), which has been shown to reduce mortality and the requirement for intubation, and shorten hospital stay in acidotic exacerbations of COPD. Patients who are drowsy and have low respiratory drive require an urgent decision regarding intubation and ventilation, as this is likely to be the only effective treatment, even though weaning off the ventilator may be difficult in severe disease. The decision is challenging, and important factors to consider include patient wishes, presence of a potentially remediable precipitating condition, prior functional capacity and quality of life. The various types of non-invasive (via a face or nasal mask) or invasive (via an endotracheal tube) ventilation are detailed on page 244. Respiratory stimulant drugs, such as doxapram, have been superseded by non-invasive or invasive ventilation.

Non-invasive ventilation for chronic respiratory failure

Non-invasive ventilation (NIV) which can be delivered in the patient's home is of significant benefit in the long-term treatment of respiratory failure due to spinal deformity, neuromuscular disease and central alveolar hypoventilation. Some patients with advanced lung diseases, such as COPD and cystic fibrosis, also benefit from NIV for respiratory failure. In these conditions, type II respiratory failure can develop slowly and insidiously. Morning headache (due to elevated $PaCO_2$) and fatigue are common symptoms but, in many cases, the diagnosis is revealed only by sleep studies or morning blood gas analysis. In the initial stages, ventilation is insufficient for metabolic needs only during sleep, when there is a physiological decline in ventilatory drive. Over time, however, CO_2 retention becomes chronic, with renal compensation of acidosis. Treatment by home-based NIV overnight is often sufficient to restore the daytime PCO_2 to normal and to relieve fatigue and headache. In advanced disease, daytime NIV may also be required.

Lung transplantation

Lung transplantation is an established treatment for carefully selected patients with advanced lung disease unresponsive to medical treatment (Box 17.18). The major factor limiting the availability of lung transplantation is the shortage of donor lungs, although techniques such as ex vivo lung perfusion are increasing the potential pool of donor organs.

Single-lung transplantation may be used for selected patients with advanced emphysema or lung fibrosis. This is contraindicated in patients with chronic bilateral pulmonary infection, such as cystic fibrosis and bronchiectasis, because the transplanted lung is vulnerable to cross-infection in the context of post-transplant immunosuppression, and for these individuals bilateral lung transplantation is the standard procedure. Combined heart–lung transplantation is still occasionally needed for patients with advanced congenital heart disease, such as Eisenmenger syndrome, and is preferred by some surgeons for the treatment of primary pulmonary hypertension unresponsive to medical therapy.

The prognosis following lung transplantation is improving steadily with modern immunosuppressive drugs: According to the International Society for Heart and Lung Transplantation, median survival for double lung transplantation is 7.8 years. Rejection and chronic lung allograft dysfunction (CLAD) continues to afflict some lung transplant recipients.

Corticosteroids are used to manage acute rejection, but drugs that inhibit cell-mediated immunity specifically, such as ciclosporin, mycophenolate and tacrolimus, are used to prevent CLAD. Azithromycin, statins and total lymphoid irradiation are employed to treat progressive CLAD, but progressive organ failure remains a significant problem.

17.17 Assessment and management of acute on chronic type II respiratory failure

Initial assessment

Patient may not appear distressed, despite being critically ill

- Conscious level (response to commands, ability to cough)
- CO_2 retention (warm periphery, bounding pulses, flapping tremor)
- Airways obstruction (wheeze, prolonged expiration, hyperinflation, intercostal indrawing, pursed lips)
- Cor pulmonale (peripheral oedema, raised jugular venous pressure, hepatomegaly, ascites)
- Background functional status and quality of life
- Signs of precipitating cause (see Box 17.16)

Investigations

- Arterial blood gases (severity of hypoxaemia, hypercapnia, acidaemia, bicarbonate)
- CXR

Management

- Maintenance of airway
- Treatment of specific precipitating cause
- Frequent physiotherapy ± pharyngeal suction
- Nebulised bronchodilators
- Controlled oxygen therapy:
  Start with 24% Venturi mask
  Aim for a $PaO_2 > 7$ kPa (52 mmHg) (a $PaO_2 < 5$ (37 mmHg) is dangerous)
- Antibiotics if evidence of infection
- Diuretics if evidence of fluid overload

Progress

- If $PaCO_2$ continues to rise or a safe PaO_2 cannot be achieved without severe hypercapnia and acidaemia, mechanical ventilatory support may be required

17.18 Indications for lung transplantation

Parenchymal lung disease

- Cystic fibrosis
- Emphysema
- Pulmonary fibrosis
- Obliterative bronchiolitis
- Langerhans cell histiocytosis
- Lymphangioleiomyomatosis
- Interstitial lung disease

Pulmonary vascular disease

- Primary pulmonary hypertension
- Thromboembolic pulmonary hypertension
- Veno-occlusive disease
- Eisenmenger syndrome

Obstructive pulmonary diseases

Asthma

Asthma is a chronic inflammatory disorder of the airways, in which many cells and cellular elements play a role. Chronic inflammation is associated with airway hyper-responsiveness that leads to recurrent episodes of wheezing, breathlessness, chest tightness and coughing, particularly at night and in the early morning. These episodes are usually associated with widespread but variable airflow obstruction within the lung that is often reversible, either spontaneously or with treatment.

The prevalence of asthma has increased steadily over the latter part of last century. As asthma affects all age groups, it is one of the most common and important long-term respiratory conditions in terms of global years lived with disability (Fig. 17.16).

The development and course of asthma and the response to treatment are influenced by genetic determinants, while the rapid rise in prevalence implies that environmental factors are critically important in the development and expression of the disease. The potential role of indoor and outdoor allergens, microbial exposure, diet, vitamins, breastfeeding, tobacco smoke, air pollution and obesity have been explored, but no clear consensus has emerged.

Pathophysiology

Airway hyper-reactivity (AHR) – the tendency for airways to narrow excessively in response to triggers that have little or no effect in normal individuals – is integral to the diagnosis of asthma and appears to be related, although not exclusively, to airway inflammation (Fig. 17.17). Other factors likely to be important in the behaviour of airway smooth muscle include the degree of airway narrowing and neurogenic mechanisms.

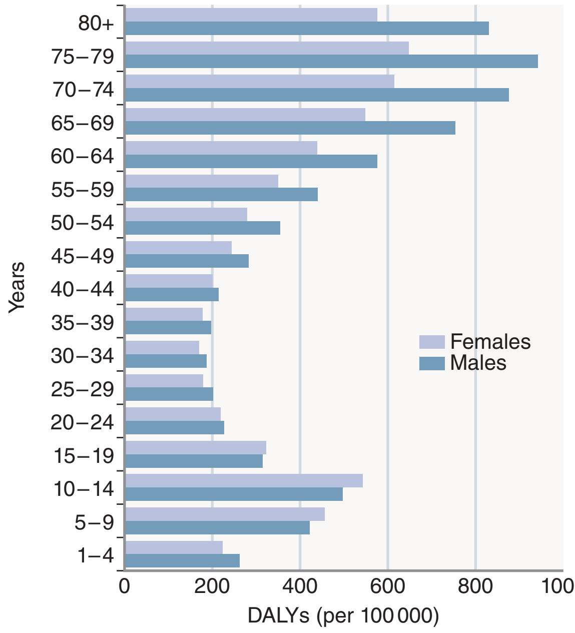

Fig. 17.16 The burden of asthma, measured by disability-adjusted life years (DALYs) per 100 000 population. The burden of asthma is greatest in children approaching adolescence and in old age. The burden is similar in males and females at ages below 30–34, but at older ages the burden is higher in males. *From The Global Asthma Report 2014. Copyright 2014 The Global Asthma Network.*

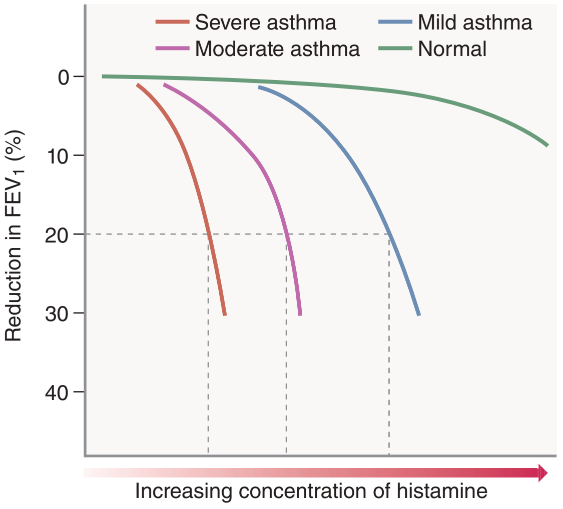

Fig. 17.17 Airway hyper-reactivity in asthma. This is demonstrated by bronchial challenge tests with sequentially increasing concentrations of either histamine, or methacholine or mannitol. The reactivity of the airways is expressed as the concentration or dose of either chemical required to produce a specific decrease (usually 20% or 15%) in the forced expired volume in 1 second (FEV$_1$) (PC$_{20}$ [histamine and methacholine challenges] or PD$_{15}$ [mannitol challenges], respectively). (PC = concentration of drug; PD = dose of drug)

The relationship between atopy (the propensity to produce IgE) and asthma is well established. In many individuals there is a clear relationship between sensitisation and allergen exposure, as demonstrated by skin-prick reactivity or elevated serum-specific IgE. Common examples of allergens include house dust mites, pets, insect pests and fungi. Inhalation of an allergen into the airway is followed by early and late-phase bronchoconstrictor responses (Fig. 17.18). Allergic mechanisms are also implicated in some cases of occupational asthma.

In cases of NSAID-induced asthma, the ingestion of salicylates results in inhibition of the cyclo-oxygenase enzymes, preferentially shunting the metabolism of arachidonic acid through the lipoxygenase pathway with resultant production of pro-inflammatory leukotrienes. In exercise-induced asthma, hyperventilation results in water loss from the pericellular lining fluid of the respiratory mucosa, which, in turn, triggers mediator release. Heat loss from the respiratory mucosa may also be important.

In persistent asthma, a chronic and complex inflammatory response ensues, characterised by an influx of numerous inflammatory cells, the transformation and participation of airway structural cells, and the secretion of an array of cytokines, chemokines and growth factors. Examination of the inflammatory cell profile in induced sputum samples demonstrates that, although asthma is predominantly characterised by airway eosinophilia, neutrophilic inflammation predominates in some patients while in others scant inflammation is observed ('pauci-granulocytic' asthma).

With increasing severity and chronicity of the disease, remodelling of the airway may occur, leading to fibrosis of the airway wall, fixed narrowing of the airway and a reduced response to bronchodilator medication.

Clinical features

Typical symptoms include recurrent episodes of wheezing, chest tightness, breathlessness and cough. Asthma is commonly mistaken for a cold or a persistent chest infection. Classical precipitants include exercise, particularly in cold weather, exposure to airborne allergens or pollutants, and viral upper respiratory tract infections. Wheeze apart, there is often very little to find on examination. An inspection for nasal polyps and eczema should be performed. Rarely, eosinophilic granulomatosis with polyangiitis (EGPA; formerly known as Churg–Strauss syndrome) can present with asthma and should be suspected when a vasculitic rash and systemic symptoms are present.

Patients with mild intermittent asthma are usually asymptomatic between exacerbations. Individuals with persistent asthma report ongoing breathlessness and wheeze, but these are variable, with symptoms fluctuating over the course of one day, or from day to day or month to month.

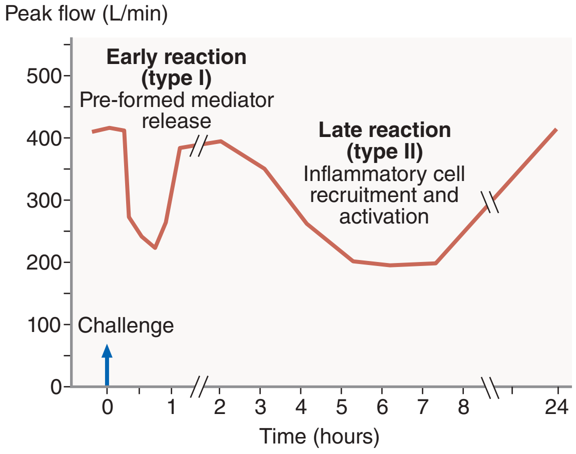

Fig. 17.18 Changes in peak flow following allergen challenge. A similar biphasic response is observed following a variety of different challenges. Occasionally, an isolated late response is seen with no early reaction.

Asthma characteristically displays a diurnal pattern, with symptoms and lung function being worse in the early morning. Particularly when poorly controlled, symptoms such as cough and wheeze disturb sleep. Cough may be the dominant symptom in some patients, and the lack of wheeze or breathlessness may lead to a delay in reaching the diagnosis of so-called cough-variant asthma.

Some patients with asthma have a similar inflammatory response in the upper airway. Careful enquiry should be made as to a history of sinusitis, sinus headache, a blocked or runny nose and loss of sense of smell.

Although the aetiology of asthma is often elusive, an attempt should be made to identify any agents that may contribute to the appearance or aggravation of the condition. Particular enquiry should be made about potential allergens, such as exposure to pets or other animals, pest infestation, exposure to moulds following water damage to a home or building, and any potential occupational agents.

In some circumstances, asthma can be triggered by prescription drugs. Beta-adrenoceptor antagonists (β-blockers), even when administered topically as eye drops, may induce bronchospasm, as may aspirin and other non-steroidal anti-inflammatory drugs (NSAIDs). The classical NSAID-induced asthma patient is female and presents in middle age with asthma, rhinosinusitis and nasal polyps. Aspirin-sensitive patients may also report symptoms following alcohol and foods containing salicylates. Other medications implicated include the oral contraceptive pill, cholinergic agents and prostaglandin F$_{2\alpha}$. Betel nuts contain arecoline, which is structurally similar to methacholine and can aggravate asthma. An important minority of patients develop a particularly severe form of asthma and this appears to be more common in women. Allergic triggers are less important and airway neutrophilia predominates.

Diagnosis

The diagnosis of asthma is predominantly clinical and is based on the combination of history, lung function and other tests, which allows high, intermediate or low probability of asthma to emerge. The approach may vary from patient to patient and may need to be re-evaluated following the introduction of treatment.

Measurement of exhaled nitric oxide (FeNO) where available is a useful first-line test for corticosteroid-naïve patients as a measure of eosinophilic airways inflammation. An elevated FeNO value (adults >50 ppb; children >35 ppb) supports the diagnosis of asthma particularly in the context of blood eosinophilia and suggests that the patient's symptoms are highly likely to respond to corticosteroids.

Supportive evidence is provided by the demonstration of variable airflow obstruction, preferably by using spirometry (Box 17.19) to measure FEV$_1$ and FVC. This identifies the obstructive defect, defines its severity, and provides a baseline for bronchodilator reversibility (Fig. 17.19). If spirometry is not available, a peak flow meter may be used. Symptomatic

17.19 Diagnosis of asthma

Compatible clinical history *plus either/or*:

- Elevated exhaled FeNO
- $FEV_1 \geq 12\%$ (and 200 mL) increase following administration of a bronchodilator/trial of glucocorticoids. Greater confidence is gained if the increase is > 15% and > 400 mL
- > 20% diurnal variation on ≥ 3 days in a week for 2 weeks on PEF diary
- $FEV_1 \geq 15\%$ decrease after 6 mins of exercise
- Positive bronchial hyperreactivity test (mannitol, methacholine or histamine challenge)

(FEV_1 = forced expiratory volume in 1 sec; PEF = peak expiratory flow)

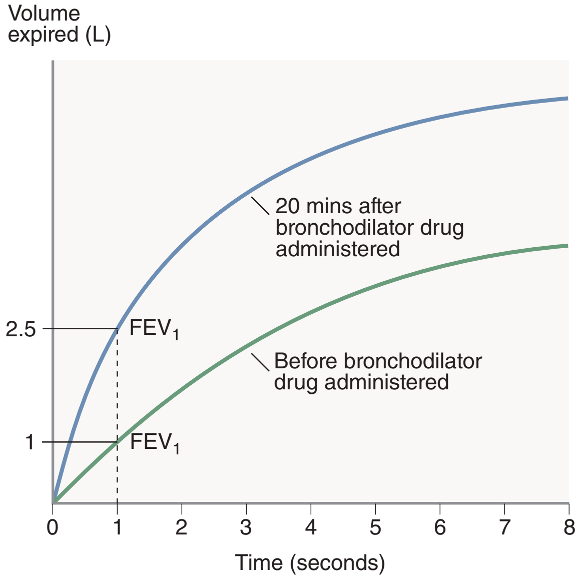

Fig. 17.19 Reversibility test of FEV_1. Forced expiratory manoeuvres before and 20 minutes after inhalation of a β_2-adrenoceptor agonist. Note the increase in forced expiratory volume in 1 second (FEV_1) from 1.0 to 2.5 L.

patients should be instructed to record peak flow readings after rising in the morning and before retiring in the evening. A diurnal variation in PEF of more than 20% (the lowest values typically being recorded in the morning) is considered diagnostic and the magnitude of variability provides some indication of disease severity (Fig. 17.20).

It is not uncommon for patients whose symptoms are suggestive of asthma to have normal lung function. In these circumstances, the demonstration of AHR by challenge tests may be useful to confirm the diagnosis (see Fig. 17.17). AHR has a high negative predictive value but positive results may be seen in other conditions such as COPD, bronchiectasis and cystic fibrosis. Exercise tests are useful when symptoms are predominantly related to exercise (Fig. 17.21).

The diagnosis may be supported by the presence of peripheral blood eosinophilia or atopy demonstrated by skin-prick tests or measurement of total and allergen-specific IgE. The CXR appearances are often normal, but lobar collapse may be seen if mucus occludes a large bronchus and, if accompanied by the presence of flitting infiltrates, may suggest that asthma has been complicated by allergic bronchopulmonary aspergillosis.

Management

Setting goals

Asthma is a chronic condition but may be controlled with appropriate treatment in the majority of patients. The goal of treatment should be to obtain and maintain complete control (Box 17.20), but aims may be modified according to the circumstances and the patient. Unfortunately, surveys consistently demonstrate that the majority of individuals with asthma report suboptimal control, perhaps reflecting the poor expectations of patients and their clinicians. Pregnancy raises specific issues in asthma management, which are shown in Box 17.21.

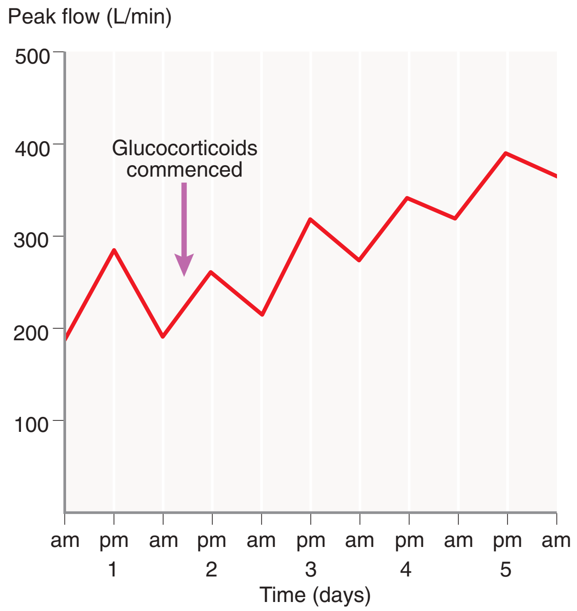

Fig. 17.20 Serial recordings of peak expiratory flow (PEF) in a patient with asthma. Note the sharp overnight fall (morning dip) and subsequent rise during the day. Following the introduction of glucocorticoids, there is an improvement in PEF rate and reduction of morning dipping.

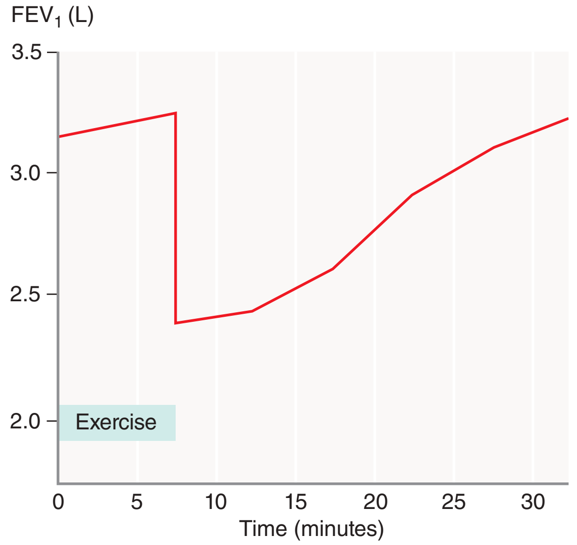

Fig. 17.21 Exercise-induced asthma. Serial recordings of forced expiratory volume in 1 second (FEV_1) in a patient with bronchial asthma before and after 6 minutes of strenuous exercise. Note initial rise on completion of exercise, followed by sudden fall and gradual recovery. Adequate warm-up exercise or pre-treatment with a β_2-adrenoceptor agonist, nedocromil sodium or a leukotriene antagonist can protect against exercise-induced symptoms.

Self-management

Patients should be supported to take responsibility for managing their own disease. A key aspect of self-management is education, ensuring that the patient understands the relationship between symptoms and inflammation, key symptoms such as nocturnal waking and the indications for medication. The patient must also be able to use the prescribed inhalers and understand the importance of concordance with therapy. A variety of different inhaled devices are available, and the choice of device should be guided by patient preference and competence in its use. The

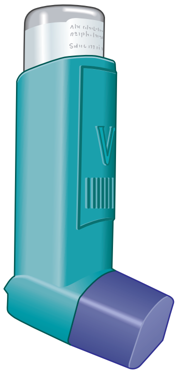
17.20 Levels of asthma control

Characteristic	Controlled	Partially controlled	Uncontrolled
Daytime symptoms	None or less than twice a week	Twice a week or more	≥ 3 features of partly controlled asthma present in any week
Limitation of activities	None	Any	
Nocturnal symptoms	None	Any	
Need for rescue (reliever) treatment	None or less than twice a week	Twice a week or more	
Lung function (PEV or FEV$_1$)	Normal	$<$ 80% predicted or personal best (if known) on any day	
Exacerbation	None	One or more episodes annually	One in any week

(FEV$_1$ = forced expiratory volume in 1 sec; PEF = peak expiratory flow)

17.21 Asthma in pregnancy

- **Clinical course**: women with well-controlled asthma usually have good pregnancy outcomes. Pregnancy in women with asthma can precipitate a worsening or an improvement in asthma control.
- **Labour and delivery**: 90% have no symptoms.
- **Safety data**: good for β_2-agonists, inhaled glucocorticoids, theophyllines, and oral prednisolone.
- **Oral leukotriene receptor antagonists**: no evidence that these harm the fetus and they should not be stopped in women who have previously demonstrated significant improvement in asthma control prior to pregnancy.
- **Glucocorticoids**: women on maintenance prednisolone $>$ 7.5 mg/day should receive hydrocortisone 100 mg 3–4 times daily during labour.
- **Biological therapies**: safety data insufficient to recommend use.
- **Prostaglandin $F_{2\alpha}$**: may induce bronchospasm and should be used with extreme caution.
- **Breastfeeding**: use medications as normal.
- **Uncontrolled asthma**: associated with maternal (hyperemesis, hypertension, pre-eclampsia, vaginal haemorrhage, complicated labour) and fetal (intrauterine growth restriction and low birth weight, preterm birth, increased perinatal mortality, neonatal hypoxia) complications.



- Remove the cap and shake the inhaler
- Breathe out gently and place the mouthpiece into the mouth
- Incline the head backwards to minimise oropharyngeal deposition
- Simultaneously, begin a slow deep inspiration, depress the canister and continue to inhale
- Hold the breath for 10 seconds

Fig. 17.22 How to use a metered-dose inhaler.

metered-dose inhaler remains the most widely prescribed (Fig. 17.22). Written action plans can be helpful in developing self-management skills, and they can be guided by symptoms or PEF.

Avoidance of aggravating factors

This is particularly important in the management of occupational asthma but may also be relevant in atopic patients, for whom removing or reducing exposure to relevant antigens may effect improvement. House dust mite exposure may be reduced by replacing carpets with floorboards and using mite-impermeable bedding, but these measures have not demonstrated major improvements in asthma control. Many patients are sensitised to several ubiquitous aeroallergens, making avoidance strategies impracticable. Measures to reduce fungal exposure may be applicable in specific circumstances, and medications known to precipitate or aggravate asthma should be avoided. Smoking cessation is particularly important, as smoking not only encourages sensitisation but also induces a relative corticosteroid resistance in the airway.

Pharmacological management of asthma

Prior to any step up in a patient's asthma therapy, they should be reviewed to ensure that aggravating factors have been addressed, concordance assessed and inhaler technique checked.

Once asthma control is established, the dose of inhaled corticosteroid (ICS) should be titrated to the lowest dose at which effective control is maintained. The Global Initiative for Asthma now recommend this titration is done via control and reliever therapy (Track 1) or a fixed dose approach (Track 2), summarised in Figure 17.23. This can be achieved due to the rapid bronchodilator effect of formoterol compared to other long-acting β-agonists (LABAs).

Track 1: Use of ICS-formoterol as controller and reliever

Step 1–2: As needed only low-dose ICS-formoterol The initial therapy for a patient diagnosed with asthma is a low dose of ICS-formoterol. The starting dose would be budesonide/formoterol (200 µg/6 µg) used as and when required for relief of symptoms.

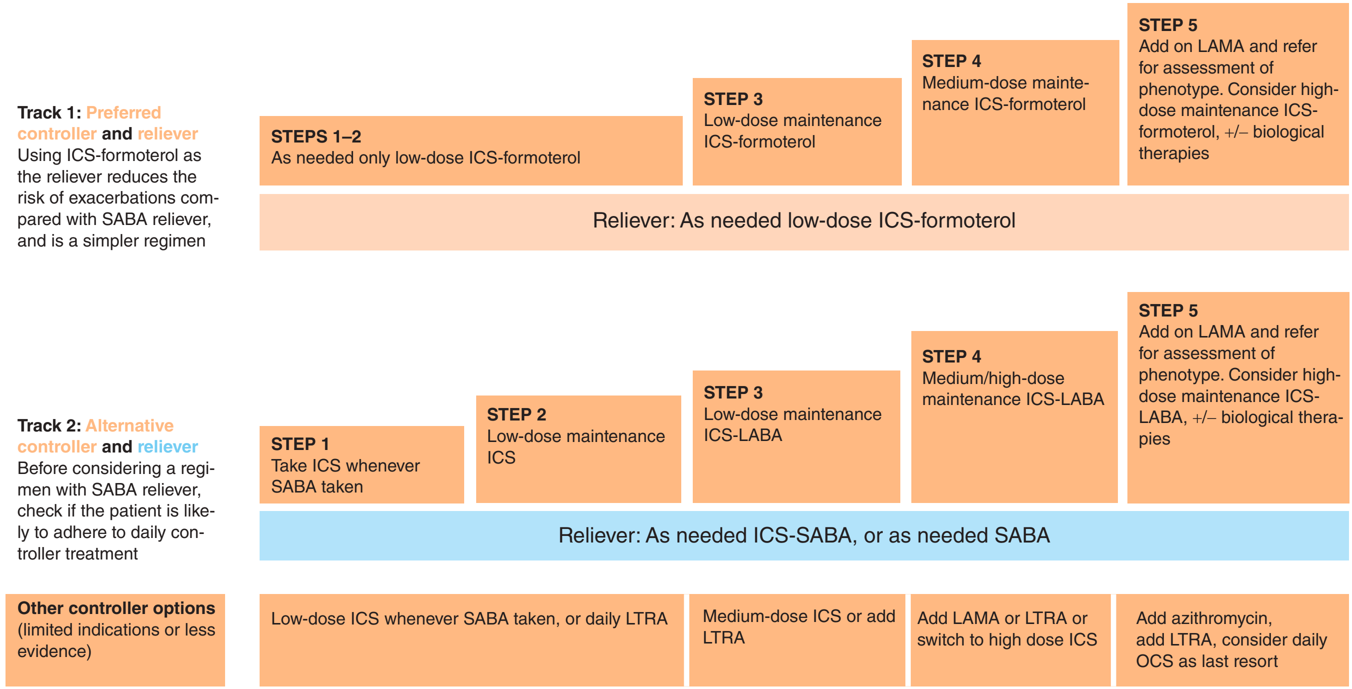
Step 3: Low-dose ICS-formoterol as controller and reliever If the patient is not controlled at step 1–2, then regular low-dose ICS-formoterol should be started regularly at a dose of one inhalation twice daily, and one inhalation in response to symptoms.

Step 4: Medium-dose ICS-formoterol as controller and reliever Ongoing poor control of asthma at step 3 should result in an increase of the regular ICS-formoterol to a medium dose by increasing the regular inhalation to twice daily, with ongoing use of one inhalation as required to relieve symptoms.

Track 2: Separate controller and reliever

Step 1: As needed ICS Patients should take their inhaled corticosteroid whenever they take their short-acting β-agonist (SABA) reliever. This can be achieved by using separate inhalers or a combined SABA/ICS inhaler.

Step 2: Low-dose maintenance ICS If control is not adequate at step 1, then patients should be started on a low dose of regular ICS. For adults, a starting dose equivalent to beclometasone dipropionate (BDP) 400 µg per day is reasonable, although higher doses may be required in smokers.



Track 1: Preferred controller and reliever
Using ICS-formoterol as the reliever reduces the risk of exacerbations compared with SABA reliever, and is a simpler regimen
STEPS 1–2
As needed only low-dose ICS-formoterol
STEP 3
Low-dose maintenance ICS-formoterol
STEP 4
Medium-dose maintenance ICS-formoterol
STEP 5
Add on LAMA and refer for assessment of phenotype. Consider high-dose maintenance ICS-formoterol, +/– biological therapies
Reliever: As needed low-dose ICS-formoterol
Track 2: Alternative controller and reliever
Before considering a regimen with SABA reliever, check if the patient is likely to adhere to daily controller treatment
STEP 1
Take ICS whenever SABA taken
STEP 2
Low-dose maintenance ICS
STEP 3
Low-dose maintenance ICS-LABA
STEP 4
Medium/high-dose maintenance ICS-LABA
STEP 5
Add on LAMA and refer for assessment of phenotype. Consider high-dose maintenance ICS-LABA, +/– biological therapies
Reliever: As needed ICS-SABA, or as needed SABA
Other controller options (limited indications or less evidence)
Low-dose ICS whenever SABA taken, or daily LTRA
Medium-dose ICS or add LTRA
Add LAMA or LTRA or switch to high dose ICS
Add azithromycin, add LTRA, consider daily OCS as last resort

Fig. 17.23 Management approach in adults based on asthma control. (ICS = inhaled corticosteroids; LABA = long-acting β_2-agonist; LAMA = long-acting muscarinic antagonist; LTRA = leukotriene receptor antagonist; OCS = oral corticosteroids; SABA = short-acting β-agonist) *From Global Initiative for Asthma; ginasthma.org.*

Step 3: Low-dose maintenance ICS-LABA If the asthma remains poorly controlled despite regular ICS therapy, then a LABA should be added. This should be done via a combination ICS/LABA inhaler to prevent inadvertent administration of LABA monotherapy and risk of asthma death. An alternative to a LABA at this step would be to add a leukotriene receptor antagonist (LTRA) such as montelukast 10 mg once daily.

Step 4: Medium/high ICS-LABA If asthma control remains poor despite addition of regular low-dose ICS-LABA, then the ICS dose should be titrated up in an effort to gain control of symptoms. It is also important to review the diagnosis and ensure that asthma is the main driver for symptoms. Other strategies at this step would be to consider addition of a long-acting muscarinic agent (LAMA) or an LTRA if not trialled already.

Track 1+2: Step 5: Severe asthma Patients with severe asthma should be considered for trials of high-dose ICS-LABA, LTRA or LAMAs if not already trialled. They should be referred for specialist assessment, phenotyping of their asthma and consideration of biological therapy if indicated.

Biological therapies for severe asthma

There are a number of biological therapies available for patients with severe asthma targeting different inflammatory mediators. These include omalizumab (anti-IgE), benralizumab (anti-IL-5 receptor), mepolizumab (anti-IL-5), reslizumab (anti-IL5), dupilumab (anti-IL-4/IL-13) or tezepelumab (anti-thymic stromal lymphopoietin).

These therapies require detailed specialist assessment and phenotyping of the patient's asthma to determine the optimum therapy (Box 17.22).

Exacerbations of asthma

The course of asthma may be punctuated by exacerbations with increased symptoms, deterioration in lung function, and an increase in airway inflammation. Exacerbations are most commonly precipitated by viral infections, but moulds, pollens (particularly following thunderstorms) and air pollution are also implicated. Most attacks are characterised by a gradual deterioration over several hours to days, but some appear to occur with little or no warning: so-called brittle asthma. An important minority of patients appear to have a blunted perception of airway narrowing and fail to appreciate the early signs of deterioration.

Management of mild to moderate exacerbations

Doubling the dose of inhaled corticosteroids does not prevent an impending exacerbation. Short courses of at least 5 days of 'rescue' corticosteroids (prednisolone 40–50 mg/day) are therefore often required to regain control. Tapering of the corticosteroid dose to withdraw treatment is not necessary, unless it has been given for more than 3 weeks. Indications for 'rescue' courses include:

- symptoms and PEF progressively worsening day by day, with a fall of PEF below 75% of the patient's personal best recording
- onset or worsening of sleep disturbance by asthma
- persistence of morning symptoms until midday
- progressively diminishing response to an inhaled bronchodilator
- symptoms that are sufficiently severe to require treatment with nebulised bronchodilators.

Management of acute severe asthma

The immediate assessment requirements in acute asthma are summarised in Box 17.23. Measurement of PEF is mandatory, unless the patient is too ill to cooperate, and is most easily interpreted when expressed as a percentage of the predicted normal or of the previous best value obtained on optimal treatment (Fig. 17.24). Analysis of an ABG is essential for those patients with life-threatening asthma to determine the $PaCO_2$, a normal or elevated level being a concerning finding. A CXR is not immediately necessary, unless pneumothorax is suspected.

17.22 Biological therapies for severe asthma*

Drug	Mechanism of action	Indication	Criteria for initiation	NICE guidance
Omalizumab	Antibody to IgE	Severe persistent allergic (IgE-mediated) asthma	Four or more courses, or continuous oral corticosteroids in the previous year, and IgE and weight in dosing range	TA278
Mepolizumab	Antibody to IL-5	Severe eosinophilic asthma	Blood eosinophils > 300 cells/μL and 4 courses of oral corticosteroids in the last 12 months or	TA671
Benralizumab	Antibody to IL-5 receptor		Blood eosinophils > 300 cells/μL and continuous oral corticosteroids greater than prednisolone 5 mg/day or	TA565
Reslizumab	Antibody to IL-5		Blood eosinophils > 400 cells/μL and 3 courses of oral corticosteroids in the last 12 months	TA479
Dupilumab	Antibody to IL-4 receptor alpha	Severe asthma with type 2 inflammation	Blood eosinophils > 150 cells/μL, FeNO > 25 ppb, and 4 courses of oral corticosteroids in the last 12 months	TA751
Tezepelumab	Antibody to thymic stromal lymphopoietin	Severe asthma	Three or more courses or maintenance oral corticosteroids in the previous year	TA880

*All biological therapies for severe asthma require assessment and an optimised standard treatment plan. Please see 'Further information' for links to the individual NICE Technology Appraisal documents.
(IgE = immunoglobulin E; IL = interleukin)

17.23 Immediate assessment of acute severe asthma

Acute severe asthma

- PEF 33%–50% predicted (< 200 L/min)
- Heart rate ≥ 110 beats/min
- Respiratory rate ≥ 25 breaths/min
- Inability to complete sentences in 1 breath

Life-threatening features

- PEF < 33% predicted (< 100 L/min)
- SpO_2 < 92% or PaO_2 < 8 kPa (60 mmHg) (especially if being treated with oxygen)
- Normal or raised $PaCO_2$
- Silent chest
- Cyanosis
- Feeble respiratory effort
- Bradycardia or arrhythmias
- Hypotension
- Exhaustion
- Delirium
- Coma

Near-fatal asthma

- Raised $PaCO_2$ and/or requiring mechanical ventilation with raised inflation pressures

(PEF = peak expiratory flow)

Treatment includes the following measures:

- *Oxygen*. Controlled supplemental oxygen should be administered to maintain SaO_2 94%–98%. The presence of a high $PaCO_2$ should not be taken as an indication to reduce oxygen concentration but as a warning sign of a severe or life-threatening attack. Failure to achieve appropriate oxygenation is an indication for assisted ventilation.
- *High doses of inhaled bronchodilators*. Short-acting β_2-agonists such as salbutamol 5 mg nebulised are the agent of choice. If a nebuliser is not available then salbutamol can be administered via multiple doses of a metered dose inhaler (MDI) using a spacer device. Nebulised ipratropium bromide 500 μg can provide additional bronchodilation and should be added if there is a failure to respond to salbutamol or in life-threatening attacks.
- *Systemic corticosteroids*. These reduce the inflammatory response, reduce mortality, subsequent hospital admission and requirement for bronchodilators. They should be administered to all patients with an acute severe attack. They can usually be administered orally as prednisolone but intravenous hydrocortisone may be used in patients who are vomiting or unable to swallow.

There is no evidence base for the use of intravenous fluids but many patients are dehydrated due to high insensible water loss and may benefit. Potassium supplements may be necessary to counteract hypokalaemia caused by repeated doses of β-agonists.

If patients fail to improve or for patients with life-threatening or near-fatal attacks, a number of further options may be considered including intravenous magnesium and intravenous aminophylline, although cardiac monitoring and therapeutic drug level monitoring are recommended with these therapies.

The PEF should be recorded 15–30 minutes after starting therapy and thereafter according to response every 4–6 hours, and pulse oximetry should be monitored to ensure that SaO_2 94%–98% is maintained. Repeat arterial blood gases are necessary if the initial $PaCO_2$ measurements were normal or raised, the PaO_2 was below 8 kPa (60 mmHg) or the patient deteriorates. If the patient fails to respond adequately to these measures, endotracheal intubation and intermittent positive pressure ventilation (IPPV) may be required. Indications for this are shown in Box 17.24.

Prognosis

The outcome from acute severe asthma is generally good, but a considerable number of deaths occur in young people and many are preventable. Failure to recognise the severity of an attack, on the part of either the assessing physician or the patient, contributes to delay in delivering appropriate therapy and under-treatment.

Prior to discharge, patients should be stable on discharge medication (nebulised therapy should be discontinued for at least 24 hours), and the PEF should have reached 75% of predicted or personal best. The acute attack should prompt a review of any trigger factors, the delivery of asthma education, assessment of treatment concordance including inhaler technique, and the provision of a written self-management plan. The patient should be offered an appointment with a general practitioner or asthma nurse within 2 working days of discharge, and follow-up at a specialist hospital clinic within a month.

Chronic obstructive pulmonary disease

Chronic obstructive pulmonary disease (COPD) is defined as a preventable and treatable disease characterised by persistent respiratory symptoms and airflow limitation that is due to airway and/or alveolar abnormalities, usually caused by significant exposure to noxious particles or gases. The spectrum of COPD includes chronic bronchitis and emphysema. Chronic bronchitis is defined as cough and sputum for at least 3 consecutive months in each of 2 consecutive years. Emphysema is abnormal permanent enlargement of the airspaces distal to the terminal bronchioles, accompanied by destruction of their walls. Exacerbations

17.24 Indications for assisted ventilation in acute severe asthma

- Coma
- Respiratory arrest
- Deterioration of arterial blood gas tensions despite optimal therapy:
  PaO_2 < 8 kPa (60 mmHg) and falling
  PaCO_2 > 6 kPa (45 mmHg) and rising
  pH low and falling (H^+ high and rising)
- Exhaustion, delirium, drowsiness

and comorbidities contribute to the overall severity in individual patients. Extrapulmonary effects include weight loss and skeletal muscle dysfunction (see Fig. 17.25). Commonly associated comorbid conditions include cardiovascular disease, cerebrovascular disease, the metabolic syndrome, osteoporosis, depression and lung cancer.

The prevalence of COPD is directly related to the prevalence of risk factors in the community, such as tobacco smoking, coal dust exposure or the use of biomass fuels, and to the age of the population being studied. Risk factors for COPD are shown in Box 17.25. Cigarette smoking represents the most significant risk factor and the magnitude of risk relates to both the amount and duration of smoking. It is unusual to develop COPD with less than 10 pack years (1 pack year = 20 cigarettes daily per year), and not all smokers develop the condition, suggesting that individual host susceptibility factors are important.

Pathophysiology

The pathophysiology of COPD and pulmonary and systemic features are summarised in Figure 17.25. The presence of airflow limitation combined with premature airway closure leads to gas trapping and hyperinflation, adversely affecting pulmonary and chest wall compliance. Pulmonary hyperinflation also results, which flattens the diaphragmatic muscles and leads to an increasingly horizontal alignment of the intercostal muscles, placing the respiratory muscles at a mechanical disadvantage. The work of breathing is therefore markedly increased – first on exercise, when the time for expiration is further shortened, but then, as the disease advances, at rest.

Emphysema may be classified by the pattern of the enlarged airspaces: centriacinar, panacinar and paraseptal (Fig. 17.26). Some individuals develop bullae – permanent air-filled spaces within the lung that are more than 1 cm in diameter. This results in impaired gas exchange and respiratory failure.

Clinical features

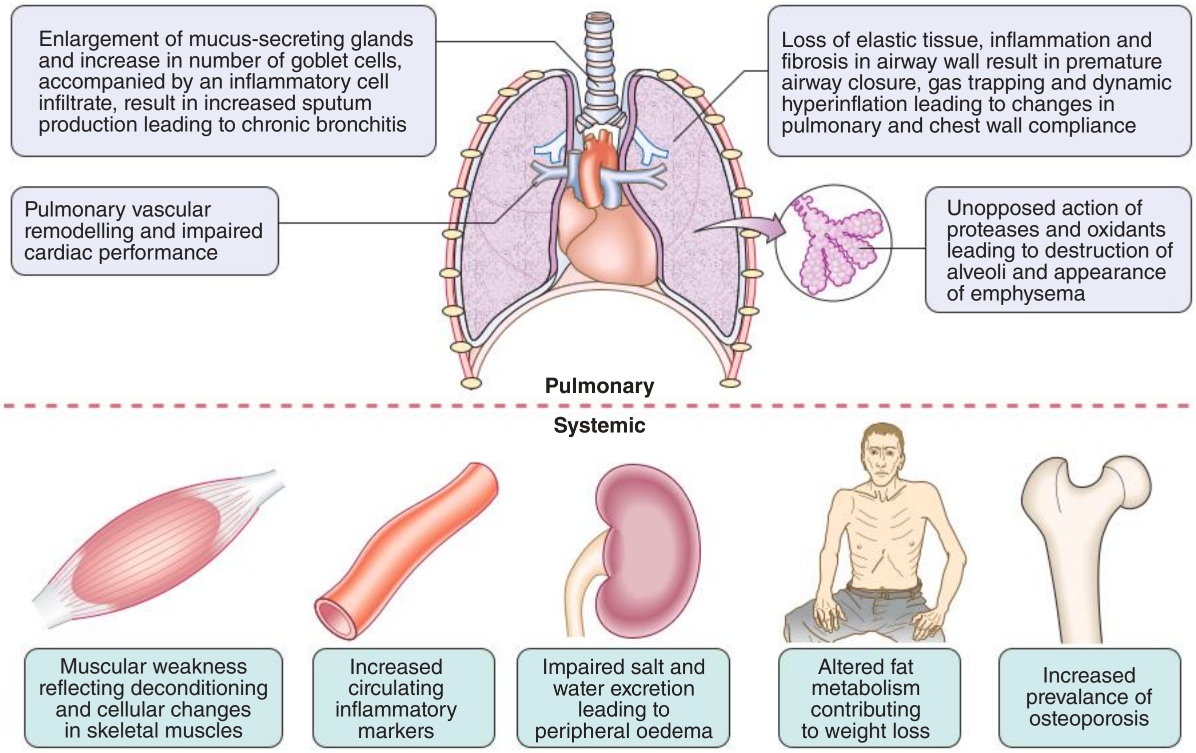
Chronic obstructive pulmonary disease should be suspected in any patient over 40 years old who presents with symptoms of chronic bronchitis and/or breathlessness. Depending on the presentation, important differential diagnoses include asthma, tuberculosis, bronchiectasis and congestive cardiac failure.

Cough and associated sputum production are usually the first symptoms and are often referred to as a ‘smoker’s cough’. Haemoptysis may complicate exacerbations of COPD but should not be attributed to COPD without thorough investigation.

Breathlessness usually prompts presentation to a health professional. The level should be quantified for future reference by documenting what the patient can manage before stopping; scales such as the modified Medical Research Council (mMRC) dyspnoea scale may be useful (Box 17.26). In advanced disease, enquiry should be made as to the presence of oedema (which may be seen for the first time during an exacerbation) and morning headaches (which may suggest hypercapnia).

Physical signs are non-specific, correlate poorly with lung function, and are seldom obvious until the disease is advanced. Breath sounds are typically quiet; crackles may accompany infection but, if persistent, raise the possibility of bronchiectasis. Finger clubbing is not a feature of COPD and should trigger further investigation for lung cancer, pulmonary fibrosis or bronchiectasis. People with advanced COPD may have pitting oedema as a result of right heart failure. Fatigue, anorexia and weight loss may lead to concerns about the development of lung cancer or tuberculosis, but these features are common in patients with severe COPD. Reduced body mass index is of prognostic significance, and depression and anxiety are also common.

Two classical phenotypes have been described: ‘pink puffers’ and ‘blue bloaters’. The former are typically thin and breathless and maintain a normal *Pa*CO_2 until the late stage of disease. The latter develop (or



Enlargement of mucus-secreting glands and increase in number of goblet cells, accompanied by an inflammatory cell infiltrate, result in increased sputum production leading to chronic bronchitis
Loss of elastic tissue, inflammation and fibrosis in airway wall result in premature airway closure, gas trapping and dynamic hyperinflation leading to changes in pulmonary and chest wall compliance
Pulmonary vascular remodelling and impaired cardiac performance
Unopposed action of proteases and oxidants leading to destruction of alveoli and appearance of emphysema
Pulmonary
Systemic
Muscular weakness reflecting deconditioning and cellular changes in skeletal muscles
Increased circulating inflammatory markers
Impaired salt and water excretion leading to peripheral oedema
Altered fat metabolism contributing to weight loss
Increased prevalence of osteoporosis

Fig. 17.25 **The pulmonary and systemic features of chronic obstructive pulmonary disease.**

17.25 Risk factors for development of chronic obstructive pulmonary disease

Environmental factors

- Tobacco smoke: accounts for 95% of cases in the UK
- Indoor air pollution: cooking with biomass fuels in confined areas in low-income countries
- Occupational exposures, such as coal dust, silica and cadmium
- Low birth weight: may reduce maximally attained lung function in young adult life
- Lung growth: childhood infections or maternal smoking may affect growth of lung during childhood, resulting in a lower maximally attained lung function in adult life
- Infections: recurrent infection may accelerate decline in FEV_1; persistence of adenovirus in lung tissue may alter local inflammatory response, predisposing to lung damage; HIV infection is associated with emphysema
- Low socioeconomic status
- Cannabis smoking

Host factors

- Genetic factors: α_1-antitrypsin deficiency; other COPD susceptibility genes are likely to be identified
- Airway hyper-reactivity

(FEV_1 = forced expiratory volume in 1 sec)

tolerate) hypercapnia earlier and may develop oedema and secondary polycythaemia. In practice, these phenotypes often overlap.

Investigations

Although there are no reliable radiographic signs that correlate with the severity of airflow limitation, a CXR is essential to identify alternative diagnoses such as cardiac failure, lung cancer and the presence of bullae. A blood count is useful to exclude anaemia or document polycythaemia, and all patients should be tested for α_1-antitrypsin deficiency.

The diagnosis requires objective demonstration of airflow obstruction by spirometry and is established when the post-bronchodilator FEV_1/FVC is <70% or below the lower limit of normal. The severity of COPD may be defined in relation to the post-bronchodilator FEV_1 (Box 17.27).

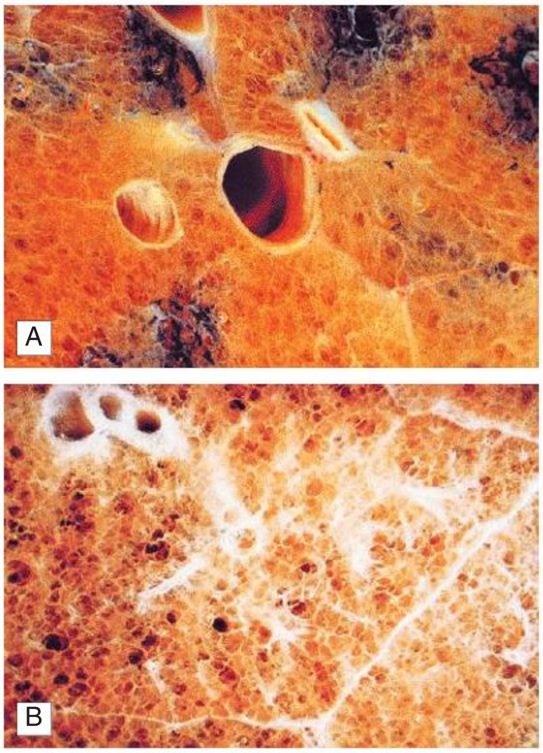


Fig. 17.26 **The pathology of emphysema.** **A** Normal lung. **B** Emphysematous lung, showing gross loss of the normal surface area available for gas exchange. *(B) Courtesy of the British Lung Foundation.*

Measurement of lung volumes provides an assessment of hyperinflation. This is generally performed by helium dilution technique (p. 526); however, in patients with severe COPD, and in particular large bullae, body plethysmography is preferred because the use of helium may under-estimate lung volumes. The presence of emphysema is suggested

17.26 Modified Medical Research Council dyspnoea scale

Grade	Degree of breathlessness related to activities
0	No breathlessness, except with strenuous exercise
1	Breathlessness when hurrying on the level or walking up a slight hill
2	Walks slower than contemporaries on level ground because of breathlessness or has to stop for breath when walking at own pace
3	Stops for breath after walking about 100 m or after a few minutes on level ground
4	Too breathless to leave the house, or breathless when dressing or undressing

17.27 Spirometric classification of COPD severity based on post-bronchodilator FEV_1

		Severity of airflow obstruction post-bronchodilator		
PD FEV_1/FVC	FEV_1% predicted	ATS/ERS (2004)	GOLD (2020)	NICE Clinical Guideline 101 (2010)
<0.7	$\geq 80\%$	Mild	Stage I – mild	Stage I – mild[1]
<0.7	50%–79%	Moderate	Stage II – moderate	Stage II – moderate
<0.7	30%–49%	Severe	Stage III – severe	Stage III – severe
<0.7	$<30\%$	Very severe	Stage IV – very severe	Stage IV – very severe[2]

[1] Mild COPD should not be diagnosed on lung function alone if the patient is asymptomatic.

[2] Or FEV_1 $<50\%$ with respiratory failure.

(ATS/ERS = American Thoracic Society/European Respiratory Society; FEV_1 = forced expiratory volume in 1 sec; GOLD = Global Initiative for Chronic Obstructive Lung Disease; PD = post-bronchodilator)

Adapted from National Institute for Health and Care Excellence (NICE) Guideline NG115, July 2019. Chronic obstructive pulmonary disease in over 16 s: diagnosis and management. www.nice.org.uk/guidance/ng115.

by a low gas transfer. Exercise tests provide an objective assessment of exercise tolerance and provide a baseline on which to judge the response to bronchodilator therapy or rehabilitation programmes; they may also be valuable when assessing prognosis. Pulse oximetry may prompt referral for a domiciliary oxygen assessment if less than 93%.

The assessment of health status by the St George's Respiratory Questionnaire (SGRQ) is commonly used for research. In practice, the COPD Assessment Test and the COPD Control Questionnaire are easier to administer (see further information). HRCT is likely to play an increasing role in the assessment of COPD, as it allows the detection, characterisation and quantification of emphysema (Fig. 17.27) and is more sensitive than the CXR at detecting bullae. HRCT is also used in combination with a ventilation perfusion (VQ) scan to guide lung volume reduction surgery.

Assessment of severity

The severity of COPD has traditionally been defined in relation to the FEV% predicted. However, assessing the impact of COPD on individual patients in terms of the symptoms and limitations in activity that they experience and whether they suffer frequent or significant exacerbations may provide a more clinically relevant assessment and help guide management.

Management

The management of COPD focuses on improving breathlessness, reducing the frequency and severity of exacerbations, and improving health status and prognosis.

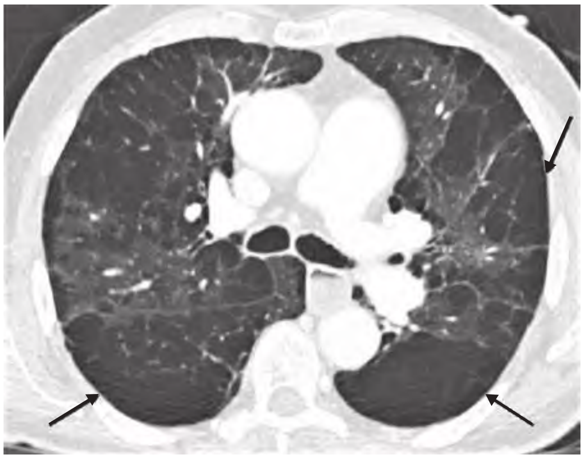

Fig. 17.27 **Emphysema**. High-resolution CT scan demonstrating severe centrilobular emphysema in both upper lobes.

Reducing exposure to noxious particles and gases

Smoking cessation is accompanied by an improvement in lung function and deceleration in the rate of FEV_1 decline compared to persistent smoking (Fig. 17.28), and cessation remains the only strategy that impacts favourably on the natural history of COPD. In regions where the indoor burning of biomass fuels is important, the introduction of non-smoking cooking devices or alternative fuels should be encouraged.

Pulmonary rehabilitation

Exercise should be encouraged at all stages, and patients should be reassured that breathlessness, while distressing, is not dangerous. Multidisciplinary programmes that incorporate physical training, disease education and nutritional counselling reduce symptoms, improve health status and enhance confidence. Most programmes include two to three sessions per week, last between 6 and 12 weeks, and are accompanied by demonstrable and sustained improvements in exercise tolerance and health status.

Bronchodilators

Bronchodilator therapy is central to the management of breathlessness. Choice should be informed by patient preference and inhaler assessment. Short-acting bronchodilators are used as relievers and may be used as sole treatment for patients with very mild disease, but combination longer-acting bronchodilators are preferred. Long-acting β-agonists (LABA) and long-acting muscarinic antagonists (LAMA) are available in single agent or combination inhalers. Combination treatment with LABA and LAMA reduces symptoms and exacerbations and improves FEV_1 compared to monotherapy, so is the treatment of choice for all except those with the very mildest COPD. Nebulised short-acting bronchodilators can be used in those unable to take inhalers. Significant improvements in breathlessness may be reported despite minimal changes in FEV_1, probably reflecting improvements in lung emptying that reduce dynamic hyperinflation and ease the work of breathing. Oral bronchodilator therapy, such as theophylline modified release 200 mg twice daily, is only recommended when other long-acting bronchodilators are not available. Its use is limited by side-effects, unpredictable metabolism and drug interactions; hence the requirement to monitor plasma levels.

Combined inhaled corticosteroids and bronchodilators

Those with frequent exacerbations and/or persistent breathlessness despite long-acting bronchodilators may benefit from inhaled corticosteroids (ICS), in the form of a LABA/LAMA/ICS combination inhaler. These combined therapies improve lung function, reduce the frequency and severity of exacerbations and improve quality of life. However, these advantages may be accompanied by an increased risk of pneumonia, particularly in older people, or recurrence of mycobacterial disease.

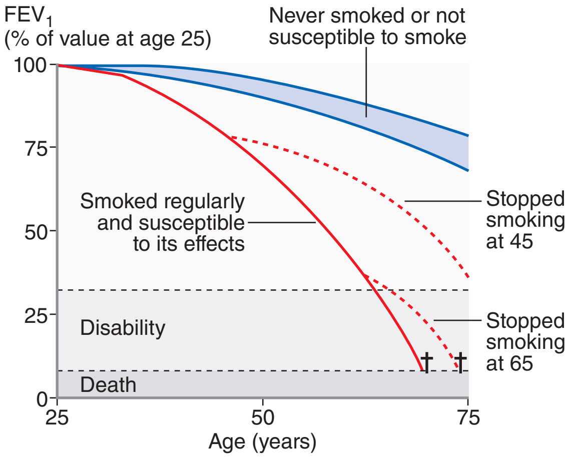

Fig. 17.28 Model of annual decline in FEV$_1$ with accelerated decline in susceptible smokers. When smoking is stopped, subsequent loss is similar to that in healthy non-smokers. (FEV$_1$ = forced expiratory volume in 1 second)

Combination ICS inhalers are likely to reduce the frequency of exacerbations in patients with eosinophilia (>300 cells/μL) and should be used in patients with a history of asthma.

Oral anti-inflammatories

Oral corticosteroids are useful during exacerbations, but maintenance therapy contributes to osteoporosis and impaired skeletal muscle function and should be avoided. The phosphodiesterase-4 inhibitor roflumilast (250 μg once daily for 28 days, then 500 μg once daily) improves lung function and reduces moderate to severe exacerbations in patients with severe or very severe COPD; however, adverse effects including depression and weight loss have negatively impacted on its routine use. Azithromycin 500 mg 3 times weekly works in an anti-inflammatory rather than antimicrobial capacity and can reduce the number of exacerbations, but non-tuberculous mycobacterial infections must first be excluded. Monitoring of liver function tests (LFTs), ECG to assess QTc interval, and hearing is required.

Biological therapies in COPD

Dupilumab is a monoclonal antibody directed against the IL-4 receptor alpha, which inhibits both IL-4 and IL-13 signalling. It is approved for use for patients with COPD and eosinophilia. It can improve lung function and quality of life and reduces exacerbation rates.

Other maintenance measures

Patients with COPD should be offered pneumococcal and respiratory syncytial virus (RSV) vaccination and annual influenza and COVID-19 vaccination. Obesity, poor nutrition, depression and social isolation should be identified and, if possible, addressed. Chest physiotherapy techniques and devices and mucolytic agents ease sputum expectoration and may reduce exacerbations.

Oxygen therapy and home ventilation

Long-term domiciliary oxygen therapy (LTOT) improves survival in selected patients with COPD complicated by severe hypoxaemia (arterial $PaO_2 < 7.3$ kPa (55 mmHg); Box 17.28). It is most conveniently provided by an oxygen concentrator and patients should be instructed to use oxygen for a minimum of 15 hours a day; greater benefits are seen in those who use it for more than 20 hours a day. The aim of therapy is to increase the PaO_2 to at least 8 kPa (60 mmHg) or SaO_2 to at least 90% without causing an unacceptable rise in $PaCO_2$. Ambulatory oxygen therapy should be considered in patients who desaturate on exercise and show objective improvement in exercise capacity and/or dyspnoea with oxygen. Oxygen flow rates should be adjusted to maintain SaO_2 above 90%. Home non-invasive ventilation improves quality of life and prolongs time to readmission in patients with persistent hypercapnia.

i 17.28 Criteria for prescription of long-term oxygen therapy in COPD

- $PaO_2 < 7.3$ kPa (55 mmHg)* irrespective of $PaCO_2$
or
- PaO_2 7.3–8 kPa (55–60 mmHg)* plus pulmonary hypertension, peripheral oedema or polycythaemia (haematocrit > 55%)
- Patient has stopped smoking

*To qualify, blood gases should be measured in clinically stable patients on optimal medical therapy on at least two occasions 3 weeks apart.

Surgical intervention

Bullectomy may be considered when large bullae compress surrounding normal lung tissue. Patients with predominantly upper lobe emphysema, preserved gas transfer and no evidence of pulmonary hypertension may benefit from lung volume reduction surgery (LVRS). This involves resection of peripheral emphysematous lung tissue with the aim of reducing hyperinflation and decreasing the work of breathing. Both bullectomy and LVRS can be performed thoracoscopically, minimising morbidity. Bronchoscopic LVRS involves the use of one-way valves, lung coils or thermal ablation to collapse down areas of ineffective emphysematous lung. This enables the neighbouring areas of healthier lung to expand and work more efficiently. Lung transplantation may benefit carefully selected patients with advanced disease.

Palliative care

Addressing end-of-life needs is an important aspect of care in advanced COPD. Hand-held electric fans and morphine preparations may be used for palliation of breathlessness, and low-dose benzodiazepines may reduce anxiety. Decisions regarding resuscitation and escalation of care should be addressed in advance of critical illness.

Prognosis

The natural history of COPD is variable but it is usually a progressive disease. The prognosis is inversely related to age and directly related to the post-bronchodilator FEV$_1$. Additional poor prognostic indicators include weight loss and pulmonary hypertension. A composite score (the BODE index) comprising the body mass index (B), the degree of airflow obstruction (O), a measurement of dyspnoea (D) and exercise capacity (E) may assist in predicting death from respiratory and other causes (Box 17.29). Respiratory failure, pneumonia, cardiac disease and lung cancer represent common modes of death.

Specific challenges in diagnosis and management of obstructive pulmonary disease in older people are shown in Box 17.30.

Acute exacerbations of COPD

Acute exacerbations of COPD (AECOPD) are characterised by an increase in symptoms and deterioration in lung function and health status. They become more frequent as the disease progresses and are usually triggered by infection or a change in air quality. They may be accompanied by the development of respiratory failure and/or fluid retention and represent an important cause of death.

Many patients can be managed at home with the use of increased bronchodilator therapy, a short course of oral corticosteroids and, if appropriate, antibiotics. The presence of cyanosis, peripheral oedema or an alteration in consciousness should prompt referral to hospital. In other patients, consideration of comorbidity and social circumstances may influence decisions regarding hospital admission.

Oxygen therapy

In patients with an exacerbation of severe COPD, high concentrations of oxygen may cause respiratory depression and worsening acidosis. Controlled oxygen using a Venturi mask at 24% or 28% should be used with the aim of maintaining SaO_2 of 88%–92% or PaO_2 of more than 8 kPa (60 mmHg) without worsening acidosis.

17.29 Calculation of the BODE index

	Points on BODE index			
Variable	**0**	**1**	**2**	**3**
FEV_1	≥ 65	50–64	36–49	≤ 35
Distance walked in 6 mins (m)	≥ 350	250–349	150–249	≤ 149
mMRC dyspnoea scale*	0–1	2	3	4
Body mass index	> 21	≤ 21		
A patient with a BODE index of 0–2 has a mortality rate of 20% at 4 years, whereas a patient with a BODE index of 7–10 has a mortality rate of 82% at 4 years.				

*See Box 17.26.
(BODE – see text; FEV_1 = forced expiratory volume in 1 sec)

17.30 Chronic obstructive pulmonary disease in old age

- **Asthma**: may appear de novo in old age, so airflow obstruction should not always be assumed to be due to COPD.
- **Peak expiratory flow recordings**: older people with poor vision have difficulty reading PEF meters.
- **Perception of bronchoconstriction**: impaired by age, so an older patient's description of symptoms may not be a reliable indicator of severity.
- **Stopping smoking**: the benefits on the rate of loss of lung function decline with age but remain valuable up to the age of 80.
- **Metered-dose inhalers**: many older people cannot use these because of difficulty coordinating and triggering the device. Aids are available, and frequent demonstration and re-instruction in the use of all devices are required.
- **Mortality rates for acute asthma**: higher in old age, partly because patients under-estimate the severity of bronchoconstriction and also develop a lower degree of tachycardia and pulsus paradoxus for the same degree of bronchoconstriction.
- **Treatment decisions**: advanced age in itself is not a barrier to intensive care or mechanical ventilation in an acute episode of asthma or COPD, but this decision may be difficult and should be shared with the patient (if possible), the relatives and the wider medical team.

(COPD = chronic obstructive pulmonary disease; PEF = peak expiratory flow)

Nebulised bronchodilators

Nebulised short-acting β_2-agonists combined with an anticholinergic agent (such as salbutamol 5 mg and ipratropium 500 µg) should be administered routinely. However, the latter is only appropriate if the patient is unable to use their LAMA inhaler. Nebulisers can be driven with oxygen, but due to concern regarding oxygen sensitivity, they are more safely driven by compressed air with supplemental oxygen delivered by nasal cannula.

Oral corticosteroids

Oral prednisolone reduces symptoms and improves lung function. Doses of 30 mg for 5 days are currently recommended but weaning courses are required if the patient has had a recent course of steroids. Prophylaxis against osteoporosis should be considered in patients who receive repeated courses of corticosteroids annually, amounting to an equivalent of > 7.5 mg prednisolone daily for 3 months.

Antibiotic therapy

The role of bacteria in exacerbations remains controversial. There is little evidence for the routine administration of antibiotics. Antibiotic use can be guided by C-reactive protein or procalcitonin to aid antibiotic stewardship. In most cases simple regimens are advised, such as an aminopenicillin, a tetracycline or a macrolide. However, local practice will depend on local guidance and epidemiology.

Non-invasive ventilation

Non-invasive ventilation (NIV) reduces mortality and invasive ventilation rates in patients with an acute exacerbation of COPD complicated by mild to moderate respiratory acidosis (pH < 7.35 and $PaCO_2$ > 6.5 kPa). It should be considered when respiratory acidosis is not corrected within an hour of identification despite optimal medical therapy, including controlled oxygen therapy with a target saturation of 88%–92%. Invasive ventilation should be considered in patients with deteriorating acidosis despite optimal NIV settings, those unable to tolerate or wear the interface and those who cannot protect their airway.

Additional therapy

Exacerbations may be accompanied by the development of peripheral oedema; this usually responds to diuretics. Hospital admission provides a good opportunity to address smoking cessation, mobility and sputum clearance, inhaler technique and concordance, nutrition and swallowing concerns.

Discharge

Discharge from hospital may be contemplated once patients are clinically stable on their usual maintenance medication. Hospital-at-home teams may provide a nebuliser on loan for short-term use, improving discharge rates and providing additional support for the patient.

Asthma–COPD overlap syndrome

Asthma–COPD overlap syndrome (ACOS) is a term used to describe patients with airways disease that have features associated with both asthma and COPD. These patients are usually over the age of 40 years, have a previous history of asthma and have some exertional breathlessness, but variability may be prominent. In terms of lung function testing, these patients have evidence of airflow obstruction which is not fully reversible. The treatment approach is generally to use ICS with long-acting bronchodilators similar to the approach in asthma, rather than to treat with bronchodilators alone. The rationale behind this is related to the importance of ICS in reducing morbidity and mortality in asthma.

Bronchiectasis

Bronchiectasis means abnormal dilatation of the bronchi. Chronic suppurative airway infection with sputum production, progressive scarring and lung damage occur, whatever the underlying cause.

Aetiology and pathology

Bronchiectasis may result from a congenital defect affecting airway ion transport or ciliary function, such as cystic fibrosis (see below), or may be acquired secondary to damage to the airways by a destructive infection, inhaled toxin or foreign body. Common causes of bronchiectasis are shown in Box 17.31. Worldwide, the most important of these is tuberculosis.

Localised bronchiectasis may occur due to the accumulation of pus beyond an obstructing bronchial lesion, such as enlarged tuberculous hilar lymph nodes, a bronchial tumour or an inhaled foreign body.

The bronchiectatic cavities may be lined by granulation tissue, squamous epithelium or normal ciliated epithelium. There may also be inflammatory changes in the deeper layers of the bronchial wall and hypertrophy of the bronchial arteries. Chronic inflammatory and fibrotic changes are usually found in the surrounding lung tissue, causing progressive destruction of the normal lung architecture in advanced cases.

Clinical features

The symptoms of bronchiectasis are shown in Box 17.32. Physical signs on examination of the chest may be unilateral or bilateral. If the bronchiectatic airways do not contain secretions and there is no associated lobar collapse, there are no abnormal physical signs. When there are large amounts of sputum in the bronchiectatic spaces, numerous coarse crackles may be heard over the affected areas. Collapse with retained secretions blocking a proximal bronchus may lead to locally diminished breath sounds, while advanced disease may cause scarring and overlying bronchial breathing. Acute haemoptysis is an important complication of bronchiectasis; management is described on page 530.

17.31 Causes of bronchiectasis

Congenital

- Cystic fibrosis
- Ciliary dysfunction syndromes:
    - Primary ciliary dyskinesia (immotile cilia syndrome)
    - Kartagener syndrome (sinusitis and transposition of the viscera)
- Primary hypogammaglobulinaemia

Acquired: children

- Severe infections in infancy (whooping cough, measles or pneumonia)
- Primary tuberculosis
- Inhaled foreign body

Acquired: adults

- Suppurative pneumonia
- Pulmonary tuberculosis
- Allergic bronchopulmonary aspergillosis complicating asthma
- Bronchial tumours

17.32 Symptoms of bronchiectasis

- **Cough**: chronic, daily, persistent
- **Sputum**: copious, continuously purulent
- **Pleuritic pain**: when infection spreads to involve pleura, or with segmental collapse due to retained secretions
- **Haemoptysis**:
    - Streaks of blood common, larger volumes with exacerbations of infection
    - Massive haemoptysis requiring bronchial artery embolisation sometimes occurs
- **Infective exacerbation**: increased sputum volume with fever, malaise, anorexia
- **Halitosis**: frequently accompanies purulent sputum
- **General debility**: difficulty maintaining weight, anorexia, exertional breathlessness

Investigations

In addition to common respiratory pathogens, sputum culture may identify *Pseudomonas aeruginosa*, *Staphylococcus aureus*, fungi such as *Aspergillus fumigatus* and non-tuberculous mycobacteria.

Mild bronchiectasis may not be apparent on a plain CXR. In advanced disease, thickened airway walls, cystic bronchiectatic spaces and associated areas of pneumonic consolidation or collapse may be visible. CT is much more sensitive and shows thickened, dilated airways (Fig. 17.29).

If the patient is suspected of having a ciliary dysfunction syndrome, a nasal FeNO sample should be taken as a screening test, then consideration of nasal brush biopsy and genetic testing. The nasal biopsies should be assessed for ciliary beat frequency and structural ciliary abnormalities assessed by electron microscopy.

Management

Physiotherapy

Patients should be shown how to perform regular daily physiotherapy to assist the drainage of excess bronchial secretions. This reduces the amount of cough and sputum and prevents recurrent episodes of bronchopulmonary infection. Patients should lie in a position in which the lobe to be drained is uppermost. Deep breathing, followed by forced expiratory manoeuvres (the 'active cycle of breathing' technique), helps to move secretions in the dilated bronchi towards the trachea, from which they can be cleared by vigorous coughing. Devices that increase airway pressure either by a constant amount (positive expiratory pressure mask) or in an oscillatory manner (flutter valve) aid sputum clearance in some patients, and a variety of techniques should be tried to find the one that suits the individual. The optimum duration and frequency of physiotherapy depend on the amount of sputum, but 5–10 minutes twice daily is a minimum for most patients.

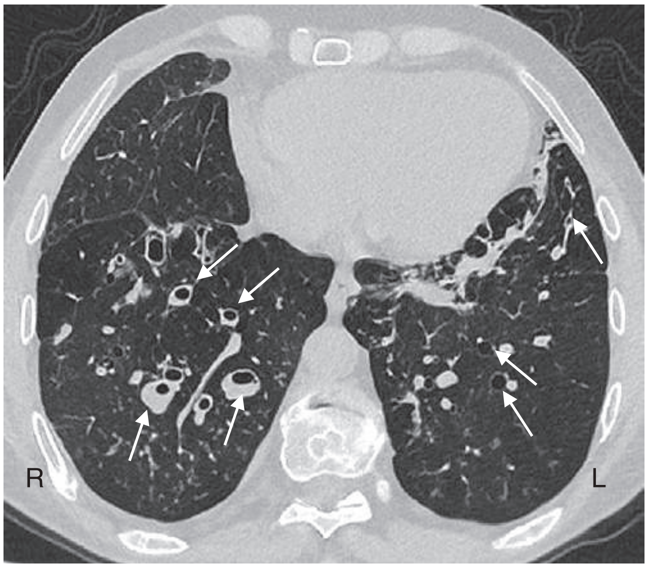

Fig. 17.29 **Bronchiectasis**. Chest CT demonstrating bilateral lower lobe bronchiectasis, more severe in the right lung base. The arrows indicate dilated bronchi which, on the right, are associated with bronchial wall thickening.

Antibiotic therapy

For most patients with bronchiectasis, the appropriate antibiotics are the same as those used in COPD but larger doses and longer courses are required. When secondary infection occurs with staphylococci and gram-negative bacilli, in particular *Pseudomonas* species, antibiotic therapy becomes more challenging and should be guided by microbiological sensitivities. For *Pseudomonas aeruginosa*, oral ciprofloxacin (500–750 mg twice daily) or an intravenous anti-pseudomonal β-lactam (such as piperacillin–tazobactam 4.5 g 4 times daily or ceftazidime 2 g 3 times daily) will be required. Haemoptysis in bronchiectasis often responds to treatment of the underlying infection, although percutaneous embolisation of the bronchial circulation by an interventional radiologist can be indicated in the event of massive or repeated haemoptysis.

Surgical treatment

Surgical resection of bronchiectatic areas is indicated in a minority of patients where the bronchiectasis is confined to a single lobe or segment on CT. Unfortunately, many of those in whom medical treatment proves unsuccessful are unsuitable for surgery because of either extensive bilateral bronchiectasis or reduced lung function. In progressive forms of bronchiectasis, resection of destroyed areas of lung that are acting as a reservoir of infection should be considered only as a last resort.

Prognosis

The disease is progressive when associated with ciliary dysfunction or cystic fibrosis and eventually causes respiratory failure. In other patients, the prognosis can be relatively good if physiotherapy is performed regularly and antibiotics are used aggressively.

Prevention

As bronchiectasis can start at a young age following measles, whooping cough or a primary tuberculous infection, adequate prevention and treatment of these conditions are essential. Early recognition and treatment of bronchiectasis is important to prevent progressive lung damage.

Cystic fibrosis

Genetics, pathogenesis and epidemiology

Cystic fibrosis (CF) is the most common life-limiting genetic disease in people of predominantly European descent. It is inherited in an autosomal recessive manner; the carrier rate is about 1 in 25, giving an incidence of about 1 in 2500 live births in the European population, although worldwide the incidence of CF varies widely. It is the result of pathogenic variants affecting the cystic fibrosis transmembrane conductance regulator *(CFTR)* gene on the long arm of chromosome 7, which encodes a chloride channel that influences salt and water movement across epithelial cell membranes. The most common pathogenic *CFTR* variant in northern European and American populations is ΔF508 (F508del-CFTR), but over 2000 pathogenic variants have now been identified. The genetic defect causes increased sodium and chloride content in sweat and increased resorption of sodium and water from respiratory epithelium (Fig. 17.30). Relative dehydration of the airway epithelium is thought to predispose to chronic bacterial infection, ciliary dysfunction and bronchiectasis. The gene defect also causes disorders in the gut epithelium, pancreas, liver and reproductive tract (see below).

In the 1960s, few patients with CF survived infancy. In modern practice, life expectancy has dramatically improved by aggressive treatment of airway infection, nutritional support and most recently the introduction of CFTR modulator therapies. In high-income countries there are now more adults than children with CF. Until recently, the diagnosis was most commonly made from the clinical picture (bowel obstruction, failure to thrive, steatorrhoea and/or chest symptoms in a young child), supported by sweat electrolyte testing and genotyping. However, neonatal screening for CF using immunoreactive trypsin and genetic testing of newborn blood samples is now routinely performed in many countries to reduce diagnostic delay and improve clinical outcomes. Pre-implantation and/or prenatal testing may also be offered to those known to be at high risk.

Clinical features

The lungs are macroscopically normal at birth, but bronchiolar inflammation and infections usually lead to bronchiectasis in childhood. At this stage, the lungs are most commonly infected with *Staph. aureus*, while in adulthood, many patients become colonised with antibiotic-resistant gram-negative bacilli. Recurrent exacerbations of bronchiectasis, initially in the upper lobes but subsequently throughout both lungs, cause progressive lung damage, resulting ultimately in death from respiratory failure. Other clinical manifestations and complications are shown in Box 17.33. Most men with CF are infertile due to failure of development of the vas deferens, but microsurgical sperm aspiration and in vitro fertilisation are possible for males with CF. Genotype is a poor predictor of disease severity in individuals; even siblings with matching genotypes may have different phenotypes. This suggests that other modifier genes, as yet unidentified, influence clinical outcome.

Management

Treatment of CF lung disease

The management of CF lung disease is that of severe bronchiectasis. All patients with CF who produce sputum should perform chest physiotherapy daily, and more frequently during exacerbations. While infections with *Staph. aureus* can often be managed with oral antibiotics, intravenous treatment (frequently self-administered at home through an implanted subcutaneous vascular access device) is usually needed for *Pseudomonas aeruginosa* infections.

Over time, patients with CF become chronically infected with antibiotic-resistant organisms. These include *P. aeruginosa*, *Stenotrophomonas*

i 17.33 Clinical features and complications of cystic fibrosis

Respiratory

- Progressive airway obstruction
- Infective exacerbations of bronchiectasis
- Respiratory failure
- Spontaneous pneumothorax
- Allergic bronchopulmonary aspergillosis
- Haemoptysis
- Lobar collapse due to secretions
- Pulmonary hypertension
- Nasal polyps

Gastrointestinal and hepatic

- Malabsorption and steatorrhoea
- Distal intestinal obstruction syndrome
- Increased risk of gastrointestinal malignancy
- Cystic fibrosis–associated liver disease (CFLD), including biliary cirrhosis, portal hypertension, varices and splenomegaly
- Gallstones

Others

- Diabetes (25% of adults)
- Delayed puberty
- Male infertility
- Stress incontinence due to repeated forced cough
- Psychosocial problems
- Osteoporosis
- Arthropathy
- Cutaneous vasculitis

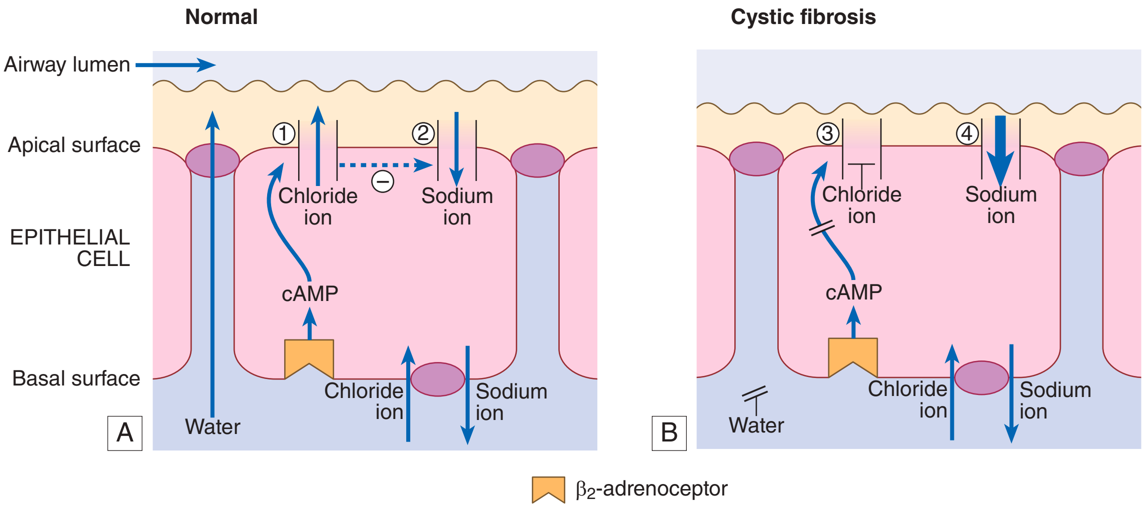

Fig. 17.30 Molecular mechanism of cystic fibrosis. **A** The cystic fibrosis gene *(CFTR)* encodes for a chloride channel (1) expressed in the apical (luminal) membrane of epithelial cells in the conducting airways. This is normally controlled by cyclic adenosine monophosphate (cAMP) and indirectly by β-adrenoceptor stimulation and is one of several apical ion channels that control the quantity and solute content of airway-lining fluid. Normal channels appear to inhibit the adjacent epithelial sodium channels (2). **B** In cystic fibrosis, one of many cystic fibrosis pathogenic variants causes absence or defective function of this chloride channel (3). This leads to reduced chloride secretion and loss of inhibition of sodium channels, with excessive sodium resorption (4) and dehydration of the airway lining. The resulting abnormal airway-lining fluid predisposes to infection by mechanisms still to be fully explained.

maltophilia and *Burkholderia cepacia* complex, which may require prolonged treatment with combinations of intravenous antibiotics. The impact of non-tuberculous mycobacteria is less clear, with the exception of *Mycobacterium abscessus*. This organism is often pan-antibiotic resistant and may be transmitted between patients with CF causing progressive lung destruction and potentially precluding lung transplantation. Fungi such as *Aspergillus fumigatus* may cause airways infection or allergic bronchopulmonary aspergillosis.

There has been a rapid advance in the maintenance therapies for patients with CF, including mucolytic therapies, long-term inhaled antibiotics, anti-inflammatory agents and, more recently, CFTR modulator therapies (Box 17.34), as discussed in more detail below.

For advanced CF lung disease, home oxygen and NIV may be necessary to treat respiratory failure. Ultimately, lung transplantation can produce dramatic improvements but is limited by donor organ availability and the long-term issues associated with chronic lung allograft dysfunction (CLAD).

The transition from paediatric to adult CF care raises specific management issues in adolescence, which are summarised in Box 17.35.

17.34 Treatments that reduce chest exacerbations and/or improve lung function in cystic fibrosis

Therapy	Drugs
Mucolytic therapies	Nebulised recombinant human DNase 2.5 mg daily Nebulised hypertonic saline (7%) 4 mL twice daily Inhaled mannitol 400 mg twice daily
Inhaled antibiotics	Nebulised tobramycin 300 mg twice daily, alternate months Inhaled powder tobramycin 28 mg twice daily, given alternate months Nebulised colistin 1 MU twice daily Nebulised colistin 2 MU twice daily Inhaled powder colistin 1.6 MU twice daily Nebulised aztreonam 75 mg 3 times daily, alternate months Nebulised levofloxacin 240 mg twice daily, alternate months
Anti-inflammatory therapy	Azithromycin 250 mg/500 mg once a day 3 times weekly
CFTR modulator therapy	Ivacaftor Ivacaftor/lumacaftor Ivacaftor/tezacaftor Ivacaftor/tezacaftor/elexacaftor

(CFTR = cystic fibrosis transmembrane conductance regulator; FEV_1 = forced expiratory volume in 1 sec; FVC = forced vital capacity)

17.35 Cystic fibrosis in adolescence

Issues for the patient

- Move to adult CF centre – loss of trusted paediatric team
- Feelings of being different from peers due to chronic illness
- Demanding treatments that conflict with social and school life
- Pressure to take responsibility for self-care
- Relationship/fertility concerns

Issues for the patient's parents

- Loss of control over patient's treatment – feeling excluded
- Loss of trusted paediatric team
- Need to develop trust in adult team
- Feelings of helplessness when adolescent rebels or will not take treatment

Issues for the CF team

- Reluctance or refusal by patient to engage with transition
- Management of deterioration due to non-adherence
- Motivation of adolescents to self-care
- Provision of adolescent-friendly health-care environment

(CF = cystic fibrosis)

Treatment of non-respiratory manifestations of CF

There is a clear link between good nutrition and prognosis in CF. Malabsorption occurs in 85% of patients due to exocrine pancreatic failure and is treated with oral pancreatic enzymes and vitamin supplements. The increased calorie requirements of patients with CF are met by supplemental feeding, including nasogastric or gastrostomy tube feeding if required. Diabetes eventually develops in over 25% of patients and needs insulin therapy. Screening and treatment of osteoporosis secondary to malabsorption and chronic ill health should be undertaken routinely.

CFTR modulator therapies

CFTR modulators are small molecules that can be taken orally, designed to target specific CFTR mutations. 'Correctors' act by correcting CFTR misfolding, thereby improving trafficking to the cell surface; and 'potentiators' act by improving the function of CFTR that is already at the cell surface.

Ivacaftor, a CFTR potentiator, is an oral treatment for the 5% of patients with the G551D variant and several other gating mutations. It causes sustained improvements in FEV_1 and weight, and normalisation of the sweat chloride levels. Newer combinations of CFTR correctors and potentiators (lumacaftor/ivacaftor and elexacaftor/tezacaftor/ivacaftor) are now used to treat patients with the more common ΔF508 variant and represent a major step forward in therapy.

Infections of the respiratory system

Infections of the upper and lower respiratory tract are a major cause of morbidity and mortality, particularly in patients at the extremes of age and those with pre-existing lung disease or immune suppression. Features that are specific to older people are shown in Box 17.36.

Upper respiratory tract infection

Upper respiratory tract infections (URTIs), such as coryza (the common cold) and acute pharyngitis, are the most common of all communicable diseases and represent the most frequent cause of short-term absence from work and school. The vast majority of such infections are caused by viruses and, in adults, are usually short-lived and rarely serious.

Acute coryza is the most common URTI and is usually caused by rhinovirus infection. The usual symptoms are general malaise, nasal

17.36 Respiratory infection in old age

- **Increased risk of and from respiratory infection**: because of reduced immune responses, increased closing volumes, reduced respiratory muscle strength and endurance, altered mucus layer, poor nutritional status and the increased prevalence of chronic lung disease.
- **Predisposing factors**: other medical conditions may predispose to infection, such as swallowing difficulties due to stroke increase the risk of aspiration pneumonia.
- **Atypical presentation**: older patients often present with delirium, rather than breathlessness or cough.
- **Mortality**: the vast majority of deaths from pneumonia in high-income countries occur in older people.
- **Influenza**: has a much higher morbidity and mortality rate. Vaccination significantly reduces morbidity and mortality in old age but uptake is poor.
- **COVID-19**: increasing age is recognised as a highly significant risk factor for morbidity and mortality.
- **Tuberculosis**: most cases in old age represent reactivation of previous, often unrecognised, disease and may be precipitated by glucocorticoid therapy, diabetes mellitus and the factors above. Cryptic miliary tuberculosis is an occasional alternative presentation. Older people more commonly suffer adverse effects from antituberculous chemotherapy and require close monitoring.

discharge, sneezing and cough. Involvement of the pharynx causes a sore throat, and that of the larynx a hoarse or 'lost' voice. If complicated by tracheitis or bronchitis within the lower respiratory tract, chest tightness and wheeze typical of asthma occur. These complications are generally self-limiting and often do not require specific investigation, and treatment is usually symptomatic. Symptoms usually resolve quickly, but if repeated URTIs 'go to the chest', a more formal diagnosis of asthma ought to be considered. A variety of viruses causing URTI may also trigger exacerbations of asthma or COPD and aggravate other lung diseases.

Bordetella pertussis, the cause of whooping cough (pertussis), is an important cause of URTI. Vaccination confers protection and is usually offered in infancy, but its efficacy wanes in adult life and the infection is easily spread. Adults usually experience a mild illness similar to acute coryza but some individuals develop paroxysms of coughing that can persist for weeks to months, earning whooping cough the designation of 'the cough of 100 days'. The diagnosis may be confirmed by bacterial culture, polymerase chain reaction (PCR) from a nasopharyngeal swab or serological testing. If the illness is recognised early in the clinical course, macrolide antibiotics may ameliorate the course. Pertussis is a reportable disease in the UK.

Rhinosinusitis typically manifests as a combination of nasal congestion, blockage or discharge and may be accompanied by facial pain/pressure or loss of smell. Examination usually confirms erythematous swollen nasal mucosa, and pus may be evident. Nasal polyps should be sought and dental infection excluded. Treatment with topical corticosteroids, nasal decongestants and regular nasal douching is usually sufficient and, although bacterial infection is often present, antibiotics are indicated only if symptoms persist for more than 5 days. Persistent symptoms or recurrent episodes should prompt a referral to an ear, nose and throat specialist.

Viral respiratory tract infections with the potential to cause more severe disease (including COVID-19) are discussed in Chapter 14.

Pneumonia

Pneumonia is as an acute respiratory illness associated with recently developed radiological pulmonary shadowing that may be segmental, lobar or multilobar. The context in which pneumonia develops is highly suggestive of the likely organism(s) involved; therefore, pneumonias are usually classified as community- or health care–associated, or those occurring in immunocompromised hosts. Lobar pneumonia is a radiological and pathological term referring to homogeneous consolidation of one or more lung lobes, often with associated pleural inflammation; bronchopneumonia refers to more patchy alveolar consolidation associated with bronchial and bronchiolar inflammation, affecting more than one lobe of the lung.

Community-acquired pneumonia

Figures from the UK suggest that an estimated 5–11/1000 adults suffer from community-acquired pneumonia (CAP) each year, accounting for around 5%–12% of all lower respiratory tract infections. CAP may affect all age groups but is commonest at the extremities of age.

Most cases are spread by droplet infection, and while CAP may occur in previously healthy individuals, several factors may impair the effectiveness of local defences and predispose to CAP (Box 17.37). *Streptococcus pneumoniae* (Fig. 17.31) remains the most common infecting agent, and the likelihood that other organisms may be involved depends on the age of the patient and the clinical context. Viral infections are recognised as important causes of CAP in children, and their contribution to adult CAP is increasingly recognised. The common causative organisms are shown in Box 17.38.

17.37 Factors that predispose to community-acquired pneumonia

- Cigarette smoking
- Upper respiratory tract infections
- Alcohol
- Glucocorticoid therapy
- Old age
- Recent influenza infection
- Pre-existing lung disease
- HIV
- Indoor air pollution

Clinical features

Pneumonia, particularly lobar pneumonia, usually presents as an acute illness. Systemic features, such as fever, rigors, shivering and malaise, predominate and delirium may be present. The appetite is invariably lost and headache frequently reported.

Pulmonary symptoms include cough, which at first is characteristically short, painful and dry, but later is accompanied by the expectoration of mucopurulent sputum. Rust-coloured sputum may be produced by patients with *Strep. pneumoniae* infection and the occasional patient may report haemoptysis. Pleuritic chest pain may be a presenting feature and on occasion may be referred to the shoulder or anterior abdominal wall. Upper abdominal tenderness is sometimes apparent in patients with lower lobe pneumonia or those with associated hepatitis. Less typical presentations may be seen in childhood and old age.

While different organisms often give rise to a similar clinical and radiological picture, it may be possible to infer the likely agent from the clinical context. *Mycoplasma pneumoniae* is more common in young people and rare in old age, whereas *Haemophilus influenzae* is more common in older people, particularly those with underlying lung disease. *Legionella pneumophila* occurs in local outbreaks centred on contaminated cooling towers in hotels, hospitals and other industries. *Staphylococcus aureus* is more common following an episode of influenza. *Klebsiella* pneumonia has a specific association with alcohol abuse and often presents with a particularly severe bacteraemic illness and cavitation on the CXR. Recent foreign travel raises the possibility of infections that may otherwise be unusual in the UK, such as Middle East respiratory syndrome (MERS), melioidosis (South-east Asia and northern Australia) and endemic fungal

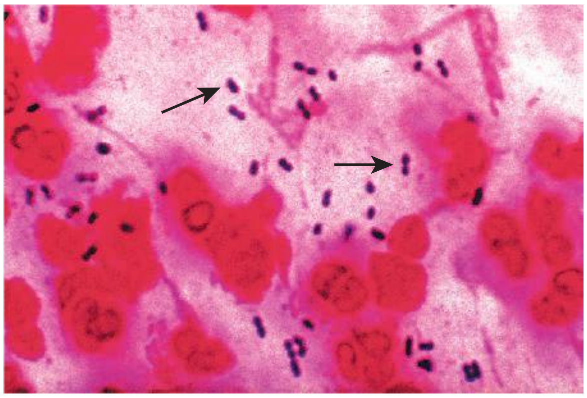

Fig. 17.31 Gram stain of sputum. The slide shows gram-positive diplococci (arrows) characteristic of *Streptococcus pneumoniae.*

17.38 Organisms causing community-acquired pneumonia

Bacteria

- *Streptococcus pneumoniae*
- *Mycoplasma pneumoniae*
- *Legionella pneumophila*
- *Chlamydia pneumoniae*
- *Haemophilus influenzae*
- *Staphylococcus aureus*
- *Chlamydophila psittaci*
- *Coxiella burnetii* (Q fever)
- *Klebsiella pneumoniae*

Viruses

- Influenza, parainfluenza
- Measles
- Herpes simplex
- Varicella
- Adenovirus
- Cytomegalovirus
- Coronaviruses (SARS-CoV-2 and MERS-CoV)

(MERS = Middle East respiratory syndrome; SARS = severe acute respiratory syndrome) infection (North, Central or South America). Certain occupations may be associated with exposure to specific bacteria (p. 586).

Clinical examination should first focus on the respiratory and pulse rates, blood pressure and an assessment of the mental state, as these are important in assessing the severity of the illness. In the UK, severity is assessed using the CURB-65 score, which takes findings on physical examination and investigations into account (Fig. 17.32). Chest signs vary, depending on the inflammatory response, which proceeds through stages of acute exudation, red and then grey hepatisation, and finally resolution. When consolidated, the lung is typically dull to percussion and, as conduction of sound is enhanced, auscultation reveals bronchial breathing and whispering pectoriloquy; crackles are heard throughout. An assessment of the state of nutrition is important, particularly in old age and frailty. The differential diagnosis of pneumonia is shown in Box 17.39.

Investigations

The object of investigations, which are summarised in Box 17.40, is to confirm the diagnosis, assess severity and identify the development of complications.

Management

The most important aspects of management are oxygenation, fluid balance and antibiotic therapy. In severe or prolonged illness, nutritional support may be required.

Oxygen

Oxygen should be administered to all patients with tachypnoea, hypoxaemia, hypotension or acidosis to maintain the target oxygen saturations specified on p. 232. Continuous positive airway pressure (CPAP) should be considered in those who remain hypoxic despite high-concentration oxygen therapy, and these patients should be managed in a high-dependency or critical care environment where invasive ventilation is available. Indications for referral to a critical care unit are summarised in Box 17.41.

Fluid balance

Intravenous fluids should be considered in those with severe illness, in older patients and those with vomiting. It may be appropriate to discontinue hypertensive agents temporarily, particularly if there is evidence of acute kidney injury secondary to sepsis. Otherwise, an adequate oral intake of fluid should be encouraged. Vasopressor support may be required in patients with shock.

Antibiotic treatment

Prompt administration of appropriate antibiotics improves the outcome. The initial choice of antibiotic is guided by clinical context, severity assessment, local knowledge of antibiotic resistance patterns and antibiotic guidelines. Current treatment regimens are detailed in Box 17.42. In most patients with uncomplicated pneumonia a 5-day course is adequate, although treatment is usually required for longer in patients with pneumonia due to *Legionella pneumophila*, *Staph. aureus* or *Klebsiella pneumoniae*.

Treatment of pleural pain

It is important to relieve pleural pain in order to allow the patient to breathe normally and cough efficiently. For the majority, simple analgesia with paracetamol, co-codamol or NSAIDs is sufficient. In some patients, opiates may be required but must be used with caution in individuals with poor respiratory function.

Physiotherapy

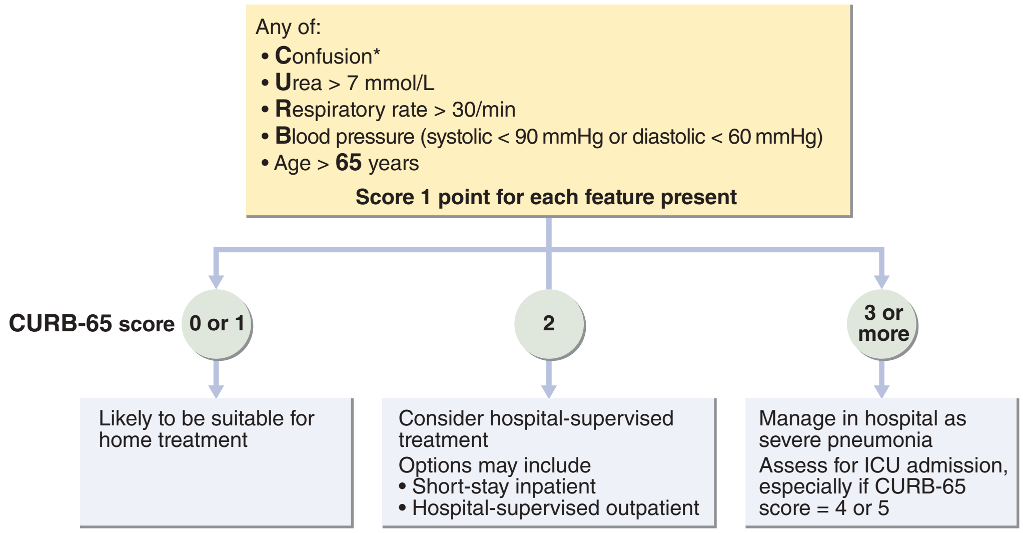
Physiotherapy is not usually indicated in patients with CAP, although it may be helpful to assist expectoration in patients who suppress cough because of pleural pain.

Prognosis

Most patients respond promptly to antibiotic therapy. Fever may persist for several days, however, and the CXR often takes several weeks or even months to resolve, especially in old age. Delayed recovery suggests either that a complication has occurred (Box 17.43) or that the diagnosis is incorrect (see Box 17.39). Alternatively, the pneumonia may be secondary to a proximal bronchial obstruction or recurrent aspiration. The mortality rate of adults with mild pneumonia is low (<5%); hospital death

17.39 Differential diagnosis of pneumonia

- Pulmonary infarction
- Pulmonary/pleural tuberculosis
- Pulmonary oedema (can be unilateral)
- Pulmonary eosinophilia
- Malignancy: bronchoalveolar cell carcinoma
- Cryptogenic organising pneumonia/bronchiolitis obliterans organising pneumonia (COP/BOOP)



Any of:
• **C**onfusion*
• **U**rea > 7 mmol/L
• **R**espiratory rate > 30/min
• **B**lood pressure (systolic < 90 mmHg or diastolic < 60 mmHg)
• Age > **65** years
Score 1 point for each feature present
CURB-65 score
0 or 1
2
3 or more
Likely to be suitable for home treatment
Consider hospital-supervised treatment
Options may include
• Short-stay inpatient
• Hospital-supervised outpatient
Manage in hospital as severe pneumonia
Assess for ICU admission, especially if CURB-65 score = 4 or 5

Fig. 17.32 Hospital CURB-65 score. Confusion is defined as an Abbreviated Mental Test Score of 8 or less or new disorientation in person, place or time. (ICU = intensive care unit; urea of 7 mmol/L ≅ 42 mg/dL)

17.40 Investigations in community-acquired pneumonia*

Blood

Full blood count

- Very high (> 20 × 10^9/L) or low (< 4 × 10^9/L) white cell count: marker of severity
- Neutrophil leucocytosis > 15 × 10^9/L: suggests bacterial aetiology
- Haemolytic anaemia: occasional complication of *Mycoplasma*

Urea and electrolytes

- Urea > 7 mmol/L (~20 mg/dL): marker of severity
- Hyponatraemia: marker of severity

Liver function tests

- Abnormal if basal pneumonia inflames liver
- Hypoalbuminaemia: marker of severity

Procalcitonin

- A high procalcitonin is more suggestive of bacterial than viral infection (see Ch. 7)

C-reactive protein/erythrocyte sedimentation rate

- Non-specifically elevated

Blood culture

- Bacteraemia is a marker of severity

Arterial blood gases

- Measure when SpO_2 < 93% or when clinical features are severe to assess ventilatory failure or acidosis

Sputum

Sputum samples

- Gram stain, culture and antimicrobial sensitivity testing

Pharyngeal swab

- NAAT for respiratory viruses (influenza, parainfluenza, coronaviruses) and bacteria (*Mycoplasma pneumoniae*)

Urine

- Pneumococcal and/or *Legionella* antigen

CXR

Lobar pneumonia

- Patchy opacification evolves into homogeneous consolidation of affected lobe (Fig. 17.33)
- Air bronchogram (air-filled bronchi appear lucent against consolidated lung tissue) may sometimes be visible

Bronchopneumonia

- Typically, patchy and segmental shadowing

Complications

- Para-pneumonic effusion, intrapulmonary abscess or empyema

Staphylococcus aureus

- Suggested by multilobar shadowing, cavitation, pneumatoceles and abscesses

Pleural fluid

- Always aspirate and culture when present in more than trivial amounts, preferably with ultrasound guidance

*These investigations are for moderate- to high-severity community-acquired pneumonia (CAP). Low-severity CAP is usually managed empirically without the need for blood tests and microbiological investigations, unless the patient has risk factors for underlying disease or an atypical clinical course.
(NAAT = nucleic acid amplification test)

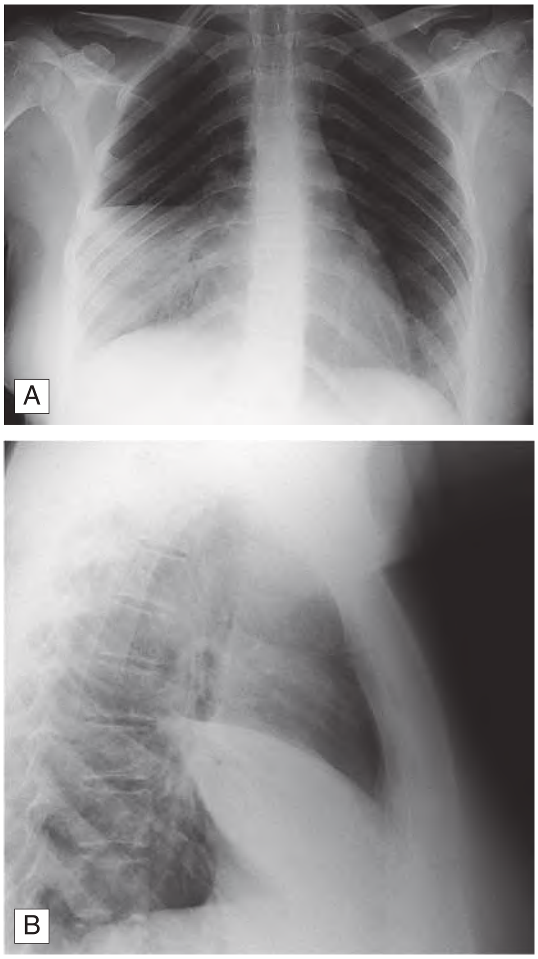


Fig. 17.33 Pneumonia of the right middle lobe. **A** Posteroanterior view: consolidation in the right middle lobe with characteristic opacification beneath the horizontal fissure and loss of normal contrast between the right heart border and lung. **B** Lateral view: consolidation confined to the anteriorly situated middle lobe.

17.41 Indications for referral to critical care in pneumonia

- CURB-65 score of 4–5 (see Fig. 17.32), failing to respond rapidly to initial management
- Persisting hypoxia (PaO_2 < 8 kPa (60 mmHg)), despite high concentrations of oxygen
- Progressive hypercapnia
- Severe acidosis
- Circulatory shock
- Reduced conscious level

rates are typically between 5% and 10% but may be as high as 50% in severe pneumonia.

Discharge and follow-up

The decision to discharge a hospitalised patient depends on the home circumstances and the likelihood of complications. A CXR need not be repeated before discharge in patients making a satisfactory clinical recovery. Clinical review by general practitioner or hospital should be arranged around 6 weeks later and a CXR obtained if there are persistent symptoms, physical signs or reasons to suspect underlying malignancy, such as tobacco exposure.

Prevention

Current smokers should be advised to stop. Influenza and pneumococcal vaccination should be offered to those over 65 and individuals with chronic lung, heart, liver or kidney disease, diabetes or immunosuppression, who are at increased risk of pneumonia. Causes of pneumonia that have important public health implications must be notified to the

17.42 Antibiotic treatment regimens for community-acquired pneumonia[1]

Low severity CAP (CURB-65 score 0–1)

- Amoxicillin 500 mg 3 times daily orally (or IV if necessary[2])

If patient is allergic to penicillin

- Doxycycline 200 mg loading dose then 100 mg/day orally *or* clarithromycin 500 mg twice daily orally

Moderate severity CAP (CURB-65 score 2)

- Amoxicillin 500 mg–1 g 3 times daily orally (or IV if oral medication not possible[2]) *or* benzylpenicillin 1.2 g 4 times daily IV
- *plus* clarithromycin 500 mg twice daily orally/IV

If patient is allergic to penicillin

- Doxycycline 200 mg loading dose then 100 mg/day orally *or* levofloxacin 500 mg/day orally

Severe CAP (CURB-65 score 3–5)

- Co-amoxiclav 1.2 g 3 times daily IV or cefuroxime 1.5 g 3 times daily IV *or* ceftriaxone 1–2 g daily IV
- *plus* clarithromycin 500 mg twice daily IV
- *or* benzylpenicillin 1.2 g 4 times daily IV *plus* levofloxacin 500 mg twice daily IV

If *Legionella* is strongly suspected

- Consider adding levofloxacin 500 mg twice daily IV

[1] Note that antibiotic use in individual patients should consider local guidance and antibiotic sensitivity patterns. The usual duration of antibiotic treatment for all forms of CAP is 5 days.
[2] Reasons would include impaired consciousness, impaired swallowing reflex and functional or anatomical reasons for malabsorption.
(CURB-65 – see Fig. 17.32; IV = intravenous).
Adapted from British Thoracic Society Guidelines.

17.43 Complications of pneumonia

- Para-pneumonic effusion – common
- Empyema
- Retention of sputum causing lobar collapse
- Deep vein thrombosis and pulmonary embolism
- Pneumothorax, particularly with *Staphylococcus aureus*
- Suppurative pneumonia/lung abscess
- ARDS, renal failure, multi-organ failure
- Ectopic abscess formation *(Staphylococcus aureus)*
- Hepatitis, pericarditis, myocarditis, meningoencephalitis
- Cardiac arrhythmias
- Pyrexia due to drug hypersensitivity

(ARDS = acute respiratory distress syndrome)

appropriate health authority for appropriate investigation and follow-up (see Box 7.11). In resource-poor settings, tackling malnourishment and indoor air pollution, and encouraging immunisation against measles, pertussis and *Haemophilus influenzae* type b, are particularly important in children.

Hospital-acquired pneumonia

Hospital-acquired pneumonia (HAP) is defined as an episode of pneumonia that presents at least 48 hours after admission to hospital and was not incubating at the time of admission. It is the second most common health care–associated infection (HAI) after surgical-site infections and the leading cause of HAI-associated death. Older patients are particularly at risk, as are patients in intensive care units. The term ventilator-associated pneumonia (VAP) is used to describe pneumonia that develops in a person who is mechanically ventilated. The factors predisposing to the development of HAP are listed in Box 17.44.

17.44 Factors predisposing to hospital-acquired pneumonia

Reduced host defences against bacteria

- Reduced immune defences (glucocorticoids, immunosupressives, diabetes, malignancy)
- Reduced cough reflex post-operatively
- Disordered mucociliary clearance following anaesthetic agents
- Bulbar or vocal cord palsy

Aspiration of nasopharyngeal or gastric secretions

- Immobility or reduced conscious level
- Vomiting, dysphagia, stroke, achalasia or severe reflux
- Nasogastric intubation

Bacteria introduced into lower respiratory tract

- Endotracheal intubation/tracheostomy
- Infected ventilators, nebulisers or bronchoscopes
- Dental or sinus infection

Bacteraemia

- Abdominal sepsis
- Intravenous cannula infection
- Infected emboli

Clinical features and investigation

The diagnosis should be considered in any hospitalised patient who develops purulent sputum (or endotracheal secretions), new radiological infiltrates, an otherwise unexplained increase in oxygen requirement, a core temperature > 38.3°C, and a leucocytosis or leucopenia. The clinical features and radiographic signs are variable and non-specific, however, raising a broad differential diagnosis that includes pulmonary embolism, ARDS, pulmonary oedema, pulmonary haemorrhage and drug toxicity. Therefore, in contrast to CAP, microbiological confirmation should be sought whenever possible. Adequate sputum samples may be difficult to obtain and physiotherapy should be considered to aid expectoration. In patients who are mechanically ventilated, bronchoscopy-directed protected brush specimens, bronchoalveolar lavage (BAL) or endotracheal aspirates may be obtained.

Management

The principles of management are similar to those of CAP, focusing on adequate oxygenation, appropriate fluid balance and antibiotics. The choice of empirical antibiotic therapy is considerably more challenging, however, given the diversity of pathogens and the potential for drug resistance.

The organisms implicated in early-onset HAP (occurring within 4–5 days of admission) are similar to those involved in CAP. The initial choice of agents is most appropriately guided by knowledge of local patterns of microbiology and antibiotic resistance (Box 17.45). If the infecting organism is identified, antibiotic therapy should be refined, with the narrowest possible spectrum agent(s) being used. The most appropriate duration of antibiotic therapy has not been established and is a matter of clinical judgement. Physiotherapy is important to aid expectoration in less mobile patients, and adequate nutritional support is often required.

Prevention

Despite appropriate management, the mortality from HAP is high (approximately 30%), mandating prevention whenever possible. Good hygiene is paramount, particularly with regard to hand-washing and any equipment used. Steps should be taken to minimise the chances of aspiration and to limit the use of stress ulcer prophylaxis with proton pump inhibitors. Oral antiseptic (chlorhexidine 2%) may be used to decontaminate the upper airway, and some intensive care units employ selective

17.45 Antibiotics for adults aged 18 years and over with hospital-acquired pneumonia

Antibiotic	Dosage and course length
First-choice oral antibiotic for non-severe symptoms or signs and not at higher risk of resistance[1]	
Co-amoxiclav	500/125 mg 3 times daily, for 5 days, then review
Alternative oral antibiotics for non-severe symptoms or signs and not at higher risk of resistance, if penicillin allergy or if co-amoxiclav unsuitable[2]	
Options include:	
Doxycycline	200 mg on first day, then 100 mg daily for 4 days (5-day course), then review
Cefalexin (caution in penicillin allergy)	500 mg 3 times or twice daily (can be increased to 1 g to 1.5 g 4 or 3 times daily) for 5 days, then review
Co-trimoxazole	960 mg twice daily for 5 days, then review
Levofloxacin (only if switching from IV levofloxacin with specialist advice; consider safety issues)	500 mg daily or twice daily for 5 days, then review
First-choice IV antibiotics if severe symptoms or signs or at higher risk of resistance. Review IV antibiotics by 48 hrs and consider switching to oral antibiotics as above for a total of 5 days, then review[2]	
Options include:	
Piperacillin with tazobactam	4.5 g 3 times daily (increased to 4.5 g 4 times daily if severe infection)
Ceftazidime	2 g 3 times daily
Ceftriaxone	2 g once daily
Cefuroxime	750 mg 4 or 3 times daily (increased to 1.5 g 4 or 3 times daily if severe infection)
Meropenem	0.5 g to 1 g 3 times daily
Ceftazidime with avibactam	2/0.5 g 3 times daily
Levofloxacin (consider safety issues)	500 mg daily or twice daily (use higher dosage if severe infection)
Antibiotics to be added if suspected or confirmed MRSA infection (dual therapy with an IV antibiotic listed above)	
Vancomycin	15 mg/kg to 20 mg/kg 3 times or twice daily IV, adjusted according to serum vancomycin concentration (a loading dose of 25 mg/kg to 30 mg/kg can be used in seriously ill people); maximum 2 g per dose
Teicoplanin	Initially 6 mg/kg twice daily for 3 doses, then 6 mg/kg daily
Linezolid (if vancomycin cannot be used; specialist advice only)	600 mg twice daily or IV

[1] Guided by microbiological results when available.
[2] Choice should be based on specialist microbiological advice and local resistance data.
Adapted from National Institute for Health and Care Excellence (NICE). Pneumonia (hospital-acquired): antimicrobial prescribing. NICE Guideline [NG139]; September 2019. www.nice.org.uk/guidance/ng139.

decontamination of the digestive tract when the anticipated requirement for ventilation will exceed 48 hours.

Suppurative pneumonia, aspiration pneumonia and pulmonary abscess

These conditions are considered together, as their aetiology and clinical features overlap. Suppurative pneumonia is characterised by destruction of the lung parenchyma by the inflammatory process. Although microabscess formation is a characteristic histological feature, 'pulmonary abscess' is usually taken to refer to lesions in which there is a large, localised collection of pus, or a cavity lined by chronic inflammatory tissue, from which pus has escaped by rupture into a bronchus.

Suppurative pneumonia and pulmonary abscess often develop after the inhalation of septic material during operations on the nose, mouth or throat, under general anaesthesia, or of vomitus during anaesthesia or coma, particularly if oral hygiene is poor. Additional risk factors for aspiration pneumonia include bulbar or vocal cord palsy, achalasia or oesophageal reflux, and alcoholism. Aspiration tends to localise to dependent areas of the lung, such as the apical segment of the lower lobe in a supine patient. These conditions may also complicate local bronchial obstruction from a neoplasm or foreign body.

Infections are usually due to a mixture of anaerobes and aerobes in common with the typical flora encountered in the mouth and upper respiratory tract. Isolates of *Prevotella melaninogenica*, *Fusobacterium necrophorum*, anaerobic or microaerophilic cocci and *Bacteroides fragilis* may be identified. When suppurative pneumonia or a pulmonary abscess occurs in a previously healthy lung, the most likely infecting organisms are *Staph. aureus* or *K. pneumoniae*. *Actinomyces* spp. cause chronic suppurative pulmonary infections, which may be associated with poor dental hygiene.

Bacterial infection of a pulmonary infarct or a collapsed lobe may also produce a suppurative pneumonia or lung abscess. The organism(s) isolated from the sputum include *Strep. pneumoniae*, *Staph. aureus*, *Strep. pyogenes*, *H. influenzae* and, in some cases, anaerobic bacteria. In many cases, however, no pathogen can be isolated, particularly when antibiotics have been given.

Some strains of *Staph. aureus*, often community-acquired methicillin-resistant *Staph. aureus* (MRSA) (CA-MRSA), produce the cytotoxin Panton–Valentine leukocidin (PVL). PVL-producing strains are mainly responsible for suppurative skin infection but also cause a rapidly progressive severe necrotising pneumonia.

Lemierre syndrome is a rare cause of pulmonary abscesses. The usual causative agent is the anaerobe *Fusobacterium necrophorum*. The illness typically commences as a sore throat, painful swollen neck, fever, rigor, haemoptysis and dyspnoea; spread into the jugular veins leads to thrombosis and metastatic dispersal of the organisms.

Injection drug-users are at particular risk of developing haematogenous lung abscess, often in association with endocarditis affecting the pulmonary and tricuspid valves. These abscesses are usually caused by staphylococci and streptococci, and occasionally by fungi such as *Candida* spp.

A non-infective form of aspiration pneumonia – exogenous lipid pneumonia – may follow the aspiration of animal, vegetable or mineral oils.

The clinical features of suppurative pneumonia are summarised in Box 17.46.

Investigations

Radiological features of suppurative pneumonia include homogeneous lobar or segmental opacity consistent with consolidation or collapse. Abscesses are characterised by cavitation and a fluid level. Occasionally, a pre-existing emphysematous bulla becomes infected and appears as a cavity containing an air–fluid level.

Management

Aspiration pneumonia can usually be treated with amoxicillin and metronidazole. Further modification of antibiotics should be informed by clinical response and microbiological results. MRSA is usually susceptible to a variety of oral non-β-lactam antibiotics, such as trimethoprim–sulfamethoxazole, clindamycin, tetracyclines and linezolid. Parenteral therapy with vancomycin or linezolid can also be considered. *Fusobacterium necrophorum* is highly susceptible to β-lactam antibiotics and to metronidazole, clindamycin and third-generation cephalosporins. Prolonged treatment for 4–6 weeks may be required in some patients with lung abscess. Established pulmonary actinomycosis requires 6–12 months' treatment with intravenous or oral penicillin, or with a tetracycline in penicillin-allergic patients.

Physiotherapy is of great value, especially when suppuration is present in the lower lobes or when a large abscess cavity has formed. In most patients there is a good response to treatment, and although residual fibrosis and bronchiectasis are common sequelae, these seldom give rise to serious morbidity. Surgery should be contemplated if no improvement occurs despite optimal medical therapy. Removal or treatment of any obstructing endobronchial lesion is essential.

Pneumonia in the immunocompromised patient

Patients immunocompromised by drugs or disease (particularly human immunodeficiency virus (HIV) infection) are at increased risk of pulmonary infection, and pneumonia is the most common cause of death in this group. The majority of infections are caused by the same pathogens that cause pneumonia in immunocompetent individuals, but in patients with more profound immunosuppression, less common organisms, or those normally considered to be of low virulence or non-pathogenic, may become opportunistic pathogens. Depending on the clinical context, clinicians should consider the possibility of gram-negative bacteria, especially *P. aeruginosa*, viruses, fungi, mycobacteria and less common organisms such as *Nocardia* spp. Infection is often due to more than one organism.

17.46 Clinical features of suppurative pneumonia

Symptoms

- Cough with large amounts of sputum, sometimes fetid and blood-stained
- Pleural pain common
- Sudden expectoration of copious amounts of foul sputum if abscess ruptures into a bronchus

Clinical signs

- High remittent pyrexia
- Profound systemic upset
- Digital clubbing may develop quickly (10–14 days)
- Consolidation on chest examination; signs of cavitation rarely found
- Pleural rub common
- Rapid deterioration in general health, with marked weight loss if not adequately treated

Clinical features

These typically include fever, cough and breathlessness but are influenced by the degree of immunosuppression, and the presentation may be less specific in the more profoundly immunosuppressed. The onset of symptoms tends to be swift in those with a bacterial infection but more gradual in patients with opportunistic organisms such as *Pneumocystis jirovecii* and mycobacterial infections. In *P. jirovecii* pneumonia, symptoms of cough and breathlessness can be present several days or weeks before the onset of systemic symptoms or the appearance of radiographic abnormality. The clinical features of invasive pulmonary aspergillosis are dealt with on p. 564.

Investigations

The approach is informed by the clinical context and severity of the illness. Invasive investigations, such as bronchoscopy, BAL, transbronchial biopsy or surgical lung biopsy, are often impractical, as many patients are too ill to undergo these safely; however, 'induced sputum' (p. 525) offers a relatively safe method of obtaining microbiological samples. HRCT can be helpful:

- focal unilateral airspace opacification favours bacterial infection, mycobacteria or *Nocardia*
- bilateral opacification favours *P. jirovecii* pneumonia, fungi, viruses and unusual bacteria, such as *Nocardia*
- cavitation may be seen with *N. asteroides*, mycobacteria and fungi
- the presence of a 'halo sign' (a zone of intermediate attenuation between the nodule and the lung parenchyma) may suggest aspergillosis or other invasive fungal infection
- pleural effusions suggest pyogenic bacterial infections and are uncommon in *P. jirovecii* pneumonia
- β-1,3-D-glucan levels are characteristically elevated in *P. jirovecii* pneumonia.

Management

In theory, treatment should be based on an established aetiological diagnosis; in practice, however, the causative agent is frequently unknown. Factors that favour a bacterial aetiology include neutropenia, rapid onset and deterioration. In these circumstances, broad-spectrum antibiotic therapy should be commenced immediately, such as a third-generation cephalosporin, or a quinolone plus an antistaphylococcal antibiotic, or an antipseudomonal penicillin plus an aminoglycoside. Thereafter, treatment may be tailored according to the results of investigations and the clinical response. Depending on the clinical context and response to treatment, antifungal or antiviral therapies may be added. The management of *P. jirovecii* infection is detailed on page 328 and that of invasive aspergillosis on page 566.

Tuberculosis

Epidemiology

Tuberculosis (TB) is caused by infection with *Mycobacterium tuberculosis* (MTB), which is part of a complex of organisms including *M. bovis* (reservoir cattle) and *M. africanum* (reservoir humans). As in many countries, the UK recorded TB incidence decreased during and rebound after the coronavirus pandemic. Although a 41% drop occurred between 2011 and 2023, UK TB incidence is now higher than it was pre-pandemic and climbing. The UK incidence of TB is expected to exceed 10 per 100,000 by 2026, rising beyond the definition of a low-incidence country. TB has a significant impact on world health. An estimated 10.8 million new cases were recorded in 2023, with the majority of these presenting in the world's poorest nations, which struggle to cover the costs associated with management and control programmes (Fig. 17.34). In the same year, 1.25 million men, women and children died of TB, making TB the leading cause of death from a single infectious agent worldwide in that year.

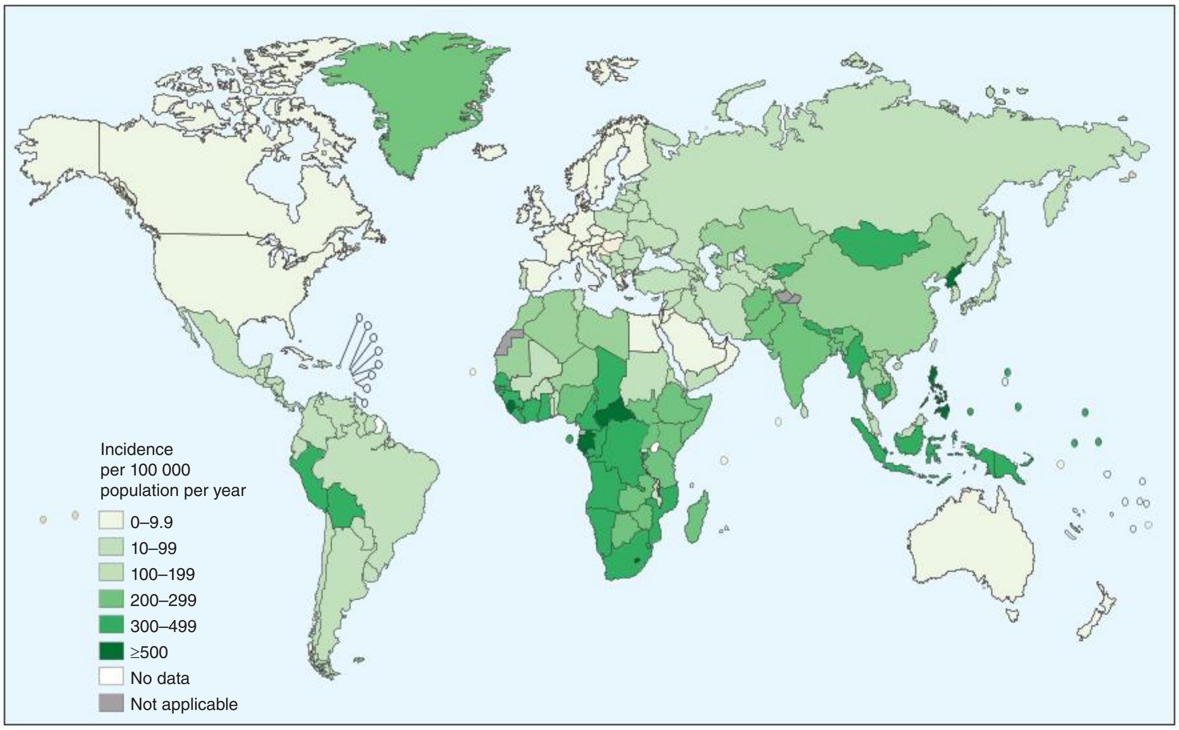

Fig. 17.34 Worldwide incidence of tuberculosis. The figures represent the estimated number of new cases (all forms) per 100 000 population. Map lines delineate study areas and do not necessarily depict accepted national boundaries. *Data are from 2022 as published by the World Health Organization Global tuberculosis report 2023. Geneva: WHO; 2023.*

Pathology and pathogenesis

Tuberculosis is spread by the inhalation of aerosolised droplet nuclei from other infected patients. Once inhaled, the *M. tuberculosis* organisms lodge in the alveoli and initiate the recruitment of macrophages and lymphocytes. Macrophages undergo transformation into epithelioid and Langhans cells, which aggregate with the lymphocytes to form the classical tuberculous granuloma (Fig. 17.35). Numerous granulomas aggregate to form a primary lesion or 'Ghon focus' (a pale yellow, caseous nodule, usually a few millimetres to 1–2 cm in diameter), which is characteristically situated in the periphery of the lung. Spread of organisms to the hilar lymph nodes is followed by a similar pathological reaction, and the combination of the primary lesion and regional lymph nodes is referred to as the 'primary complex of Ranke'. Reparative processes encase the primary complex in a fibrous capsule, limiting the spread of bacilli. If no further complications ensue, this lesion eventually calcifies and is clearly seen on a CXR. Lymphatic or haematogenous spread may occur before containment is established, however, seeding secondary foci in other organs, including lymph nodes, serous membranes, meninges, bones, liver, kidneys and lungs, which may lie dormant for years. The only clue that infection is present may be the appearance of a cell-mediated, delayed-type hypersensitivity reaction to tuberculin, demonstrated by tuberculin skin testing (TST) or an interferon-gamma release assay (IGRA): so-called latent TB infection (LTBI). If these controlling processes fail, primary progressive disease ensues (Fig. 17.36). The estimated lifetime risk of developing active disease after infection is 10%, with roughly half of this risk occurring in the first 2 years after infection. Factors predisposing to TB are summarised in Box 17.47 and the natural history of infection with TB is summarised in Box 17.48.

Clinical features: pulmonary disease

Primary pulmonary TB

Primary TB refers to the infection of a previously uninfected (tuberculin-negative) individual. A few patients develop a self-limiting febrile illness but clinical disease occurs only if there is a hypersensitivity reaction or progressive infection (Box 17.49). Progressive primary disease may appear during the course of the initial illness or after a latent period of weeks or months.

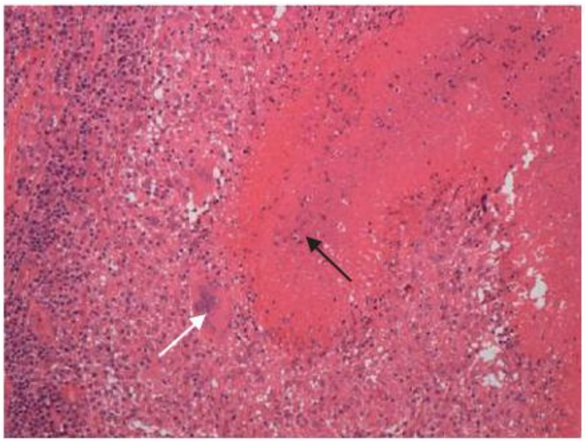

Fig. 17.35 Tuberculous granuloma. Normal lung tissue is lost and replaced by a mass of fibrous tissue with granulomatous inflammation characterised by large numbers of macrophages and multinucleate giant cells (white arrow). The central area of this focus shows caseous degeneration (black arrow). *Courtesy of Dr William Wallace, Department of Pathology, Royal Infirmary of Edinburgh.*

Miliary TB

Blood-borne dissemination gives rise to miliary TB, which may present acutely but more frequently is characterised by 2–3 weeks of fever, night sweats, anorexia, weight loss and a dry cough. Hepatosplenomegaly may develop and the presence of a headache may indicate coexistent tuberculous meningitis. Auscultation of the chest is frequently normal, but in more advanced disease widespread crackles are evident. Fundoscopy may show choroidal tubercles. The classical appearances on CXR are of fine 1–2 mm lesions ('millet seed') distributed throughout the lung fields, although occasionally the appearances are coarser. Anaemia and leucopenia reflect bone marrow involvement.

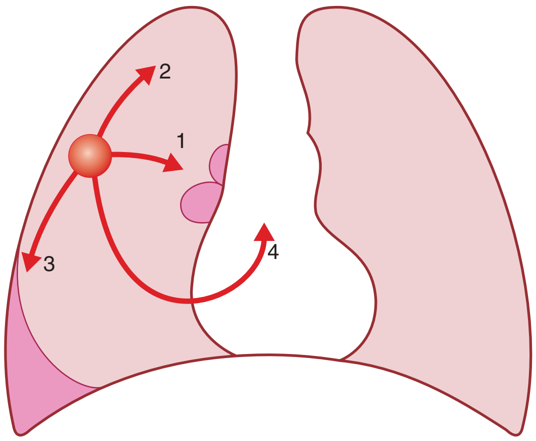

Fig. 17.36 **Primary pulmonary tuberculosis.** (1) Spread from the primary focus to hilar and mediastinal lymph glands to form the 'primary complex', which heals spontaneously in most cases. (2) Direct extension of the primary focus – progressive pulmonary tuberculosis. (3) Spread to the pleura – tuberculous pleurisy and pleural effusion. (4) Blood-borne spread: *few bacilli* – pulmonary, skeletal, renal, genitourinary infection, often months or years later; *massive spread* – miliary pulmonary tuberculosis and meningitis.

17.47 Risk factors for tuberculosis

Patient-related

- Age (children > young adults < old age)
- First-generation immigrants from high-prevalence countries
- Close contacts of patients with smear-positive pulmonary TB
- Overcrowding (prisons, collective dormitories); homelessness (shelters and hostels)
- CXR evidence of primary TB infection
- Primary infection <1 year previously
- Smoking: cigarettes, bidis (Indian cigarettes made of tobacco wrapped in tembhurni leaves) and cannabis

Associated diseases

- Immunosuppression: HIV (reduced by ART), anti-tumour necrosis factor (TNF) and other biologic therapies, high-dose glucocorticoids, cytotoxic agents
- Malignancy (especially lymphoma and leukaemia)
- Diabetes mellitus
- Chronic kidney disease
- Silicosis
- Gastrointestinal disease associated with malnutrition (gastrectomy, jejuno-ileal bypass, cancer of the pancreas, malabsorption)
- Deficiency of vitamin D or A
- Recent measles in children

(ART = antiretroviral therapy; HIV = human immunodeficiency virus; TB = tuberculosis)

17.48 Natural history of untreated primary tuberculosis

Time from infection	Manifestations
3–8 weeks	Primary complex, positive tuberculin skin test
3–6 months	Meningeal, miliary and pleural disease
Up to 3 years	Gastrointestinal, bone and joint, and lymph node disease
Around 8 years	Renal tract disease
From 3 years onwards	Post-primary disease due to reactivation or re-infection

Adapted from Davies PDO, ed. Clinical tuberculosis. London: Hodder Arnold; 1998.

17.49 Features of primary tuberculosis

Infection (4–8 weeks)

- Influenza-like illness
- Skin test conversion
- Primary complex

Disease

- Lymphadenopathy: hilar (often unilateral), paratracheal or mediastinal
- Collapse (especially right middle lobe)
- Consolidation (especially right middle lobe)
- Obstructive emphysema
- Cavitation (rare)
- Pleural effusion
- Miliary disease
- Meningitis
- Pericarditis

Hypersensitivity

- Erythema nodosum
- Phlyctenular conjunctivitis
- Dactylitis

17.50 Clinical presentations of pulmonary tuberculosis

- Chronic cough, often with haemoptysis
- Pyrexia of unknown origin
- Unresolved pneumonia
- Exudative pleural effusion
- Asymptomatic (diagnosis on CXR)
- Weight loss, general debility
- Spontaneous pneumothorax

Post-primary pulmonary TB

Post-primary disease refers to new exogenous infection or endogenous infection (reactivation of a dormant primary lesion) in a person who has been sensitised by earlier exposure. It is most frequently pulmonary and characteristically occurs in the apex of an upper lobe, where the oxygen tension favours survival of the strictly aerobic organism. The onset is usually insidious, developing slowly over several weeks. Systemic symptoms include fever, night sweats, malaise and loss of appetite and weight, and are accompanied by progressive pulmonary symptoms (Box 17.50). Radiological changes include ill-defined opacification in one or both of the upper lobes, and as progression occurs, consolidation, collapse and cavitation develop to varying degrees (Fig. 17.37). It is often difficult to distinguish active from quiescent disease on radiological criteria alone, but the presence of a miliary pattern or cavitation favours active disease. In extensive disease, collapse may be marked and results in significant displacement of the trachea and mediastinum. Occasionally, a caseous lymph node may drain into an adjoining bronchus, leading to tuberculous pneumonia.

Clinical features: extrapulmonary disease

Extrapulmonary TB accounts for 20% of cases in those who are HIV-negative but is more common in HIV-positive patients.

Lymphadenitis

Lymph nodes are the most common extrapulmonary site of disease. Cervical and mediastinal glands are affected most frequently, followed by axillary and inguinal, and more than one region may be involved. Disease may represent primary infection, spread from contiguous sites or reactivation. Supraclavicular lymphadenopathy is often the result of spread from mediastinal disease. The nodes are usually painless and initially mobile but become matted together with time. When caseation and liquefaction occur, the swelling becomes fluctuant and may discharge through the skin with

the formation of a 'collar-stud' abscess and sinus formation. Approximately half of cases fail to show any constitutional features, such as fevers or night sweats. During or after treatment, paradoxical enlargement, development of new nodes and suppuration may all occur but without evidence of continued infection; surgical excision is rarely necessary. In non-immigrant children in the UK, most mycobacterial lymphadenitis is caused by opportunistic mycobacteria, especially of the *M. avium* complex.

Pleural tuberculosis

Tuberculous pleural effusions are common. Patients present with pleuritic chest pain in addition to the classic clinical features of pulmonary TB. Effusions are caused by both primary and reactivated TB but can also result from a delayed hypersensitivity reaction to TB in the pleural cavity. Pseudochylothorax, due to compression from TB lymphadenitis, and empyema occur infrequently. Pleural fluid analysis demonstrates a lymphocytic exudate, with low glucose and pH. Pleural fluid smear and culture have sensitivities of only 10% and 25%, respectively; however, pleural tissue culture increases this to 80%. Raised adenosine deaminase has high sensitivity but low specificity as it occurs in malignancy and empyema also. Effusion volume fluctuates during treatment, even when successful. Therapeutic drainage is performed when necessary and steroids are sometimes used as an alternative.

Gastrointestinal tuberculosis

Any part of the bowel can be affected by TB and patients may present with a wide range of symptoms and signs (Fig. 17.38). Upper gastrointestinal tract involvement is rare and is usually an unexpected histological finding in an endoscopic or laparotomy specimen. Ileocaecal disease accounts for approximately half of abdominal TB cases. Fever, night sweats, anorexia and weight loss are usually prominent and a right iliac fossa mass may be palpable. Up to 30% of patients present with an acute abdomen. Ultrasound or CT may reveal thickened bowel wall, abdominal

lymphadenopathy, mesenteric thickening or ascites. The diagnosis rests on obtaining histology by either colonoscopy or mini-laparotomy. The main differential diagnosis is Crohn disease. Tuberculous peritonitis is characterised by abdominal distension, pain and constitutional symptoms. The ascitic fluid is exudative and cellular, with a predominance of lymphocytes. Laparoscopy reveals multiple white 'tubercles' over the peritoneal and omental surfaces. Low-grade hepatic dysfunction is common in miliary disease, in which biopsy reveals granulomas.

Pericardial disease

This occurs in two forms: pericardial effusion and constrictive pericarditis (see Fig. 17.38). Fever and night sweats are rarely prominent and the presentation is usually insidious, with breathlessness and abdominal swelling. Coexistent pulmonary disease is very rare, with the exception of pleural effusion. Pulsus paradoxus, a raised JVP, hepatomegaly, prominent ascites and peripheral oedema are common to both types. Pericardial effusion is associated with increased pericardial dullness and a globular enlarged heart on CXR, and pericardial calcification occurs in around 25% of cases. Constriction is associated with an early third heart sound and, occasionally, atrial fibrillation. The diagnosis is based on clinical, radiological and echocardiographic findings. The effusion is frequently blood-stained. Open pericardial biopsy can be performed where there is diagnostic uncertainty. The addition of corticosteroids to antituberculous chemotherapy has been shown to be beneficial in constrictive pericarditis.

Central nervous system disease

Meningeal disease represents the most important form of central nervous system TB. Unrecognised and untreated, it is rapidly fatal. Even when appropriate treatment is prescribed, mortality rates of 30% have been reported, while survivors may be left with neurological sequelae. Clinical features, investigations and management are described on p. 1217.

Bone and joint disease

The spine is the most common site for bony TB (Pott disease), which usually presents with chronic back pain and typically involves the lower thoracic and lumbar spine (see Fig. 17.38 and Fig. 25.30). The infection starts as a discitis and then spreads along the spinal ligaments to involve the adjacent anterior vertebral bodies, causing angulation of the vertebrae with subsequent kyphosis. Paravertebral and psoas abscess formation is common and the disease may present with a large (cold) abscess in the inguinal region. Imaging with CT or MRI is valuable in gauging the extent of disease, the degree of cord compression and the site for needle biopsy or open exploration, if required. The major differential diagnosis is malignancy, which tends to affect the vertebral body and leave the disc intact. Important complications include spinal instability or cord compression.

Any joint can be affected by TB, but the most frequently involved sites are the hip and knee. Presentation is usually insidious, with pain and swelling; fever and night sweats are uncommon. Radiological changes are often non-specific but, as disease progresses, reduction in joint space and erosions appear. Poncet arthropathy is an immunologically mediated polyarthritis that usually resolves within 2 months of starting treatment.

Genitourinary disease

Fever and night sweats are rare with renal tract TB, and patients are often only mildly symptomatic for many years. Haematuria, frequency and dysuria are often present, with sterile pyuria found on urine microscopy and culture. In women, infertility from endometritis, or pelvic pain and swelling from salpingitis or a tubo-ovarian abscess, occurs occasionally. In men, genitourinary TB may present as epididymitis or prostatitis.

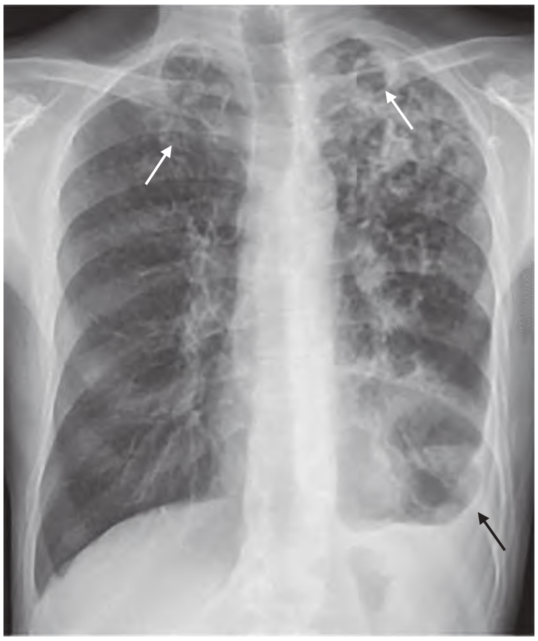

Fig. 17.39 Typical changes of tuberculosis on chest X-ray. Chest X-ray from a patient with TB showing bilateral upper lobe consolidation with areas of cavitation (white arrows) and a small pleural effusion at the left base (black arrow).

17.51 Diagnosis of tuberculosis

Specimens required

Pulmonary

- Sputum[1] (induced with nebulised hypertonic saline if patient not expectorating)
- Bronchoscopy with washings or BAL
- Gastric washing[1] (mainly used for children)

Extrapulmonary

- Fluid examination (cerebrospinal, ascitic, pleural, pericardial, joint): yield classically very low
- Tissue biopsy (from affected site or enlarged lymph node): bone marrow/liver may be diagnostic in disseminated disease

Diagnostic tests

- Stain
  Auramine fluorescence
  Ziehl–Neelsen
- Nucleic acid amplification[2]
- Culture
  Solid media (Löwenstein–Jensen, Middlebrook)
  Liquid media (MGIT)
- Pleural fluid: adenosine deaminase
- Response to empirical antituberculous drug treatment

Baseline blood tests

- Full blood count, C-reactive protein, urea and electrolytes, liver function tests

[1] Preferably three morning samples.
[2] Tests such as the Xpert MTB/RIF assay simultaneously detect TB and resistance to rifampicin.
(BAL = bronchoalveolar lavage; MGIT = mycobacteria growth indicator tube)

Investigations

The presence of an otherwise unexplained cough for more than 3 weeks, particularly in a region where TB is prevalent, or the finding of typical CXR or CT changes (Fig. 17.39) should prompt further investigation (Box 17.51). Direct microscopy of a sputum smear remains one of the most important first steps. At least two sputum samples (including at least one obtained in the early morning) from a spontaneously produced deep cough should be obtained. Induced sputum may be used in those unable to expectorate. In selected cases, bronchoscopy and lavage or aspiration of a lymph node by EBUS may be used.

Light-emitting diode fluorescent microscopy with auramine staining (Fig. 17.40) is increasingly replacing the more traditional standard light microscopy and Ziehl–Neelsen stain. A positive smear is sufficient for the presumptive diagnosis of TB, but definitive diagnosis requires either culture or the detection of *M. tuberculosis* DNA. The probability of visualising acid-fast bacilli (AFB) is proportional to the bacillary burden in the sputum. Smear-negative sputum should also be cultured, as only 10–100 viable organisms are required for sputum to be culture-positive. A diagnosis of smear-negative TB may be considered in advance of culture if the CXR appearances are typical of TB.

The slow growth of MTB on solid (typically between 4 and 6 weeks) and liquid (typically around 2 weeks) culture media has prompted the development of rapid NAATs. The WHO now recommends use of the GeneXpert MTB/RIF as an initial diagnostic test for MTB detection and rifampicin-resistance in sputum rather than smear microscopy, although for practical purposes a smear is still usually performed first, particularly in countries of low TB prevalence.

The diagnosis of extrapulmonary TB can be more challenging. There are generally fewer organisms (particularly in meningeal or pleural fluid), so culture, histopathological examination of tissue and/or NAAT may be required. Stimulation of T cells by mycobacterial antigens leads to increased levels of adenosine deaminase (ADA) in pleural, pericardial, cerebrospinal and ascitic fluid, so measuring ADA in these fluids may support a diagnosis of TB but should not replace culture. The IGRA and tuberculin skin tests have low sensitivity and specificity, and are not routinely used in the diagnosis of active TB infection.

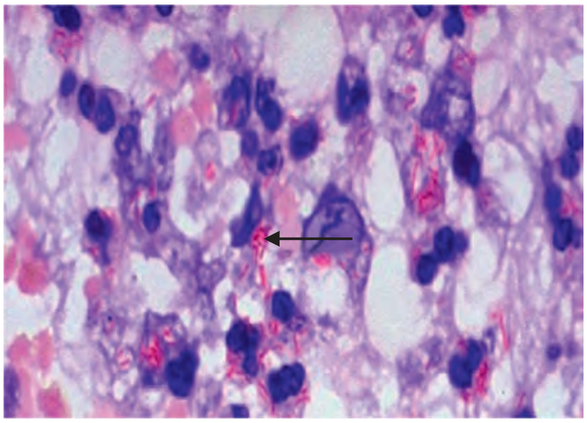

Fig. 17.40 Auramine-stained sputum sample. *Mycobacterium tuberculosis* and other mycobacteria retain the auramine stain after washing with acid and alcohol and are therefore seen as fluorescent organisms against a dark background. *Courtesy of Richard Hobson.*

Drug sensitivity testing

The rapid detection of drug resistance is central both to the management of the individual with TB and to control of the disease in the population. Molecular tests are increasingly used to provide rapid drug sensitivity testing (DST), particularly with regard to the detection of rifampicin resistance, which is important because rifampicin forms the cornerstone of 6-month chemotherapy. The GeneXpert MTB/RIF (see above) can detect molecular markers of rifampicin resistance in less than 2 hours. The gold standard is culture, followed where possible by whole genome sequencing (WGS), which is now being used routinely in resource-rich settings both for identification of mycobacterium and to predict antimicrobial susceptibility, at least to first-line agents.

Management

Chemotherapy

The treatment of TB is based on the principle of an initial intensive phase to reduce the bacterial population rapidly, followed by a continuation phase to destroy any remaining bacteria. Treatment options for newly diagnosed TB are summarised in Box 17.52. Standard WHO-recommended treatment involves 6 months' treatment with isoniazid and rifampicin (the continuation phase), supplemented in the first 2 months (the intensive phase) with pyrazinamide and ethambutol. Ethambutol is given throughout the continuation phase in countries with high levels of isoniazid resistance in new TB patients, and where DST is not performed (or results are unavailable) before the continuation phase begins. Fixed-dose tablets combining two, three or four drugs are preferred to reduce pill burden and increase adherence. A 4-month regimen of isoniazid, rifapentine, and moxifloxacin in the continuation phase, supplemented in the first 2 months with pyrazinamide in the intensive phase, was introduced by WHO in 2022. However, poor access to rifapentine, lack of fixed-dose combination tablets, and high cost have limited implementation. Unless there is reason to suspect drug resistance or non-tuberculous mycobacterium, treatment should be commenced immediately in any patient who is smear-positive, and in those who are smear-negative but with typical CXR changes and no response to standard antibiotics. Where drug resistance is not anticipated, patients can be assumed to be non-infectious after 2 weeks of appropriate therapy.

Six months of therapy is appropriate for most patients with pulmonary or extrapulmonary TB. However, extended courses of therapy are recommended for CNS and bone and joint TB (12–18 months). Extended durations of treatment should also be considered in patients whose sputum remains culture positive following the intensive phase, having first reassessed for drug resistance, poor adherence and malabsorption. Note that treatment extension relates to prolonged therapy with drugs used in the continuation phase rather than continued therapy with drugs used in the intensive phase.

17.52 Treatment of newly diagnosed tuberculosis

Intensive phase	Continuation phase	Comments
Standard regimen		
2 months of HRZE daily	4 months of HR daily	
2 months of HRZE daily	4 months of HRE	Applies only in countries with high levels of isoniazid resistance in new TB patients, and where isoniazid drug susceptibility testing in new patients is not done (or results are unavailable) before the continuation phase begins
Dosing frequency		
Daily*	Daily	Optimal
Daily*	3 times/week	No longer recommended but sometimes used in practice for patients receiving directly observed therapy
3 times/week	3 times/week	No longer recommended but sometimes used in practice for patients receiving directly observed therapy, provided the patient is *not* living with HIV or living in an HIV-prevalent setting

*Daily (rather than 3 times weekly) intensive-phase dosing may help to prevent acquired drug resistance in TB patients starting treatment with isoniazid resistance.
(H = isoniazid; R = rifampicin; Z = pyrazinamide; E = ethambutol; HIV = human immunodeficiency virus)
Adapted from World Health Organization. Guidelines for treatment of drug-susceptible tuberculosis and patient care, 2017 update.

Most patients can be treated at home. Admission to a hospital unit with appropriate isolation facilities should be considered when there is uncertainty about the diagnosis, intolerance of medication, questionable treatment adherence, adverse social conditions or a significant risk of multidrug-resistant TB.

Adverse drug reactions occur in about 10% of patients (Box 17.53). Patients treated with rifampicin should be advised that their urine, tears and other secretions will develop a bright, orange/red coloration. Rifampicin is a cytochrome P450 inducer; it accelerates the metabolism of several drugs, thereby reducing their effective dose. These medications include steroids, oral hypoglycaemic drugs, antiretrovirals, warfarin, opiates (including methadone) and contraceptives. Women taking oral or depot hormonal contraceptives must be warned that their efficacy, and that of emergency hormonal contraception, will be reduced and alternative contraception may be necessary. Standard TB medication is safe during pregnancy; however, pregnant women experience an increased rate of side-effects, so conception is not advised. In order to reduce the risk of isoniazid-related peripheral neuropathy, pyridoxine should be prescribed for those who are pregnant, malnourished, or who have HIV, chronic kidney disease (CKD), diabetes mellitus or alcohol dependence. Ethambutol should be used with caution in severe renal impairment, with appropriate dose reduction and monitoring of drug levels. Visual acuity and colour vision should be assessed before commencing ethambutol.

Baseline liver function and regular monitoring are important for patients treated with standard therapy. Rifampicin may cause asymptomatic hyperbilirubinaemia but, along with isoniazid and pyrazinamide, may also cause hepatitis. Mild asymptomatic increases in transaminases are common, but significant hepatotoxicity occurs in only 2%–5%. It is important to stop treatment and allow any symptoms to subside and the liver function tests to recover before commencing a stepwise re-introduction of the individual drugs. Less hepatotoxic regimens may be considered, including aminoglycosides, ethambutol and fluoroquinolones.

Corticosteroids reduce inflammation and limit tissue damage; they are currently recommended when treating constrictive pericarditis or CNS disease, and in children with endobronchial disease. They may confer benefit in TB of the ureter, pleural effusions and extensive pulmonary disease, and can suppress hypersensitivity drug reactions. Embolisation should be considered for treatment of massive haemoptysis. Surgery is required for patients with spinal TB causing spinal cord compression.

The effectiveness of therapy for pulmonary TB is assessed by further sputum analysis at 2 months to ensure sputum culture conversion, if the patient is still producing sputum. If sputum is culture-positive at 2 months, repeat sputum should be obtained at month 3. If this sample is culture-positive, then DST should be repeated. Treatment failure is defined as a positive sputum culture at 5 months or any patient with a newly converted multidrug-resistant strain, regardless of whether they are smear-positive or -negative. Extrapulmonary TB must be assessed clinically or radiographically, as appropriate.

Control and prevention

Active TB is preventable, particularly so in those with latent TB. Supporting the development of laboratory and health-care services to improve detection and treatment of active and latent TB is an important component of this goal.

Latent TB infection

The majority of individuals exposed to MTB harbour the bacteria, which remain dormant. They do not develop any signs of active disease and are non-infectious. They are, however, at risk of developing active TB disease and becoming infectious. The lifetime risk of TB disease for a person with documented latent TB infection (LTBI) is estimated at 5%–15%, with the majority of cases occurring within the first 5 years after initial infection.

LTBI may be identified by the presence of immune responses to *M. tuberculosis* antigens in the absence of clinical disease. Contact tracing is a legal requirement in many countries. It has the potential to identify the probable index case, other cases infected by the same index patient (with or without evidence of disease) and close contacts who should receive BCG (bacille Calmette–Guérin) vaccination (see below) or chemotherapy. Approximately 10%–20% of close contacts of patients with smear-positive pulmonary TB and 2%–5% of those with smear-negative, culture-positive disease have evidence of TB infection.

Cases are commonly identified using the tuberculin skin test (TST; Fig. 17.41) or an IGRA (Fig. 17.42). An otherwise asymptomatic contact who tests positive but has a normal CXR may be treated with chemoprophylaxis to prevent infection from progressing to clinical disease. Chemoprophylaxis should be offered to adults up to the age of 65 (although age-specific cut-off varies by country). It should also be considered for HIV-infected close contacts of a patient with smear-positive disease. A course of rifampicin and isoniazid for 3 months or isoniazid for 6 months is effective.

Tuberculin skin testing may be associated with false-positive reactions in those who have had a BCG vaccination and in areas where exposure to non-tuberculous mycobacteria is high. The skin tests may also be falsely negative in the setting of immunosuppression or overwhelming TB infection.

The IGRA detects the release of interferon-gamma (IFN-γ) from sensitised T cells in response to antigens, such as early secretory antigenic target (ESAT)-6 or culture filtrate protein (CFP)-10, which are encoded by genes specific to *M. tuberculosis* and are not shared with BCG or opportunistic mycobacteria (see Fig. 17.42). The IGRA is more specific than skin testing and logistically more convenient, as it requires a single blood test rather than two clinic visits. In the UK, IGRA represents the first choice investigation, except in children, for whom TST is recommended.

Directly observed therapy

Poor adherence to therapy is a major factor in prolonged illness, risk of relapse and the emergence of drug resistance. Directly observed therapy (DOT) involves the supervised administration of therapy every day (thrice weekly dosing is no longer recommended due to higher rates of

17.53 Main adverse reactions of first-line antituberculous drugs

[3] Reduced visual acuity and colour vision may be reported with higher doses and are usually reversible.

treatment failure, relapse and acquired drug resistance) to improve adherence. Introduction of DOT has become an important control strategy in resource-poor nations. In the UK, it is currently recommended for patients with previous TB, multidrug-resistant TB, poor adherence to treatment, denial of the diagnosis, those with a history of homelessness, alcohol or drug misuse, those currently or recently in prison, and those with major psychiatric, memory or cognitive disorders. If appropriate facilities are available, DOT can be replaced by video-observed consultation (VOT).

The release of interferon-gamma (IFN-γ) by the cells is measured by enzyme-linked immunosorbent assay (ELISA). (ELISPOT = enzyme-linked immunosorbent spot assay)

TB and HIV/AIDS

The close links between HIV and TB, particularly in sub-Saharan Africa, and the potential for both diseases to overwhelm health-care funding in resource-poor nations, have been recognised, with the promotion of programmes that link detection and treatment of TB with detection and treatment of HIV. It is recommended that all patients with TB should be tested for HIV infection, in addition to hepatitis B and C. Mortality is high and TB is a leading cause of death in HIV-positive patients. Full discussion of its presentation and management with antiretroviral therapy (ART) is given in Chapter 14.

ART should be initiated for all HIV-positive patients with TB. ART is usually initiated after 2 weeks of tuberculous therapy but should be delayed until 4 weeks of starting TB treatment in patients with CNS TB and a CD4 count under 50 cells/μL to reduce the risk of immune reconstitution inflammatory syndrome (IRIS). TB-associated (TB-)IRIS is a paradoxical increase in pre-existing, or development of new, TB signs or symptoms due to ART reactivating the immune system. The syndrome can be self-limiting, but in severe cases, steroids are used to reduce symptoms, and patients are advised to continue TB chemotherapy and ART. The choice of initial ART or changes in existing ART should reflect the need to avoid drug–drug interactions. Rifampicin interacts with some or all drugs within each class of ART. Websites such as: www.hiv-druginteractions.org provide practical advice to ensure safe and effective co-administration of ART with all other medications.

Drug-resistant TB

Drug-resistant TB is defined by the presence of resistance to any first-line agent. Multidrug-resistant tuberculosis (MDR-TB) is defined by resistance to at least rifampicin and isoniazid, with or without other drug resistance. Rifampicin-resistant TB (RR-TB) requires similar treatment to MDR-TB, as rifampicin is the cornerstone of TB treatment. Globally, an estimated 3.3% of new TB cases and 17% of previously treated cases have MDR-TB/RR-TB. In 2022, an estimated 160 000 people died of MDR/RR-TB. The term pre-extensively drug-resistant TB (pre-XDR-TB) is used to describe TB that is resistant to rifampicin and any fluoroquinolone, whilst extensively drug-resistant tuberculosis (XDR-TB) is also resistant to at least one of bedaquiline, levofloxacin, linezolid or moxifloxacin. An estimated 18% of people with MDR/RR-TB have pre-XDR TB. Whilst the prevalence of MDR-TB is stable globally, it is increasing in the Americas and South-east Asia, and remains high in India, the Russian Federation, China, Pakistan and Nigeria. It is more common in individuals with a prior history of TB, particularly if treatment has been inadequate. The factors that contribute to the emergence of drug-resistant TB are shown in Box 17.54. The diagnosis of drug-resistant TB is challenging, especially in resource-poor settings, and although cure is possible, it has traditionally required prolonged treatment with less effective, more toxic and more expensive second-line therapies. However, recent research has revolutionised management, with the introduction of new regimens reducing treatment duration from over 18 months down to 6 to 9 months. These regimens involve 3 to 7 oral antimycobacterial agents, with bedaquiline as the cornerstone of therapy; first-line treatment is with bedaquiline (titrated to 200 mg 3 times

i

17.54 Factors contributing to the emergence of drug-resistant tuberculosis

- Drug shortages
- Poor-quality drugs
- Poor concordance with drugs
- Lack of appropriate supervision
- Transmission of drug-resistant strains
- Prior antituberculosis treatment
- Treatment failure (culture-positive at 5 months)

a week), pretomanid (200 mg once daily), linezolid (600 mg once daily) and moxifloxacin (800 mg once daily).

It is estimated that only 43% of those with MDR/RR-TB commenced appropriate treatment in 2022. For those who do receive it, treatment was successful in 63% in 2021 (compared to 50% in 2012). The mortality rate from tuberculosis increases with the level of drug resistance.

Vaccines

Bacille Calmette–Guérin (BCG) is the best-established TB vaccine; it is a live attenuated vaccine derived from *M. bovis*. The BCG vaccine is administered by intradermal injection and is highly immunogenic. It appears to be effective in preventing disseminated disease, including tuberculous meningitis, in children, but its efficacy in adults is inconsistent and new vaccines are urgently needed. Current vaccination policies vary worldwide according to incidence and health-care resources but usually target children and other high-risk individuals. The BCG vaccine is very safe, with the occasional complication of local abscess formation. It should not be administered to those who are immunocompromised by HIV, those on immunosupressives or pregnant women.

Prognosis

Following successful completion of chemotherapy, cure should be anticipated in the majority of patients, though complications such as lung scarring and bronchiectasis are not uncommon (Box 17.55). There is a small (<5%) and unavoidable risk of relapse. Most relapses occur within 5 months and usually have the same drug susceptibility. In the absence of treatment, a patient with smear-positive TB will remain infectious for an average of 2 years; in 1 year, 25% of untreated cases will die. Death is more likely in those who are smear-positive and those who smoke. A few patients die unexpectedly soon after commencing therapy, and it is possible that some have subclinical hypoadrenalism that is unmasked by a rifampicin-induced increase in corticosteroid metabolism. HIV-positive patients have higher mortality rates and a modestly increased risk of relapse.

Non-tuberculous mycobacterial infection

Other species of environmental mycobacteria (termed ‘non-tuberculous’) may cause human disease (Box 17.56). The sites commonly involved are the lungs, lymph nodes, skin and soft tissues. The most widely recognised of these mycobacteria, *M. avium* complex (MAC), is well described in severe HIV disease (CD4 count <50 cells/μL). However, several others (including MAC) colonise and/or infect apparently immunocompetent patients with chronic lung diseases such as COPD, bronchiectasis, pneumoconiosis, old TB or cystic fibrosis. The clinical presentation varies from a relatively indolent course in some to an aggressive course characterised by cavitatory or nodular disease in others. Radiological appearances may be similar to classical TB, but in patients with bronchiectasis, opportunistic infection may present with lower-zone nodules. The most commonly reported organisms include *M. kansasii*, *M. malmoense*, *M. xenopi* and *M. abscessus*, but geographical variation is marked. *M. abscessus* and *M. fortuitum* grow rapidly but the majority of others grow slowly. Microscopy and culture are used to identify non-tuberculous mycobacteria, with *M. abscessus* and *M. fortuitum* growing rapidly but the majority of others more slowly. Drug sensitivity testing is often unhelpful in predicting treatment response, with the exception of macrolide susceptibility for MAC and rifampicin sensitivity for *M. kansasii*. In the UK, these organisms are not notifiable to local public health departments as they are not normally communicable; patient-to-patient transmission of *M. abscessus* in cystic fibrosis is a key exception.

17.55 Complications of pulmonary tuberculosis

- Bronchiectasis
- Massive haemoptysis
- Cor pulmonale
- Fibrosis/emphysema
- Atypical mycobacterial infection
- Aspergilloma/chronic pulmonary aspergillosis
- Obstructive airways disease
- Bronchopleural fistula
- Lung/pleural calcification and pleural thickening

Non-pulmonary complications

- Empyema necessitans
- Laryngitis
- Enteritis*
- Anorectal disease*
- Amyloidosis
- Poncet polyarthritis

*From swallowed sputum.

Respiratory diseases caused by fungi

The majority of fungi encountered by humans are harmless saprophytes, but in certain circumstances some species may cause disease by infecting human tissue, promoting damaging allergic reactions or producing toxins. ‘Mycosis’ is the term applied to disease caused by fungal infection. The predisposing factors for pulmonary fungal disease are shown in Box 17.57, and the classification of bronchopulmonary aspergillosis is shown in Box 17.58.

17.56 Site-specific opportunistic mycobacterial disease

Pulmonary

- *M. xenopi*
- *M. kansasii*
- *M. malmoense*
- MAC
- *M. abscessus* (in cystic fibrosis)

Lymph node

- MAC
- *M. malmoense*
- *M. fortuitum*
- *M. chelonei*

Soft tissue/skin

- *M. leprae*
- *M. ulcerans* (prevalent in Africa, northern Australia and South-east Asia)
- *M. marinum*
- *M. fortuitum*
- *M. chelonae*

Disseminated

- MAC (HIV-associated)
- *M. haemophilum*
- *M. genavense*
- *M. chimera* (cardiopulmonary bypass-associated)
- *M. fortuitum*
- *M. chelonae*
- BCG

(BCG = bacille Calmette–Guérin; MAC = *Mycobacterium avium* complex – *M. scrofulaceum*, *M. intracellulare* and *M. avium*)

17.57 Factors predisposing to pulmonary fungal disease

Systemic factors

- Haematological malignancy
- HIV
- Diabetes mellitus
- Chronic alcoholism
- Radiotherapy
- Glucocorticoids, cytotoxic chemotherapy, biologic therapies and other immunosuppressant medication

Local factors

- Tissue damage by suppuration or necrosis
- Alteration of normal bacterial flora by antibiotic therapy

17.58 Classification of bronchopulmonary aspergillosis

- Allergic bronchopulmonary aspergillosis (asthmatic pulmonary eosinophilia)
- Hypersensitivity pneumonitis (*Aspergillus clavatus*)
- Intracavitary aspergilloma
- Invasive pulmonary aspergillosis
- Chronic and subacute pulmonary aspergillosis

Allergic bronchopulmonary aspergillosis

Allergic bronchopulmonary aspergillosis (ABPA) occurs as a result of a hypersensitivity reaction to germinating fungal spores in the airway wall. The condition may complicate the course of asthma and cystic fibrosis and is a recognised cause of pulmonary eosinophilia. The prevalence of ABPA is approximately 1%–2% in asthma and 5%–10% in patients with CF. A variety of human leucocyte antigens (HLAs) convey both an increased and a decreased risk of developing the condition, suggesting that genetic susceptibility is important.

Clinical features

Clinical features depend on the stage of the disease. Common manifestations in the early phases include fever, breathlessness, cough productive of bronchial casts and worsening of asthmatic symptoms. The appearance of radiographic infiltrates may cause ABPA to be mistaken for pneumonia, but the diagnosis may also be suggested by segmental or lobar collapse on CXR of patients whose asthma symptoms are stable. Diagnostic features are shown in Box 17.59. If bronchiectasis develops, the symptoms and complications of that disease often overshadow those of asthma.

Management

Allergic bronchopulmonary aspergillosis is generally considered an indication for regular therapy with low-dose oral corticosteroids (prednisolone 7.5–10 mg/day) with the aim of suppressing the immunopathological responses and preventing progressive tissue damage. In some patients, itraconazole (400 mg/day) facilitates a reduction in oral corticosteroids; a 4-month trial is usually recommended to assess its efficacy, but there needs to be consideration for the interactions with inhaled corticosteroids. The use of biological therapies which target IgE, IL-5 and the IL-4/IL-13 signalling pathways are under investigation for patients with ABPA which is inadequately controlled by standard therapy. Exacerbations of ABPA, particularly when associated with new CXR changes, should be treated promptly with prednisolone (40–60 mg/day) and physiotherapy. If persistent lobar collapse occurs, bronchoscopy (usually under general anaesthetic) should be performed to remove impacted mucus and ensure prompt re-inflation.

Chronic pulmonary aspergillosis

The term chronic pulmonary aspergillosis (CPA) encompasses simple aspergilloma, chronic cavitary pulmonary aspergillosis, chronic fibrosing pulmonary aspergillosis, *Aspergillus* nodule and semi-invasive aspergillosis. They are uncommon conditions and challenging to diagnose and treat.

Simple aspergilloma

Cavities left by diseases such as TB or by damaged bronchi provide favourable conditions in which inhaled *Aspergillus* may lodge and germinate. At the earliest stage, CT scanning may identify an irregular mucosal wall and as fungal growth progresses, this finally collapses into the cavity, forming a fungal ball that may be identified on imaging (Fig. 17.43).

Simple aspergillomas are often asymptomatic. They can, however, give rise to a variety of non-specific symptoms, such as lethargy and weight loss, and may cause recurrent haemoptysis, which may be life-threatening.

i 17.59 Features of allergic bronchopulmonary aspergillosis

- Asthma (in the majority of cases)
- Proximal bronchiectasis (inner two-thirds of chest CT field)
- Positive skin test to an extract of *Aspergillus fumigatus*
- Elevated total serum IgE > 417 kU/L (1000 ng/mL)
- Elevated *A. fumigatus*-specific IgE or IgG
- Peripheral blood eosinophilia > 0.5 × 10^9/L
- Presence or history of an abnormal CXR
- Recovery of *A. fumigatus* from sputum

(CT = computed tomography; Ig = immunoglobulin)

The typical radiological picture is invariably accompanied by elevated serum IgG/precipitins to *A. fumigatus*. Sputum microscopy typically demonstrates scanty hyphal fragments and is usually positive on culture. Less than half exhibit skin hypersensitivity to extracts of *A. fumigatus*. Rarely, other filamentous fungi can cause intracavity mycetoma and are identified by culture.

Asymptomatic cases do not require treatment, but haemoptysis should be controlled by surgery. Tranexamic acid or bronchial artery embolisation may provide a bridge to surgery or palliate haemoptysis when surgery is not possible. Antifungal agents are usually not beneficial due to poor penetration into the mycetoma, and generally surgical resection is the treatment of choice. Antifungals can be tried in patients with multiple mycetomas or those who are not fit enough for surgical resection. Instillation of antifungal agents, such as amphotericin B, via a catheter placed into the cavity has been reported to be effective but is rarely used in the UK.

Chronic cavitary pulmonary aspergillosis and chronic fibrosing pulmonary aspergillosis

The features of chronic cavitary pulmonary aspergillosis (CCPA) include cough (with or without haemoptysis), weight loss, anorexia and fatigue over months or years, with associated fever, night sweats and elevated inflammatory markers. Radiological features include thick-walled cavities (predominantly apical), pulmonary infiltrates and pleural thickening (Fig. 17.44). The diagnosis rests on a combination of radiological examination, histopathology, isolation of fungus from the respiratory tract and detection of *Aspergillus* IgG in serum. Treatment usually involves prolonged courses of itraconazole or voriconazole. Cure is unusual, and the most frequent pattern is chronic relapse/remission with gradual deterioration. Surgical intervention is fraught with complications and should be avoided. Many patients are malnourished and require nutritional support. Corticosteroids should be avoided. As CCPA progresses, fibrotic destruction of the lung results, and the condition may then be referred to as chronic fibrosing pulmonary aspergillosis (CFPA).

Aspergillus nodule

The formation of one or more nodules is a less common manifestation of *Aspergillus* infection. The *Aspergillus* nodule may mimic lung cancer or TB but cavitation is unusual. Cryptococcosis or coccidioidomycosis should be considered in areas where these conditions are endemic.

Subacute invasive aspergillosis

Subacute invasive aspergillosis (SIA) was previously referred to as chronic necrotising or semi-invasive pulmonary aspergillosis. The clinical and radiological picture is similar to CCPA, but lung biopsy demonstrates invasion of lung tissue by hyphae. The development of SIA is favoured by mild immunocompromise and should be suspected in patients with

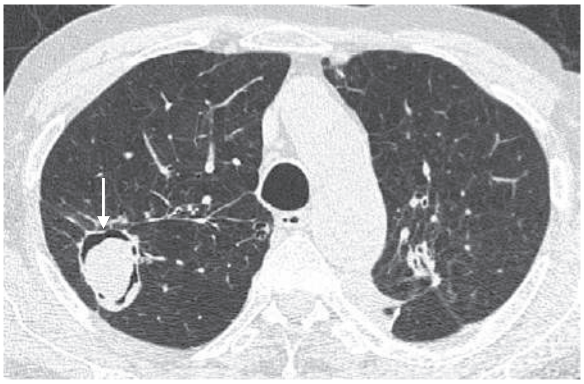

Fig. 17.43 Aspergilloma in the right upper lobe. The chest CT shows a rounded fungal ball separated from the wall of the cavity by an 'air crescent' (arrow).

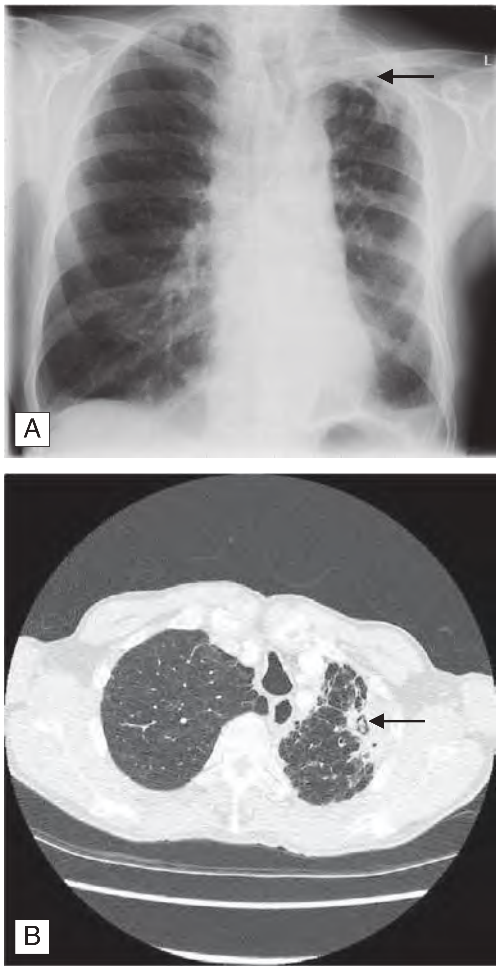

Fig. 17.44 **Chronic pulmonary aspergillosis.** **A** The CXR shows pleural thickening with loss of lung volume at the left apex (arrow). **B** High-resolution CT reveals multiple small cavities and pleural thickening with an aspergilloma and surrounding air crescent (arrow) in one of the cavities. *Courtesy of Professor David Denning, National Aspergillosis Centre, Manchester, UK.*

diabetes mellitus, malnutrition or alcoholism, or with advanced age and in prolonged corticosteroid use. It is also seen in the presence of COPD, non-tuberculous mycobacteria or HIV infection. SIA should be treated in a similar manner to invasive pulmonary aspergillosis.

Invasive pulmonary aspergillosis

Invasive pulmonary aspergillosis (IPA) is most commonly a complication of profound neutropenia caused by drugs (especially immunosuppressive agents) and/or disease (Box 17.60).

Clinical features

Acute IPA causes a severe necrotising pneumonia and must be considered in any immunocompromised patient who develops fever, new respiratory symptoms (particularly pleural pain or haemoptysis) or a pleural rub. Invasion of pulmonary vessels causes thrombosis and infarction, and systemic spread may occur to the brain, heart, kidneys and other organs. Tracheobronchial aspergillosis involvement is characterised by the formation of fungal plaques and ulceration.

Imaging with HRCT characteristically shows macronodules (usually ≥ 1 cm), which may be surrounded by a 'halo' of intermediate attenuation if captured early (< 5 days). Culture or histopathological evidence of *Aspergillus* in diseased tissues provides a definitive diagnosis, but the majority of patients are too ill for invasive tests, such as bronchoscopy or lung biopsy. Other investigations include detection of *Aspergillus* galactomannan in blood or BAL fluid, β-1,3-D-glucan in blood and (where available) *Aspergillus* DNA in blood. The diagnosis can often be inferred from a combination of features (Box 17.61).

17.60 Risk factors for invasive aspergillosis

- Neutropenia: risk related to duration and degree
- Solid organ or allogeneic stem cell transplantation
- Prolonged high-dose glucocorticoid therapy
- Leukaemia and other haematological malignancies
- Cytotoxic chemotherapy
- Advanced HIV disease
- Severe chronic obstructive pulmonary disease
- Critically ill patients on intensive care units
- Chronic granulomatous disease

17.61 Criteria for the diagnosis of probable invasive pulmonary aspergillosis

Host factors

- Recent history of neutropenia ($< 0.5 \times 10^9$/L for ≥ 10 days) temporally related to the onset of fungal disease
- Recipient of allogeneic stem cell transplant
- Prolonged use of glucocorticoids (average minimum 0.3 mg/kg daily prednisolone or equivalent) for > 3 weeks (excludes allergic bronchopulmonary aspergillosis)
- Treatment with other immunosupressants during the last 90 days
- Inherited severe immune deficiency, such as chronic granulomatous disease or severe combined immune deficiency

Clinical criteria[1]

- The presence of one of the following on CT:
  - Dense, well-circumscribed lesion(s) with or without a halo sign
  - Air crescent sign
  - Cavity

Tracheobronchitis

- Tracheobronchial ulceration, nodule, pseudomembrane, plaque or eschar seen on bronchoscopy

Mycological criteria

- Mould in sputum, BAL fluid or bronchial brush, indicated by one of the following:
  - Recovery of fungal elements indicating a mould of *Aspergillus*
  - Recovery by culture of a mould of *Aspergillus*
- Indirect tests (detection of antigen or cell wall constituents)
  - Galactomannan antigen in plasma, serum or BAL fluid
  - β-1,3-glucan detected in serum (detects other species of fungi, as well as *Aspergillus*)[2]

---

[1] Must be consistent with the mycological findings and temporally related to current episode.
[2] May be useful as a preliminary screening tool for invasive aspergillosis.
Adapted from De Pauw B, Walsh TJ, Donnelly JP, et al. Revised definitions of invasive fungal disease from the European Organisation for Research and Treatment of Cancer/Mycoses Study Group. Clin Infect Dis 2008;46:1813–1821.

Management and prevention

Invasive pulmonary aspergillosis carries a high mortality rate, especially if treatment is delayed. The drug of choice is voriconazole. Second-line agents include liposomal amphotericin, caspofungin, posaconazole and isavuconazole. Response may be assessed clinically, radiologically and serologically (by estimation of the circulating galactomannan level). Recovery is dependent on immune reconstitution, which may be accompanied by enlargement and/or cavitation of pulmonary nodules.

Patients at risk of *Aspergillus* (and other fungal infections) should be managed in rooms with high-efficiency particulate air (HEPA) filters and laminar airflow. In areas with high spore counts, patients are advised to wear a mask if venturing outside their hospital room. Posaconazole (200 mg 3 times daily) or itraconazole (200 mg/day) may be prescribed for primary prophylaxis, and patients with a history of definite or probable IPA should be considered for secondary prophylaxis before further immunosuppression.

Other fungal infections

Mucormycosis may present with a pulmonary syndrome that is clinically indistinguishable from acute IPA. Diagnosis relies on histopathology (where available) and/or culture of the organism from diseased tissue. The principles of treatment are as for other forms of mucormycosis: correction of predisposing factors, antifungal therapy with high-dose lipid amphotericin B or posaconazole (second line), and surgical débridement.

The endemic mycoses (histoplasmosis, coccidioidomycosis, blastomycosis and emergomycosis) and cryptococcosis are discussed on pages 398–402. *Pneumocystis jirovecii* pneumonia is described on page 328.

Tumours of the bronchus and lung

Lung cancer is the most common cause of death from cancer worldwide, causing 1.8 million deaths in 2022 (Box 17.62). Tobacco use is the major preventable cause. Just as tobacco use and cancer rates are falling in some high-income countries, both smoking and lung cancer are rising in many low- and middle-income countries. The great majority of tumours in the lung are primary lung cancers and, in contrast to many other tumours, the prognosis remains poor, with approximately 40% and 16% of patients surviving at 1 and 5 years, respectively.

Primary tumours of the lung

Aetiology

Cigarette smoking is by far the most important cause of lung cancer. It is thought to be directly responsible for at least 85% of cases in the UK, the risk being proportional to the amount smoked and the tar content of cigarettes, but the proportion of cases not related to tobacco exposure is rising. The death rate from the disease in heavy smokers is 40 times that in non-smokers. Risk falls slowly after smoking cessation but remains above that in non-smokers for many years. It is estimated that 1 in 2 smokers dies from a smoking-related disease, about half in middle age. The effect of passive smoking is more difficult to quantify but is currently thought to be a factor in 5% of all lung cancer deaths. Exposure to naturally occurring radon is another risk. The incidence of lung cancer is slightly higher in urban than in rural dwellers, which may reflect differences in atmospheric pollution (including tobacco smoke) or occupation, since a number of industrial materials are associated with lung cancer, such as asbestos, arsenicals and beryllium-containing compounds. In recent years, the strong link between smoking and ill health has led many governments to legislate against smoking in public places, and smoking prevalence and some smoking-related diseases are already declining in these countries.

i 17.62 The burden of lung cancer

- 1.8 million new cases worldwide each year
- Most common cancer in men
- Rates rising in women:
  - Female lung cancer deaths outnumber male in some Nordic countries
  - Has overtaken breast cancer in several countries
- More than a threefold increase in deaths since 1950
- More than 50% of cases have metastatic disease at diagnosis

Lung cancer

The incidence of lung cancer increased dramatically during the 20th century as a direct result of the tobacco epidemic (Fig. 17.45). In women, smoking prevalence and deaths from lung cancer continue to increase, and more women now die of lung cancer than breast cancer in the United States and the UK.

Pathology

Lung cancers arise from the bronchial epithelium or mucous glands. The common cell types are listed in Box 17.63. When the tumour occurs in a large bronchus, symptoms arise early, but tumours originating in a peripheral bronchus can grow very large without producing symptoms, resulting in delayed diagnosis. Lung cancers may undergo central necrosis and cavitation and may resemble a lung abscess on CXR (Fig. 17.46). Lung cancer may involve the pleura directly or by lymphatic spread and may extend into the chest wall, invading the intercostal nerves or the brachial plexus and causing pain. Lymphatic spread to mediastinal and supraclavicular lymph nodes often occurs before diagnosis. Blood-borne metastases occur most commonly in liver, bone, brain, adrenals and skin. Even a small primary tumour may cause widespread metastatic deposits, and this is a particular characteristic of small-cell lung cancers.

Clinical features

Lung cancer presents in many different ways, reflecting local, metastatic or paraneoplastic tumour effects.

Cough

This is the most common early symptom. It is often dry, but secondary infection may cause purulent sputum. A change in the character of a smoker's cough, particularly if associated with other new symptoms, should always raise suspicion of lung cancer.

Haemoptysis

Haemoptysis is common, especially with central bronchial tumours. Although it may be caused by infection, haemoptysis in a smoker should always be investigated to exclude a lung cancer. Occasionally, central tumours invade large vessels, causing sudden massive haemoptysis, which is invariably a terminal event.

Bronchial obstruction

Obstruction of a large bronchus is another common presentation, but there are other causes (Box 17.64). The clinical and radiological manifestations (Fig. 17.47) depend on the site and extent of the obstruction (see Fig. 17.5), any secondary infection and the extent of coexisting lung disease. Complete obstruction causes collapse of a lobe or lung, with breathlessness, mediastinal displacement and dullness to percussion with reduced breath sounds. Partial bronchial obstruction may cause a monophonic, unilateral wheeze that fails to clear with coughing, and may also impair the drainage of secretions to cause pneumonia or lung abscess as a presenting problem. Pneumonia that recurs at the same site or responds slowly to treatment, particularly in a smoker, should always suggest an underlying lung cancer. Stridor (a harsh inspiratory noise) occurs when the larynx, trachea or a main bronchus is narrowed by the primary tumour or by compression from malignant enlargement of the subcarinal and paratracheal lymph nodes.

Breathlessness

Breathlessness may be caused by collapse or pneumonia, or by tumour causing a large pleural effusion or compressing a phrenic nerve and leading to diaphragmatic paralysis.

Pain and nerve entrapment

Pleural pain may indicate malignant pleural invasion, although it can occur with distal infection. Intercostal nerve involvement causes pain in the distribution of a thoracic dermatome. Cancer in the lung apex may cause Horner syndrome (ipsilateral partial ptosis, enophthalmos, miosis and hypohidrosis of the face) due to involvement of the sympathetic nerves to the eye at or above the stellate ganglion. Pancoast syndrome

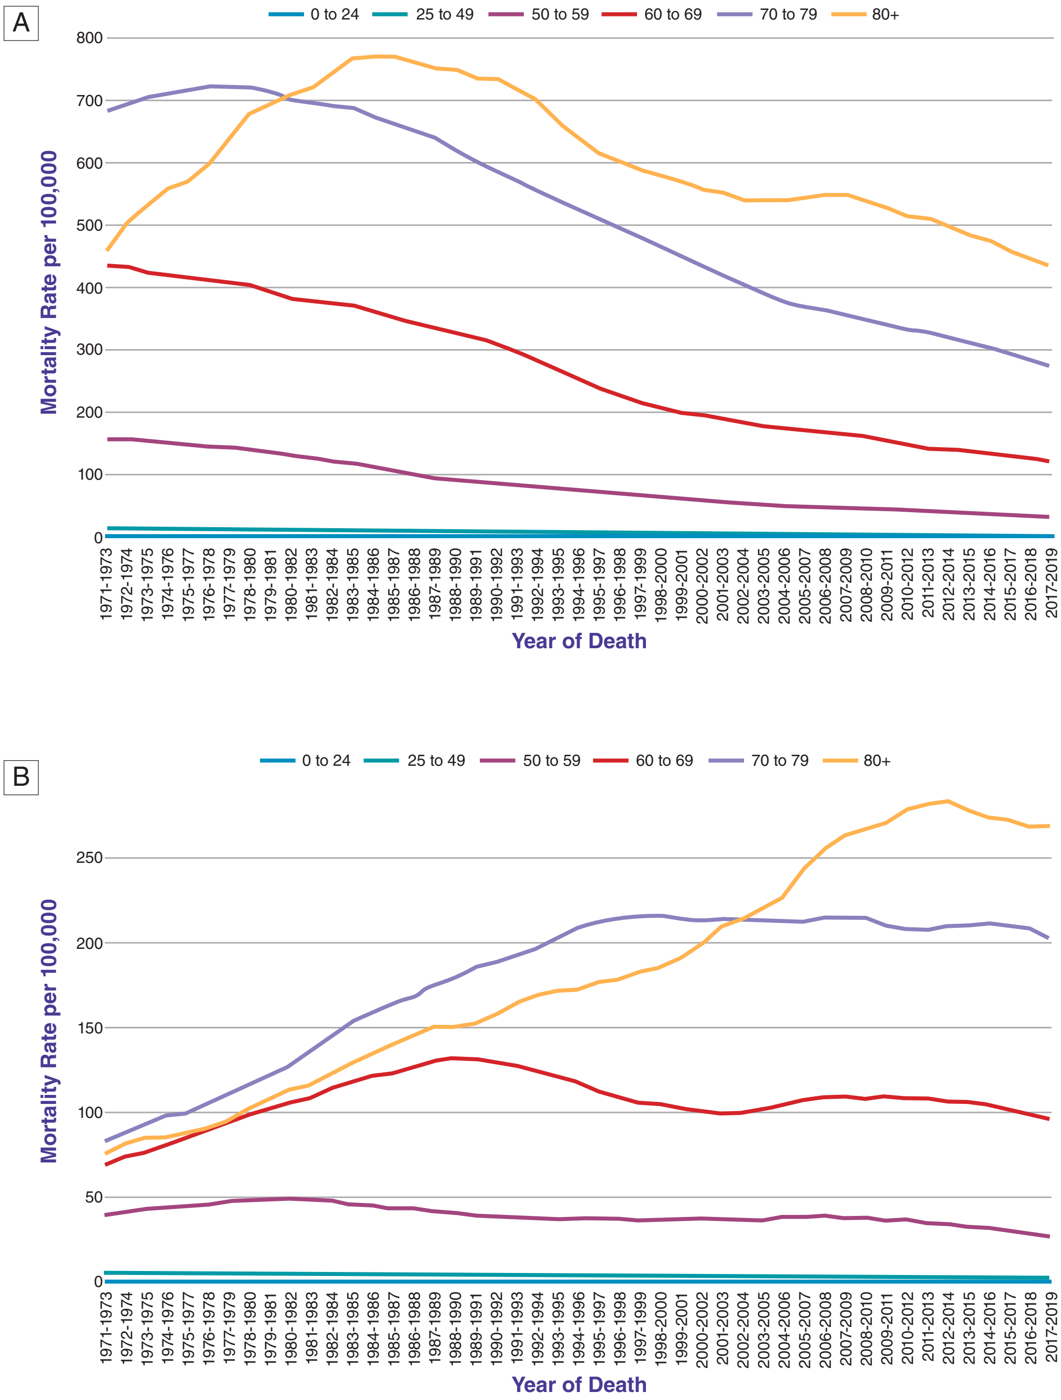

Fig. 17.45 Mortality trends from lung cancer in UK, 1971–2019, by age and year of death. **A** Males. **B** Females. Note the decline in mortality from lung cancer in men and increase in mortality in older women until 2015, reflecting changes in smoking habits. *From Cancer Research UK: www.cancerresearchuk.org/health-professional/cancer-statistics/statistics-by-cancer-type/lung-cancer/mortality#heading-Two.*

i 17.63 Common cell types in lung cancer

Cell type	%
Adenocarcinoma	35–40
Squamous	25–30
Small-cell	15
Large-cell	10–15

(pain in the inner aspect of the arm, sometimes with small muscle wasting in the hand) indicates malignant destruction of the T1 and C8 roots in the lower part of the brachial plexus by an apical lung tumour.

Mediastinal spread

Involvement of the oesophagus may cause dysphagia. If the pericardium is invaded, arrhythmia or pericardial effusion may occur. Superior vena cava obstruction by malignant nodes causes suffusion and swelling of the neck and face, conjunctival oedema, headache and dilated veins on

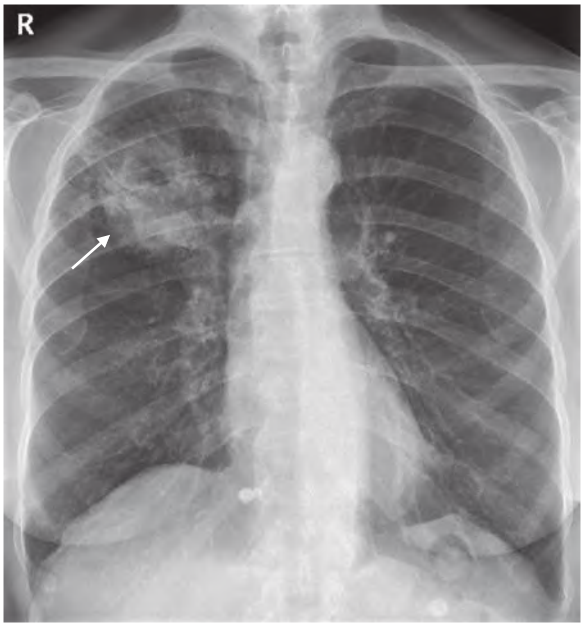

Fig. 17.46 Large cavitating tumour in the right upper lobe. Chest X-ray demonstrating a cavitating tumour in the right upper lobe.

i 17.64 Causes of large bronchus obstruction

Common

- Lung cancer or adenoma
- Enlarged tracheobronchial lymph nodes (malignant or tuberculous)
- Inhaled foreign bodies (especially right lung)
- Bronchial casts or plugs consisting of inspissated mucus or blood clot (especially asthma, cystic fibrosis, haemoptysis, debility)
- Collections of mucus or mucopus retained in the bronchi as a result of ineffective expectoration (especially post-operative following abdominal surgery)

Rare

- Aortic aneurysm
- Giant left atrium
- Pericardial effusion
- Congenital bronchial atresia
- Fibrous bronchial stricture following tuberculosis or bronchial surgery and lung transplant

the chest wall and is most commonly due to lung cancer. Involvement of the left recurrent laryngeal nerve by tumours at the left hilum causes vocal cord paralysis, voice alteration and a ‘bovine’ cough (lacking the normal explosive character). Supraclavicular lymph nodes may be palpably enlarged or identified using ultrasound; if so, a needle aspirate may provide a simple means of cytological diagnosis.

Metastatic spread

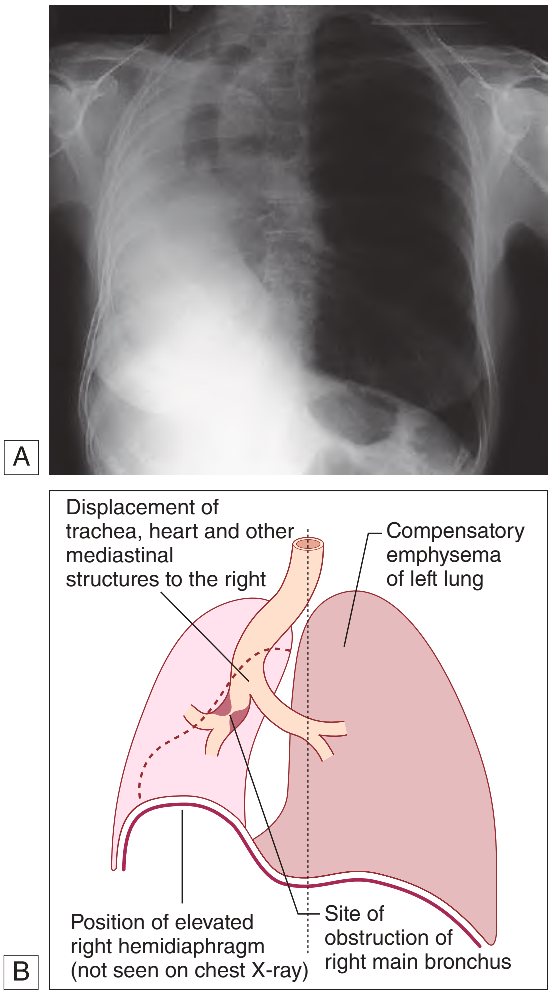
This may lead to focal neurological defects, epileptic seizures, personality change, jaundice, bone pain or skin nodules. Lassitude, anorexia and weight loss usually indicate metastatic spread.

Finger clubbing

Overgrowth of the soft tissue of the terminal phalanx, leading to increased nail curvature and nail bed fluctuation, is often seen.

Hypertrophic pulmonary osteoarthropathy

Hypertrophic pulmonary osteoarthropathy (HPOA) is a painful periostitis of the distal tibia, fibula, radius and ulna, with local tenderness and sometimes pitting oedema over the anterior shin. Radiographs reveal subperiosteal new bone formation. While most frequently associated with lung cancer, HPOA can occur with other tumours.



A
Displacement of trachea, heart and other mediastinal structures to the right
Compensatory emphysema of left lung
Position of elevated right hemidiaphragm (not seen on chest X-ray)
Site of obstruction of right main bronchus
B

Fig. 17.47 Collapse of the right lung and effects on neighbouring structures. A CXR. B The typical abnormalities are highlighted.

Non-metastatic extrapulmonary effects

A variety of non-metastatic extrapulmonary effects of lung cancer are recognised. These are summarised in Box 17.65. The syndrome of inappropriate antidiuretic hormone secretion (SIADH, p. 666) and ectopic adrenocorticotrophic hormone secretion (p. 725) are usually associated with small-cell lung cancer. Hypercalcaemia may indicate malignant bone destruction or production of parathyroid hormone-related peptide by a tumour. Associated neurological syndromes may occur with any type of lung cancer.

Investigations

The main aims of investigation are to confirm the diagnosis, establish the histological cell type and define the extent of the disease.

Imaging

Lung cancer can produce a range of appearances on CXR, from lobar collapse (see Fig. 17.5) to mass lesions, effusion or malignant rib destruction (Fig. 17.48). Imaging with CT should be performed early, as it may reveal mediastinal or metastatic spread and is helpful for planning biopsy procedures, and in establishing whether a tumour is accessible by bronchoscopy or percutaneous CT-guided biopsy.

Biopsy and histopathology

Over half of primary lung tumours can be visualised and sampled directly by biopsy and brushing using a flexible bronchoscope. Bronchoscopy

17.65 Non-metastatic extrapulmonary manifestations of lung cancer

Endocrine

- Inappropriate antidiuretic hormone (ADH, vasopressin) secretion, causing hyponatraemia
- Ectopic adrenocorticotrophic hormone secretion
- Hypercalcaemia due to secretion of parathyroid hormone-related peptide
- Carcinoid syndrome
- Gynaecomastia

Neurological

- Polyneuropathy
- Myelopathy
- Cerebellar degeneration
- Myasthenia (Lambert–Eaton syndrome)

Other

- Digital clubbing
- Hypertrophic pulmonary osteoarthropathy
- Nephrotic syndrome
- Polymyositis and dermatomyositis
- Eosinophilia

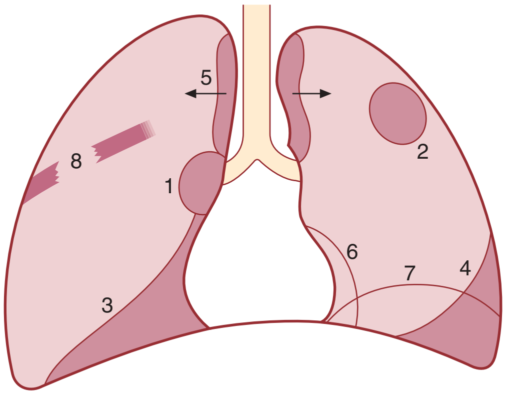


Fig. 17.48 Common radiological presentations of lung cancer. (1) Unilateral hilar enlargement suggests a central tumour or hilar glandular involvement. However, a peripheral tumour in the apex of a lower lobe can look like an enlarged hilar shadow on the PA CXR. (2) Peripheral pulmonary opacity is usually irregular but well circumscribed and may contain irregular cavitation. It can be very large. (3) Lung, lobe or segmental collapse is usually caused by tumour occluding a proximal bronchus. Collapse may also be due to compression of a bronchus by enlarged lymph glands. (4) Pleural effusion usually indicates tumour invasion of the pleural space or, very rarely, infection in collapsed lung tissue distal to a lung cancer. (5) Paratracheal lymphadenopathy may cause widening of the upper mediastinum. (6) A malignant pericardial effusion may cause enlargement of the cardiac shadow. (7) A raised hemidiaphragm may be caused by phrenic nerve palsy. Screening will show paradoxical upward movement when the patient sniffs. (8) Osteolytic rib destruction indicates direct invasion of the chest wall or metastatic spread.

also allows an assessment of operability, from the proximity of central tumours to the main carina (Fig. 17.49).

For tumours that are too peripheral to be accessible by bronchoscope, the yield of 'blind' bronchoscopic washings and brushings from the radiologically affected area is low and percutaneous needle biopsy under CT (or less commonly ultrasound) guidance is a more reliable way to obtain a histological diagnosis. There is a risk of iatrogenic pneumothorax, which may preclude the procedure if there is extensive coexisting emphysema. In patients with a peripheral tumour and enlarged hilar or paratracheal lymph nodes on CT, bronchoscopy with EBUS-guided node sampling may allow both diagnosis and staging.

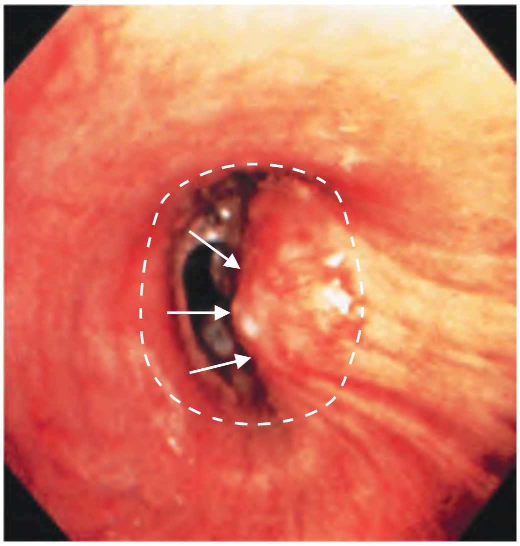

Fig. 17.49 Bronchoscopic view of a lung cancer. There is distortion of mucosal folds, partial occlusion of the airway lumen (original lumen shape illustrated by dotted line) and abnormal tumour tissue (arrows).

In patients with pleural effusions, pleural aspiration and biopsy is the preferred investigation. Where facilities exist, thoracoscopy increases yield by allowing targeted biopsies under direct vision. In patients with metastatic disease, the diagnosis can often be confirmed by needle aspiration or biopsy of affected lymph nodes, skin lesions, liver or bone marrow.

Staging to guide treatment

The propensity of small-cell lung cancer to metastasise early means these patients are usually not suitable for surgical intervention. In non-small-cell lung cancer (NSCLC), treatment and prognosis are determined by disease extent, so careful staging initially using CT scanning is required. Enlarged upper mediastinal nodes may be sampled using EBUS with a bronchoscope that has an ultrasound device attached to it or by mediastinoscopy. Nodes in the lower mediastinum can be sampled through the oesophageal wall using endoscopic ultrasound. Combined CT and whole-body FDG PET (see Fig. 17.6) is commonly used to detect occult but metabolically active metastases. Head CT, radionuclide bone scanning, liver ultrasound and bone marrow biopsy are generally reserved for patients with clinical, haematological or biochemical evidence of tumour spread to these sites. Information on tumour size and nodal and metastatic spread is then collated to assign the patient to one of nine staging groups that determine optimal management and prognosis (Fig. 17.50). Detailed physiological testing is required to assess whether respiratory and cardiac function is sufficient to allow aggressive treatment.

Management

Surgical resection carries the best hope of long-term survival but some patients treated with radical radiotherapy and chemotherapy also achieve prolonged remission or cure. In over 75% of cases, treatment with the aim of cure is not possible or is inappropriate due to extensive spread or comorbidity. Such patients are offered palliative therapy and best supportive care. Radiotherapy and, in some cases, chemotherapy can relieve symptoms.

Curative management

Surgical treatment with accurate pre-operative staging, coupled with improvements in surgical and post-operative care, now offers 5-year survival rates of over 80% in stage I disease (N0, tumour confined within visceral pleura) and over 70% in stage II disease, which includes

Fig. 17.50 **Tumour stage and survival in non-small-cell lung cancer.** *Based on data from Rami-Porta R, Nishimura KK, Giroux DJ, et al. The International Association for the Study of Lung Cancer Lung Cancer Staging Project: Proposals for Revision of the TNM Stage Groups in the Forthcoming (Ninth) Edition of the TNM Classification for Lung Cancer. J Thorac Oncol 2024;19(7):1007–1027.*

resection in patients with ipsilateral peribronchial or hilar node involvement. In NSCLC there is some evidence that adjuvant chemotherapy given before surgery may increase survival and can effectively 'down-stage' disease with limited nodal spread. Post-operative chemotherapy is now proven to enhance survival rates when operative samples show nodal involvement by tumour.

Radical radiotherapy can offer long-term survival in selected patients with localised disease in whom comorbidity precludes surgery. Radical radiotherapy is usually combined with chemotherapy when lymph nodes are involved (stage III). Highly targeted (stereotactic) radiotherapy may be given in 3–5 treatments for small lesions. Radiotherapy can be used in conjunction with chemotherapy in the treatment of small-cell carcinoma and is particularly efficient at preventing the development of brain metastases in patients who have had a complete response to chemotherapy.

Palliative management

Radiotherapy can be used for the palliation of distressing complications, such as superior vena cava obstruction, recurrent haemoptysis and pain caused by chest wall invasion or by skeletal metastatic deposits. Obstruction of the trachea and main bronchi can also be relieved temporarily.

The treatment of small-cell carcinoma with combinations of cytotoxic drugs, sometimes with radiotherapy, can increase median survival from 3 months to well over a year. The use of combinations of chemotherapeutic drugs requires considerable skill and should be overseen by multidisciplinary teams of clinical oncologists and specialist nurses. Regular cycles of therapy, including combinations of intravenous cyclophosphamide, doxorubicin and vincristine or intravenous cisplatin and etoposide, are commonly used. In NSCLC, chemotherapy is less effective, though platinum-based chemotherapy regimens offer 30% response rates and a modest increase in survival and are widely used. Nausea and vomiting are common side-effects of chemotherapy and are best treated with 5-HT$_3$ receptor antagonists, such as ondansetron 8 mg twice daily.

Some NSCLC tumours, particularly adenocarcinomas in non-smokers, carry pathogenic variants that drive tumour growth, such as gain-of-function variants in the epidermal growth factor receptor *(EGFR)* gene. Tyrosine kinase inhibitors, such as afatinib and erlotinib show improved treatment responses in metastatic NSCLC with *EGFR* variants. Similar approaches are being developed to treat other tumours where pathogenic variants in signalling pathways have been identified, such as bevacizumab, a monoclonal antibody which targets vascular endothelial growth factor (VEGF).

Palliation of symptoms caused by major airway obstruction can be achieved in selected patients using bronchoscopic laser treatment to clear tumour tissue and allow re-aeration of collapsed lung. The best results are achieved in tumours of the main bronchi. Endobronchial stents can be used to maintain airway patency in the face of extrinsic compression by malignant nodes.

General aspects of management

The best outcomes are obtained when lung cancer is managed in specialist centres by multidisciplinary teams, including oncologists, thoracic surgeons, respiratory physicians and specialist nurses. Effective communication, pain relief and attention to diet are important. Lung tumours can cause clinically significant depression and anxiety, and these may need specific therapy. The management of non-metastatic endocrine manifestations is described in Chapter 20. When a malignant pleural effusion is present, an attempt should be made to drain the pleural cavity using an intercostal drain; depending upon response to initial drainage, subsequent fluid accumulations can be managed with long-term indwelling pleural catheters or pleurodesis with sclerosing agents such as talc.

Prognosis

The overall prognosis in lung cancer is very poor, approximately 60% and over 80% of patients dying within 1 and 5 years, respectively, of diagnosis. The best prognosis is with well-differentiated squamous cell tumours that have not metastasised and are amenable to surgical resection. The clinical features and prognosis of rare lung tumours are summarised in Box 17.66.

Secondary tumours of the lung

Blood-borne metastatic deposits in the lungs may be derived from many primary carcinomas, in particular breast, kidney, uterus, ovary, testes and thyroid, and also from osteogenic and other sarcomas. These secondary deposits are usually multiple and bilateral. Often there are no respiratory symptoms and the diagnosis is incidental on CXR. Breathlessness may occur if a considerable amount of lung tissue has been replaced by metastatic tumour. Endobronchial deposits are uncommon but can cause haemoptysis and lobar collapse.

Lymphatic infiltration may develop in carcinoma of the breast, stomach, bowel, pancreas or bronchus. 'Lymphangitic carcinomatosis' causes severe, rapidly progressive breathlessness with marked hypoxaemia. The CXR shows diffuse pulmonary shadowing radiating from the hilar regions, often with septal lines, and CT shows characteristic polygonal thickened interlobular septa. Palliation of breathlessness with opiates may help.

Tumours of the mediastinum

The major compartments of the mediastinum are shown in Figure 17.51 and the causes of a mediastinal mass are shown in Box 17.67.

Benign tumours and cysts in the mediastinum are often diagnosed when a CXR is undertaken for some other reason. In general, they do not invade vital structures but may cause symptoms by compressing the trachea or the superior vena cava. A dermoid cyst may very occasionally rupture into a bronchus.

Malignant mediastinal tumours are distinguished by their power to invade, as well as compress, surrounding structures. As a result, even a small malignant tumour can produce symptoms, although, more commonly, the tumour has attained a considerable size before this happens (Box 17.68). The most common cause is mediastinal lymph node metastasis from lung cancer, but lymphomas, leukaemia, malignant thymic tumours and germ-cell tumours can cause similar features. Aortic and innominate aneurysms have destructive features resembling those of malignant mediastinal tumours.

Investigations

A benign mediastinal tumour generally appears on CXR as a sharply circumscribed mediastinal opacity encroaching on one or both lung fields (as shown in Fig. 17.52). Imaging with CT or MRI is the investigation of choice for mediastinal tumours (see Fig. 20.12). A malignant mediastinal tumour seldom has a clearly defined margin and often presents as a general broadening of the mediastinum.

i 17.66 Rare types of lung tumour

Tumour	Status	Histology	Typical presentation	Prognosis
Adenosquamous carcinoma	Malignant	Tumours with areas of unequivocal squamous and adeno-differentiation	Peripheral or central lung mass	Stage-dependent
Neuroendocrine (carcinoid) tumour	Low-grade malignant	Neuroendocrine differentiation	Bronchial obstruction, cough	95% 5-year survival with resection
Bronchial gland adenoma	Benign	Salivary gland differentiation	Tracheobronchial irritation/ obstruction	Local resection curative
Bronchial gland carcinoma	Low-grade malignant	Salivary gland differentiation	Tracheobronchial irritation/ obstruction	Local recurrence
Hamartoma	Benign	Mesenchymal cells, cartilage	Peripheral lung nodule	Local resection curative
Bronchoalveolar carcinoma	Malignant	Tumour cells line alveolar spaces	Alveolar shadowing, productive cough	Variable, worse if multifocal

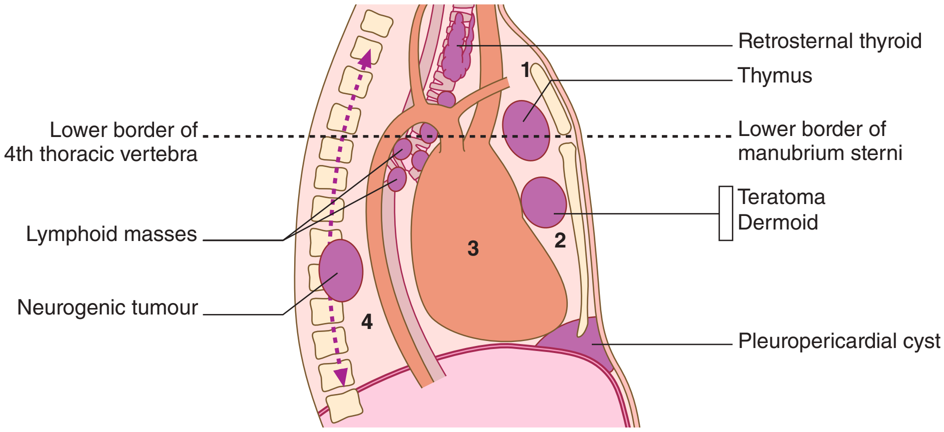

Fig. 17.51 **The divisions of the mediastinum.** (1) Superior mediastinum. (2) Anterior mediastinum. (3) Middle mediastinum. (4) Posterior mediastinum. Sites of the more common mediastinal tumours are also illustrated. *From Johnson N McL. Respiratory medicine. Oxford: Blackwell Science; 1986.*

17.67 Causes of a mediastinal mass

Superior mediastinum

- Retrosternal goitre
- Persistent left superior vena cava
- Prominent left subclavian artery
- Thymic tumour
- Dermoid cyst
- Lymphoma
- Aortic aneurysm

Anterior mediastinum

- Retrosternal goitre
- Dermoid cyst
- Thymic tumour
- Lymphoma
- Aortic aneurysm
- Germ cell tumour
- Pericardial cyst
- Hiatus hernia through the diaphragmatic foramen of Morgagni

Posterior mediastinum

- Neurogenic tumour
- Paravertebral abscess
- Oesophageal lesion
- Aortic aneurysm
- Foregut duplication

Middle mediastinum

- Lung cancer
- Lymphoma
- Sarcoidosis
- Bronchogenic cyst
- Hiatus hernia

17.68 Clinical features of malignant mediastinal invasion

Trachea and main bronchi

- Stridor, breathlessness, cough, pulmonary collapse

Oesophagus

- Dysphagia, oesophageal displacement or obstruction on barium swallow examination

Phrenic nerve

- Diaphragmatic paralysis

Left recurrent laryngeal nerve

- Paralysis of left vocal cord with hoarseness and 'bovine' cough

Sympathetic trunk

- Horner syndrome

Superior vena cava

- SVC obstruction: non-pulsatile distension of neck veins, subconjunctival oedema, and oedema and cyanosis of head, neck, hands and arms; dilated anastomotic veins on chest wall

Pericardium

- Pericarditis and/or pericardial effusion

Bronchoscopy may reveal a primary lung cancer causing mediastinal lymphadenopathy. EBUS may be used to guide sampling of peribronchial masses. The posterior mediastinum can be imaged and biopsied via the oesophagus using endoscopic ultrasound.

Mediastinoscopy under general anaesthetic can be used to visualise and biopsy masses in the superior and anterior mediastinum, but surgical exploration of the chest, with removal of part or all of the tumour, is often required to obtain a histological diagnosis.

Management

Benign mediastinal tumours should be removed surgically because most produce symptoms sooner or later. Cysts may become infected, while neural tumours have the potential to undergo malignant transformation. The operative mortality is low in the absence of coexisting cardiovascular disease, COPD or extreme age.

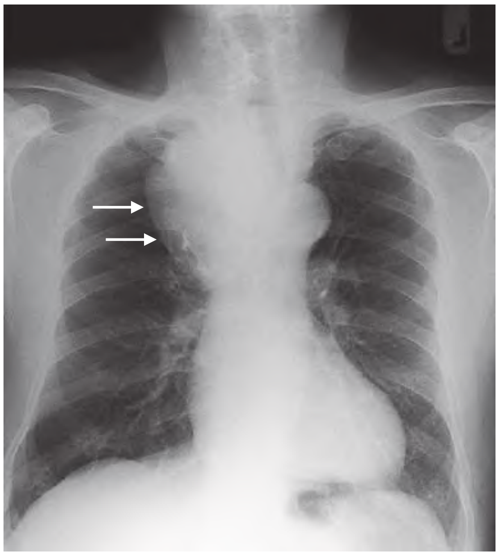

Fig. 17.52 **Intrathoracic goitre**. The goitre (arrows) extends from the right superior mediastinum into the right hemithorax.

Interstitial and infiltrative pulmonary diseases

Diffuse parenchymal lung disease

The diffuse parenchymal lung diseases (DPLDs) are a heterogeneous group of conditions affecting the pulmonary parenchyma (interstitium) and/or alveolar lumen, which are frequently considered collectively as they share a sufficient number of clinical physiological and radiographic similarities (Box 17.69). They often present with cough, which is typically dry and distressing, and breathlessness, which is often insidious in onset but thereafter relentlessly progressive. Physical examination reveals the presence of inspiratory crackles and in many cases digital clubbing develops. Pulmonary function tests typically show a restrictive ventilatory defect in the presence of small lung volumes and reduced gas transfer. The typical radiographic findings include, in the earliest stages, ground glass and reticulonodular shadowing, with progression to honeycomb cysts and traction bronchiectasis. While these appearances may be seen on a plain CXR, they are most easily appreciated on HRCT, which has assumed a central role in the evaluation of DPLD (Fig. 17.53). The current classification is shown in Figure 17.54 and the potential differential diagnoses in Box 17.70. Common features of interstitial lung disease in old age are shown in Box 17.71. First-line treatments for each DPLD are detailed below. Patients whose DPLD deteriorates despite treatment may be described as having progressive pulmonary fibrosis (PPF) if they fit specific criteria relating to their symptoms, FVC, diffusing capacity of the lungs for carbon monoxide (DLCO), and extent of fibrosis on HRCT. Patients with PPF may be offered the tyrosine kinase inhibitor nintedanib to slow the decline of lung function.

Idiopathic interstitial pneumonias

The idiopathic interstitial pneumonias represent a major subgroup of DPLD that are grouped together as a result of their unknown aetiology. They are usually classified according to the features on lung biopsy or HRCT scanning (Box 17.72). The most important of these is usual interstitial pneumonia (UIP).

Idiopathic pulmonary fibrosis

Idiopathic pulmonary fibrosis (IPF) is defined as a progressive fibrosing interstitial pneumonia of unknown cause, occurring in adults and associated with the histological or radiological pattern of UIP. Whilst IPF has the radiological–histological pattern of UIP, not all patients with a UIP pattern of disease have IPF, as the UIP pattern can occur in fibrosing diseases caused by occupational exposure, medication or connective tissue diseases. All of these must be excluded by careful history, examination and investigation before making a diagnosis of IPF.

The histological features of the condition are suggestive of repeated episodes of focal damage to the alveolar epithelium consistent with an autoimmune process, but the aetiology remains elusive: speculation has included exposure to viruses (such as Epstein–Barr virus), occupational dusts (metal or wood), drugs (antidepressants) or chronic gastro-oesophageal reflux. Familial cases are rare but genetic factors that control the inflammatory and fibrotic response are likely to be important. There is a strong association with cigarette smoking.

Clinical features

Idiopathic pulmonary fibrosis usually presents in the older adult and is uncommon before the age of 50 years. With the advent of widespread CT scanning, it may present as an incidental finding in an otherwise asymptomatic individual but more typically presents with progressive breathlessness (which may have been insidious) and a non-productive cough. Constitutional symptoms are unusual. Clinical findings include finger clubbing and the presence of bi-basal fine late inspiratory crackles likened to the unfastening of Velcro.

i 17.69 Features common to the diffuse parenchymal lung diseases

Clinical presentation

- Cough: usually dry, persistent and distressing
- Breathlessness: usually slowly progressive; insidious onset; acute in some cases

Examination findings

- Crackles: typically, bilateral and basal
- Clubbing: common in idiopathic pulmonary fibrosis but also seen in other types of lung disease (see Box 17.8)
- Central cyanosis and signs of right heart failure in advanced disease

Radiology

- CXR: typically, small lung volumes with reticulonodular shadowing but may be normal in early or limited disease
- High-resolution computed tomography: combinations of ground glass changes, reticulonodular shadowing, honeycomb cysts and traction bronchiectasis, depending on stage of disease

Pulmonary function

- Typically, restrictive ventilatory defect with reduced lung volumes and impaired gas transfer; exercise tests assess exercise tolerance and exercise-related fall in SaO_2

(SaO_2 = arterial oxygen saturation)

Investigations

These are summarised in Box 17.73. Established IPF will be apparent on CXR as a bilateral lower lobe and subpleural reticular shadowing. The CXR may be normal in individuals with early or limited disease, however. HRCT typically demonstrates a patchy, predominantly peripheral, subpleural and basal reticular pattern and, in more advanced disease, the presence of honeycombing cysts and traction bronchiectasis (Fig. 17.55). When these features are present, HRCT has a high positive predictive value for the diagnosis of IPF and recourse to biopsy is seldom necessary. HRCT appearances may also be sufficiently characteristic to suggest an alternative diagnosis such as hypersensitivity pneumonitis or sarcoidosis. The presence of pleural plaques may suggest asbestosis.

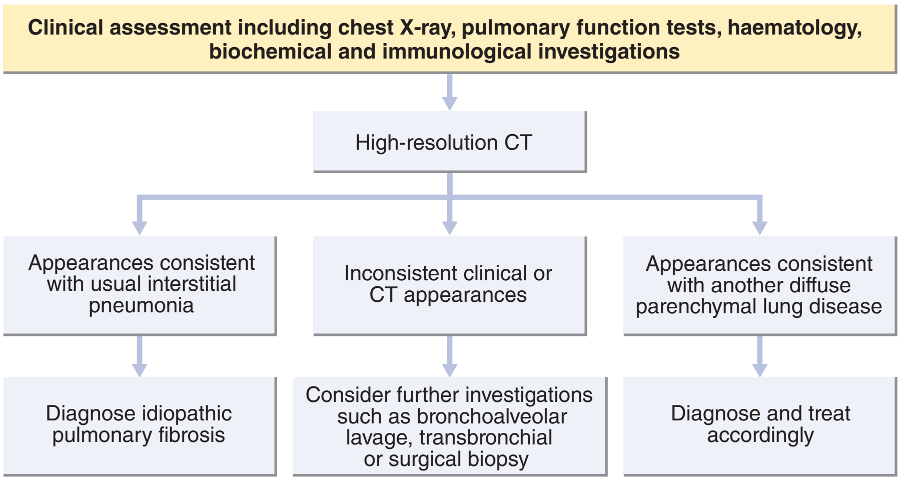
Pulmonary function tests classically show a restrictive defect with reduced lung volumes and gas transfer. However, lung volumes may be preserved in patients with concomitant emphysema. Dynamic tests are useful to document exercise tolerance and demonstrate exercise-induced arterial hypoxaemia, but as IPF advances, arterial hypoxaemia and hypocapnia are present at rest.

Bronchoscopy is seldom indicated unless there is serious consideration of differential diagnoses of infection or a malignant process; lymphocytosis may suggest chronic hypersensitivity pneumonitis. The tissue samples obtained by transbronchial lung biopsy are unlikely to be of diagnostic value, and if tissue is required, a surgical lung biopsy should be sought. Lung biopsy should be considered in cases of diagnostic uncertainty or with atypical features. UIP is the histological pattern predominantly encountered in IPF (Fig. 17.56); however, it is also found in asbestosis, hypersensitivity pneumonitis, connective tissue diseases and drug reactions.

It is not uncommon to identify a weakly positive antinuclear antibody (ANA) or anti-cyclic citrullinated peptide (anti-CCP) in people with IPF. In the absence of clinical features of an inflammatory rheumatic disease or connective tissue disease, these are likely to be non-specific findings. Having said that, it should be noted that lung disease may precede the appearance of connective tissue disease, and so re-evaluation may be required.

Management

The management options for IPF are improving. If the vital capacity is between 50% and 80% predicted, patients may be offered either pirfenidone titrated up to 901 mg thrice daily (an antifibrotic agent) or nintedanib 150 mg twice daily (a tyrosine kinase inhibitor). Both of these agents have been shown to reduce the rate of decline in lung function. Patients



Clinical assessment including chest X-ray, pulmonary function tests, haematology, biochemical and immunological investigations
High-resolution CT
Appearances consistent with usual interstitial pneumonia
Inconsistent clinical or CT appearances
Appearances consistent with another diffuse parenchymal lung disease
Diagnose idiopathic pulmonary fibrosis
Consider further investigations such as bronchoalveolar lavage, transbronchial or surgical biopsy
Diagnose and treat accordingly

Diffuse parenchymal lung disease (DPLD)
DPLD associated with drugs or connective tissue diseases
Idiopathic interstitial pneumonia
Sarcoidosis and other forms of granulomatous DPLD
DPLD associated with environmental exposures or other diseases*
Idiopathic pulmonary fibrosis
Idiopathic interstitial pneumonia other than idiopathic pulmonary fibrosis
Desquamative interstitial pneumonia
Respiratory bronchiolitis interstitial lung disease
Acute interstitial pneumonia
Cryptogenic organising pneumonia
Non-specific interstitial pneumonia
Lymphocytic interstitial pneumonia

Fig. 17.54 Classification of diffuse parenchymal lung disease. *Examples include asbestosis, occupational exposure to dust, lymphangioleiomyomatosis and histiocytosis X (see Box 17.79)

17.70 Conditions that mimic diffuse parenchymal lung disease

Infection

- Viral pneumonia
- *Pneumocystis jirovecii*
- *Mycoplasma pneumoniae*
- Tuberculosis
- Parasitic infections such as filariasis, gnathostomiasis, paragonimiasis, schistosomiasis or strongyloidiasis
- Fungal infection

Aspiration pneumonitis

Malignancy

- Leukaemia and lymphoma
- Lymphangitic carcinomatosis
- Multiple metastases
- Bronchoalveolar carcinoma

Pulmonary oedema

17.71 Interstitial lung disease in old age

- **Idiopathic pulmonary fibrosis**: the most common interstitial lung disease, with a poor prognosis.
- **Chronic aspiration pneumonitis**: must always be considered in older patients presenting with bilateral basal shadowing on a CXR.
- **Granulomatosis with polyangiitis (GPA)**: a rare condition but more common in old age. Renal involvement is more common at presentation and upper respiratory problems are fewer.
- **Asbestosis**: symptoms may appear only in old age because of the prolonged latent period between exposure and disease.
- **Drug-induced interstitial lung disease**: more common, presumably because of the increased chance of exposure to multiple drugs.
- **Rare interstitial disease**: sarcoidosis, idiopathic pulmonary haemosiderosis, alveolar proteinosis and eosinophilic pneumonia rarely present.
- **Increased dyspnoea**: coexistent muscle weakness, chest wall deformity and deconditioning may all exacerbate dyspnoea associated with interstitial lung disease.
- **Surgical lung biopsy**: often inappropriate in the very frail. A diagnosis therefore frequently depends on clinical and high-resolution computed tomography findings alone.

17.72 Idiopathic interstitial pneumonias

Clinical diagnosis	Notes
Idiopathic pulmonary fibrosis	Commonly has a UIP pattern of histology or radiology. The diagnosis can only be made when secondary causes of pulmonary fibrosis, such as occupational lung disease, medication induced lung disease and connective tissue disease, have been excluded (see text for details)
Non-specific interstitial pneumonia (NSIP)	See page 576
Respiratory bronchiolitis–interstitial lung disease	More common in men and smokers. Usually presents at age 40–60 years. Smoking cessation may lead to improvement. Natural history unclear
Acute interstitial pneumonia	Often preceded by viral upper respiratory tract infection. Severe exertional dyspnoea, widespread pneumonic consolidation and diffuse alveolar damage on biopsy. Prognosis often poor
Desquamative interstitial pneumonia (DIP)	More common in men and smokers. Presents at age 40–60 years. Insidious onset of dyspnoea. Clubbing in 50%. Biopsy shows increased macrophages in alveolar space, septal thickening and type II pneumocyte hyperplasia. Prognosis generally good
Cryptogenic organising pneumonia ('bronchiolitis obliterans organising pneumonia' – BOOP)	Presents as clinical and radiological pneumonia. Systemic features and markedly raised erythrocyte sedimentation rate common. Finger clubbing absent. Biopsy shows florid proliferation of immature collagen (Masson bodies) and fibrous tissue. Response to glucocorticoids is usually excellent
Lymphocytic interstitial pneumonia (LIP)	More common in women, slow onset over years. Investigate for associations with connective tissue disease or HIV. Unclear whether corticosteroids are helpful

(HIV = human immunodeficiency virus; UIP = usual interstitial pneumonia) taking pirfenidone should be advised to avoid direct exposure to sunlight and use photoprotective clothing and high-protection sunscreens. Nintedanib may be accompanied by diarrhoea. Neither drug improves cough or breathlessness, and treatment should be discontinued if percent predicted FVC declines by 10% or more in any 12-month period. Medication to control gastro-oesophageal reflux may improve the cough. Current smokers should be apprised of the increased risk of lung cancer and advised to stop. Influenza, COVID-19 and pneumococcal vaccination should be recommended. Patients should be encouraged to exercise and participate in pulmonary rehabilitation using ambulatory oxygen if appropriate. Domiciliary oxygen should be considered for palliation of breathlessness in severe cases. Where appropriate, lung transplantation should be considered. The optimum treatment for acute exacerbations is unknown. Treatment is largely supportive. Broad-spectrum antibiotics may be combined with corticosteroids and sometimes additional immunosuppression, but there are few data to support this approach.

i 17.73 Investigations in diffuse parenchymal lung disease

Laboratory investigations

- Full blood count: lymphopenia in sarcoidosis; eosinophilia in pulmonary eosinophilias and drug reactions; neutrophilia in hypersensitivity pneumonitis
- Hypercalcaemia may occur in sarcoidosis
- Lactate dehydrogenase: may be elevated in active alveolitis
- Serum angiotensin-converting enzyme: non-specific indicator of disease activity in sarcoidosis
- Erythrocyte sedimentation rate and C-reactive protein raised
- Autoimmune screen: anti-cyclic citrullinated peptide (anti-CCP) and other autoantibodies may suggest connective tissue disease

Radiology

- See Box 17.69

Pulmonary function

- See Box 17.69

Bronchoscopy

- Bronchoalveolar lavage: differential cell counts may point to sarcoidosis and drug-induced pneumonitis, pulmonary eosinophilias, hypersensitivity pneumonitis or cryptogenic organising pneumonia; useful to exclude infection
- Transbronchial biopsy: useful in sarcoidosis and differential of malignancy or infection
- Bronchial biopsy: occasionally useful in sarcoidosis

Video-assisted thoracoscopic lung biopsy (in selected cases)

- Allows pathological classification: presence of asbestos bodies may suggest asbestosis; silica in occupational fibrosing lung disease

Others

- Liver biopsy: may be useful in sarcoidosis
- Urinary calcium excretion: may be useful in sarcoidosis

Prognosis

The natural history is usually one of steady decline; however, some patients are prone to exacerbations accompanied by an acute deterioration in breathlessness, disturbed gas exchange, and new ground glass changes or consolidation on HRCT. In advanced disease, central cyanosis is detectable and patients may develop pulmonary hypertension and features of right heart failure. A median survival of 2–5 years is widely quoted; however, the rate of disease progression varies considerably, from death within a few months to survival for over 10 years in 20%–25%. Serial lung function testing may provide useful prognostic information, relative preservation of lung function suggesting longer survival and significantly impaired gas transfer and/or desaturation on exercise heralding a poorer prognosis. The finding of high numbers of fibroblastic foci on biopsy suggests a more rapid deterioration.

Non-specific interstitial pneumonia

The clinical picture of fibrotic non-specific interstitial pneumonia (NSIP) is similar to that of IPF, although patients tend to be women and younger in age. As with UIP, the condition may present as an isolated idiopathic pulmonary condition, but an NSIP pattern is often associated with connective tissue disease, certain drugs, chronic hypersensitivity pneumonitis or HIV infection, and care must be taken to exclude these possibilities. As with UIP, the pulmonary condition may precede the appearance of connective tissue disease. HRCT findings are less specific than with IPF, and lung biopsy may be required. The prognosis is significantly better than that of IPF, particularly in the cellular form of the condition, and the 5-year mortality rate is typically less than 15%.

Sarcoidosis

Sarcoidosis is a multisystem granulomatous disorder of unknown aetiology that is characterised by the presence of non-caseating granulomas (Fig. 17.57). The condition is more frequent in people from Northern Europe and those of Northern European descent. It also appears to be more common and more severe in those from an African Caribbean background. The tendency for sarcoidosis to present in the spring and summer has led to speculation about the role of infective agents, including mycobacteria, propionibacteria and viruses, but the cause remains elusive. Genetic susceptibility is supported by familial clustering; a range of class II HLA alleles confer protection from, or susceptibility to, the condition. Sarcoidosis occurs less frequently in smokers. It may be associated with common variable immunodeficiency.

Clinical features

Sarcoidosis is considered with other DPLDs, as over 90% of cases affect the lungs, but the condition can involve almost any organ (Fig. 17.58 and Box 17.74). Löfgren syndrome – an acute illness characterised by erythema nodosum, peripheral arthropathy, uveitis, bilateral hilar lymphadenopathy (BHL), lethargy and occasionally fever – is often seen in young women. Alternatively, BHL may be detected in an otherwise asymptomatic individual undergoing a CXR for other purposes. Pulmonary disease may also present in a more insidious manner with cough, exertional breathlessness and radiographic infiltrates; chest auscultation is often surprisingly unremarkable. Fibrosis occurs in around 20% of cases of pulmonary sarcoidosis and may cause a silent loss of lung function. Pleural disease is uncommon and finger clubbing is not a feature. Complications such as bronchiectasis, aspergilloma, pneumothorax, pulmonary hypertension and cor pulmonale have been reported but are rare.

Investigations

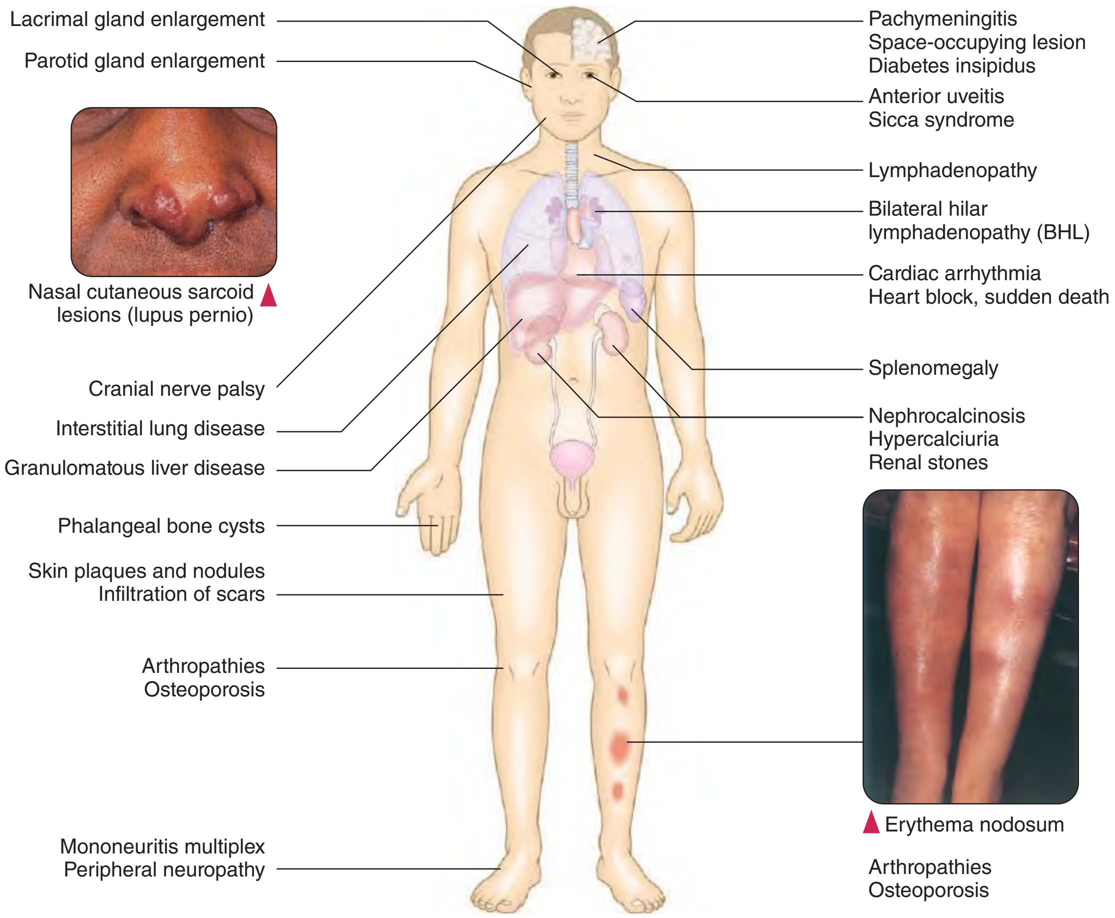
Lymphopenia is characteristic and liver function tests may be mildly deranged. Hypercalcaemia may be present (reflecting increased formation of calcitriol – 1,25-dihydroxyvitamin D – by alveolar macrophages), particularly if the patient has been exposed to strong sunlight or is taking high-dose vitamin D supplements. Hypercalciuria may also be seen and can lead to nephrocalcinosis. Serum angiotensin-converting enzyme (ACE) provides a non-specific marker of disease activity and can assist in monitoring the clinical course. Chest radiography is commonly used to stage sarcoidosis (Box 17.75). In patients with pulmonary infiltrates, pulmonary function testing may show a restrictive defect accompanied by impaired gas exchange. Exercise tests may reveal oxygen desaturation. Bronchoscopy may demonstrate a 'cobblestone' appearance of the mucosa, and bronchial and transbronchial biopsies usually show non-caseating granulomas, as may samples from the mediastinal nodes obtained by EBUS. Bronchoalveolar lavage fluid typically contains an increased CD4:CD8 T-cell ratio. Characteristic HRCT appearances include reticulonodular opacities that follow a perilymphatic distribution centred on bronchovascular bundles and the subpleural areas. FDG PET scanning can detect extrapulmonary disease.

The occurrence of erythema nodosum with BHL on CXR is often sufficient for a confident diagnosis, without recourse to a tissue biopsy. Similarly, a typical presentation with classical HRCT features may also be accepted. In other instances, however, the diagnosis should be confirmed by histological examination of the involved organ. The presence of anergy to tuberculin skin tests (an injection of protein derived from *M. tuberculosis*) can support the diagnosis.

Management

Patients who present with acute illness and erythema nodosum should receive NSAIDs and, on occasion, a short course of corticosteroids. The majority of patients enjoy spontaneous remission and so, if there is no evidence of organ damage, systemic corticosteroid therapy can be withheld for 6 months. However, prednisolone (at a starting dose of 20–40 mg/day) should be commenced immediately in the presence of hypercalcaemia, pulmonary impairment, cardiac involvement, renal impairment or uveitis. Topical corticosteroids may be useful in cases of mild uveitis, and inhaled corticosteroids have been used to shorten the duration of systemic corticosteroid use in asymptomatic parenchymal sarcoidosis. Patients should be warned that strong sunlight and high-dose vitamin D supplements may precipitate hypercalcaemia and endanger renal function.

Features suggesting a less favourable outlook include age over 40, African Caribbean ancestry, persistent symptoms for more than 6 months, the involvement of more than three organs, lupus pernio (see Fig. 17.58) and a stage III/IV CXR. In patients with severe disease, methotrexate (10–25 mg/week), azathioprine (50–150 mg/day) and biological therapies inhibiting tumour necrosis factor alpha (TNF-α) may be effective in suppressing disease activity. Chloroquine, hydroxychloroquine and low-dose thalidomide may be useful in cutaneous sarcoidosis with limited pulmonary involvement. Selected patients may be referred for consideration of single lung transplantation. The overall mortality is low (1%–5%) and usually reflects cardiac involvement or pulmonary fibrosis.



Lacrimal gland enlargement
Parotid gland enlargement
Nasal cutaneous sarcoid ▲ lesions (lupus pernio)

Fig. 17.58 **Systemic involvement in sarcoidosis.** *Inset (Erythema nodosum): From Savin JA, Hunter JAA, Hepburn NC. Skin signs in clinical medicine. London: Mosby–Wolfe; 1997.*

i 17.74 Presentation of sarcoidosis

- Asymptomatic: abnormal routine CXR (~30%) or abnormal liver function tests
- Respiratory and constitutional symptoms (20%–30%)
- Erythema nodosum and arthralgia (20%–30%)
- Ocular symptoms (5%–10%)
- Skin sarcoidosis (including lupus pernio) (5%)
- Superficial lymphadenopathy (5%)
- Other (1%), hypercalcaemia, diabetes insipidus, cranial nerve palsies, cardiac arrhythmias, nephrocalcinosis

i 17.75 CXR changes in sarcoidosis

Stage I: BHL (usually symmetrical); paratracheal nodes often enlarged

- Often asymptomatic but may be associated with erythema nodosum and arthralgia. The majority of cases resolve spontaneously within 1 year

Stage II: BHL and parenchymal infiltrates

- Patients may present with breathlessness or cough. The majority of cases resolve spontaneously

Stage III: parenchymal infiltrates without BHL

- Disease less likely to resolve spontaneously

Stage IV: pulmonary fibrosis

- Can cause progression to ventilatory failure, pulmonary hypertension and cor pulmonale

(BHL = bilateral hilar lymphadenopathy)

Lung diseases due to systemic inflammatory disease

The acute respiratory distress syndrome

The pathogenesis and treatment of this disorder is discussed in Chapter 10.

Respiratory involvement in connective tissue disorders

Pulmonary complications of connective tissue disease are common, affecting the airways, alveoli, pulmonary vasculature, diaphragm and chest wall muscles, and the chest wall itself (Box 17.76). In some instances, pulmonary disease may precede the appearance of the connective tissue disorder. Indirect associations between connective tissue disorders and respiratory complications include those due to disease in other organs, such as thrombocytopenia causing haemoptysis; pulmonary toxic effects of drugs used to treat the connective tissue disorder; and secondary infections due to the disease itself, neutropenia or immunosuppressive drug regimens.

Rheumatoid disease

Pulmonary involvement in rheumatoid disease is important, accounting for around 10%–20% of the mortality associated with the condition. The majority of cases occur within 5 years of the rheumatological diagnosis, but pulmonary manifestations may precede joint involvement in 10%–20%. Pulmonary fibrosis is the most common pulmonary manifestation. All forms of interstitial disease have been described, but NSIP is probably the most common. A rare variant of localised upper lobe fibrosis and cavitation is occasionally seen.

17.76 Respiratory complications of rheumatoid arthritis and connective tissue disorders

Disorder	Airways	Parenchyma	Pleura	Diaphragm and chest wall
Rheumatoid arthritis	Bronchitis, obliterative bronchiolitis, bronchiectasis, crico-arytenoid arthritis, stridor	Pulmonary fibrosis, nodules, upper lobe fibrosis, infections	Pleurisy, effusion, pneumothorax	Poor healing of intercostal drain sites
Systemic lupus erythematosus	–	Pulmonary fibrosis, 'vasculitic' infarcts	Pleurisy, effusion	Diaphragmatic weakness (shrinking lungs)
Systemic sclerosis	Bronchiectasis	Pulmonary fibrosis, aspiration pneumonia	–	Cutaneous thoracic restriction (hidebound chest)
Dermatomyositis/ polymyositis	Lung cancer	Pulmonary fibrosis	–	Intercostal and diaphragmatic myopathy

Pleural effusion is common, especially in men with seropositive disease. Effusions are usually small and unilateral but can be large and bilateral. Most resolve spontaneously. Biochemical testing shows an exudate with markedly reduced glucose levels and raised lactate dehydrogenase (LDH). Pleural effusions that fail to resolve spontaneously may respond to a short course of oral prednisolone (30–40 mg/day for 2–4 weeks) but some become chronic.

Rheumatoid pulmonary nodules are usually asymptomatic and detected incidentally on imaging. They are most often multiple and subpleural in site (Fig. 17.59). Solitary nodules can mimic primary lung cancer; when multiple, the differential diagnoses include pulmonary metastatic disease. Cavitation raises the possibility of TB and predisposes to pneumothorax. The combination of rheumatoid nodules and pneumoconiosis is known as Caplan syndrome.

Bronchitis and bronchiectasis are both more common in rheumatoid patients. Rarely, the potentially fatal condition obliterative bronchiolitis may develop. Bacterial lower respiratory tract infections are frequent. Treatments given for rheumatoid arthritis may also be relevant: corticosteroid therapy predisposes to infections, and anti-TNF therapy has been associated with the reactivation of TB.

Systemic lupus erythematosus

Pleuropulmonary involvement is more common in lupus than in any other connective tissue disorder and may be a presenting problem, when it is sometimes attributed incorrectly to infection or pulmonary embolism. Up to two-thirds of patients have repeated episodes of pleurisy, with or without effusions. Effusions may be bilateral and may also involve the pericardium.

The most serious manifestation of lupus is an acute pneumonitis that may be associated with diffuse alveolar haemorrhage. This condition is life-threatening and requires either immediate immunosuppression with corticosteroids or a step-up in immunosuppressive treatment, if already started.

Pulmonary fibrosis is a relatively uncommon manifestation of systemic lupus erythematosus (SLE). Some patients with SLE present with exertional dyspnoea and orthopnoea but without overt signs of pulmonary fibrosis. The CXR reveals elevated diaphragms, and pulmonary function testing shows reduced lung volumes. This condition has been described as 'shrinking lungs' and has been attributed to diaphragmatic myopathy.

Patients with SLE who have antiphospholipid antibodies are at increased risk of venous and pulmonary thromboembolism and require life-long anticoagulation.

Systemic sclerosis

Most patients with systemic sclerosis eventually develop diffuse pulmonary fibrosis; at autopsy more than 90% have evidence of lung fibrosis. In some patients it is indolent, but when progressive, as in IPF, the median survival time is around 4 years. Pulmonary fibrosis is rare in CREST syndrome, but isolated pulmonary hypertension may develop.

Other pulmonary complications include recurrent aspiration pneumonias secondary to oesophageal disease. Rarely, sclerosis of the skin of the chest wall may be so extensive and cicatrising as to restrict chest wall movement – the so-called 'hidebound chest'.

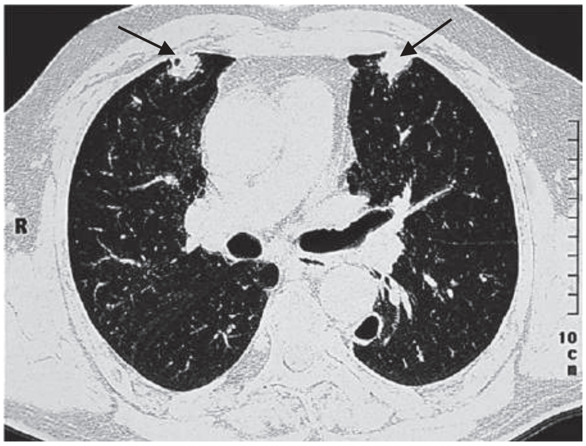

Fig. 17.59 Rheumatoid (necrobiotic) nodules. Thoracic CT just below the level of the main carina, showing the typical appearance of peripheral pleural-based nodules (arrows). The nodule in the right lower lobe shows characteristic cavitation.

Pulmonary eosinophilia and vasculitides

Pulmonary eosinophilia refers to the association of radiographic (usually pneumonic) abnormalities and peripheral blood eosinophilia. The term encompasses a group of disorders of different aetiology (Box 17.77). Eosinophils are the predominant cell recovered in sputum or BAL, and eosinophil products are likely to be the prime mediators of tissue damage.

Acute eosinophilic pneumonia

Acute eosinophilic pneumonia is an acute febrile illness (of less than 5 days' duration), characterised by diffuse pulmonary infiltrates and hypoxic respiratory failure. The pathology is usually that of diffuse alveolar damage. Diagnosis is confirmed by BAL, which characteristically demonstrates > 25% eosinophils. The condition is usually idiopathic but drug reactions should be considered. Corticosteroids invariably induce prompt and complete resolution.

Chronic eosinophilic pneumonia

Chronic eosinophilic pneumonia typically presents in an insidious manner with malaise, fever, weight loss, breathlessness and unproductive cough. It is more common in middle-aged females. The classical CXR appearance has been likened to the photographic negative of pulmonary oedema with bilateral, peripheral and predominantly upper lobe parenchymal shadowing. The peripheral blood eosinophil count is almost always very high, and the erythrocyte sedimentation rate (ESR) and total serum IgE are elevated. BAL reveals a high proportion of eosinophils in the lavage fluid. Response to prednisolone (20–40 mg/day) is usually dramatic. Prednisolone can usually be withdrawn after a few weeks without relapse but long-term, low-dose therapy is occasionally necessary.

Tropical pulmonary eosinophilia

Tropical pulmonary eosinophilia occurs as a result of a mosquito-borne filarial infection with *Wuchereria bancrofti* or *Brugia malayi* (p. 390). The condition presents with fever, weight loss, dyspnoea and asthma-like symptoms. The peripheral blood eosinophilia is marked, as is the elevation of total IgE. High antifilarial antibody titres are seen. The diagnosis may be confirmed by a response to treatment with diethylcarbamazine (6 mg/kg daily for 3 weeks). Tropical pulmonary eosinophilia must be distinguished from infection with *Strongyloides stercoralis*, in which corticosteroids may cause a life-threatening hyperinfection syndrome. Ascariasis ('larva migrans') and other hookworm infestations are covered in Chapter 14.

Granulomatosis with polyangiitis

Granulomatosis with polyangiitis (GPA) is rare vasculitis mainly affecting the nasal passages, airways and kidney. A limited pulmonary form may occur with symptoms including cough, haemoptysis and chest pain, with respiratory complications including tracheal subglottic stenosis and saddle nose deformity. Radiological features including multiple nodules and cavitation have a wide differential including primary or metastatic carcinoma, pulmonary abscesses, mycobacterial or fungal infection, as well as other pulmonary vasculitis, necrotising sarcoidosis, bronchocentric granulomatosis and lymphomatoid granulomatosis. Investigations and management of GPA are discussed in more detail in Chapter 25.

Eosinophilic granulomatosis with polyangiitis

Eosinophilic granulomatosis with polyangiitis (EGPA) is a rare form of vasculitis with prominent eosinophilia. Patients may have a prodromal phase, with symptoms of rhinitis, nasal polyposis and difficult to control late-onset asthma. Pleural or pericardial effusions and pulmonary infiltrates can occur, as well as other systemic features. It can be diagnosed when four or more of the following features are present:

- asthma
- peripheral blood eosinophilia $> 1.5 \times 10^9$/L (or > 10% of a total white cell count)
- mononeuropathy or polyneuropathy
- pulmonary infiltrates
- paranasal sinus disease
- eosinophilic vasculitis on biopsy of an affected site.

The management of EGPA is described in more detail in Chapter 25.

Goodpasture disease

This describes the association of pulmonary haemorrhage and glomerulonephritis, in which IgG antibodies bind to the glomerular or alveolar basement membranes. Pulmonary disease usually precedes renal involvement and includes radiographic infiltrates and hypoxia with or without haemoptysis. It occurs more commonly in men and almost exclusively in smokers. Goodpasture disease is described in more detail in Chapter 18.

17.77 Pulmonary eosinophilia

Extrinsic (cause known)

- Helminths: *Ascaris, Toxocara, Filaria*
- Drugs: nitrofurantoin, para-aminosalicylic acid (PAS), sulfasalazine, imipramine, chlorpropamide, phenylbutazone
- Fungi: *Aspergillus fumigatus* causing allergic bronchopulmonary aspergillosis

Intrinsic (cause unknown)

- Cryptogenic eosinophilic pneumonia
- Eosinophilic granulomatosis with polyangiitis (EGPA)
- Hypereosinophilic syndrome
- Polyarteritis nodosa

Lung diseases due to irradiation and drugs

Radiotherapy

Targeting radiotherapy to certain tumours is inevitably accompanied by irradiation of normal lung tissue. Although delivered in divided doses, the effects are cumulative. Acute radiation pneumonitis is typically seen within 6–12 weeks and presents with cough and dyspnoea. This may resolve spontaneously but responds to corticosteroid treatment. Chronic interstitial fibrosis may present several months later with symptoms of exertional dyspnoea and cough. Changes are often confined to the area irradiated but may be bilateral. Established post-irradiation fibrosis does not usually respond to corticosteroid treatment. The pulmonary effects of radiation are exacerbated by treatment with cytotoxic drugs, and the phenomenon of 'recall pneumonitis' describes the appearance of radiation injury in a previously irradiated area when chemotherapy follows radiotherapy. If the patient survives, there are long-term risks of lung cancer.

Drugs

Drugs may cause a variety of pulmonary conditions (Box 17.78). Pulmonary fibrosis may occur in response to a variety of drugs but is seen most frequently with bleomycin, amiodarone and nitrofurantoin. Eosinophilic pulmonary reactions can also be caused by drugs. The pathogenesis may be an immune reaction similar to that in hypersensitivity pneumonitis, which specifically attracts large numbers of eosinophils into the lungs. This type of reaction is well described as a rare reaction to a variety of antineoplastic agents, antibiotics, disease-modifying antirheumatic drugs and the anticonvulsants phenytoin and carbamazepine (Box 17.78). Patients usually present with breathlessness, cough and fever. The CXR characteristically shows patchy shadowing. Most cases resolve completely on withdrawal of the drug, but if the reaction is severe, rapid resolution can be obtained with corticosteroids.

17.78 Drug-induced respiratory disease

Non-cardiogenic pulmonary oedema (ARDS)

- Hydrochlorothiazide
- Thrombolytics (streptokinase)
- Intravenous β-adrenoceptor agonists
- Aspirin and opiates (in overdose)

Non-eosinophilic alveolitis

- Amiodarone, flecainide, nitrofurantoin, cytotoxic agents – especially bleomycin, busulfan, mitomycin C, methotrexate, sulfasalazine

Pulmonary eosinophilia

- Antimicrobials (nitrofurantoin, penicillin, tetracyclines, sulphonamides, nalidixic acid)
- Antirheumatic drugs (aspirin, penicillamine, naproxen)
- Cytotoxic drugs (bleomycin, methotrexate, procarbazine)
- Psychotropic drugs (chlorpromazine, dosulepin, imipramine)
- Anticonvulsants (carbamazepine, phenytoin)
- Others (sulfasalazine, nadolol)

Pleural disease

- Bromocriptine, amiodarone, methotrexate, methysergide
- Induction of systemic lupus erythematosus – phenytoin, hydralazine, isoniazid

Asthma

- Pharmacological mechanisms (β-blockers, cholinergic agonists, aspirin and NSAIDs)
- Idiosyncratic reactions (tamoxifen, dipyridamole)

(ARDS = acute respiratory distress syndrome; NSAIDs = non-steroidal anti-inflammatory drugs)

Drugs may also cause other lung diseases, such as asthma, pulmonary haemorrhage, pleural effusion and, rarely, pleural thickening. An ARDS-like syndrome of acute non-cardiogenic pulmonary oedema may present with dramatic onset of breathlessness, severe hypoxaemia and signs of alveolar oedema on the CXR. This syndrome has been reported most frequently in cases of opiate overdose in injection drug users but also after salicylate overdose, and there are occasional reports of its occurrence after therapeutic doses of drugs, including hydrochlorothiazides and some cytotoxic agents.

Rare interstitial lung diseases

There are over 200 forms of interstitial lung disease (ILD), the majority of which are extremely rare. The clinical features and presentation of the more important and more common forms of rare ILD are summarised in Box 17.79.

Occupational and environmental lung disease

The role of occupation and environmental exposure in lung disease is a particularly important area of respiratory medicine. Occupational lung disease is common and, in addition to the challenges of its diagnosis and management, often involves discussions about the workplace and, in some circumstances, litigation. Many countries encourage the registration of cases of occupational lung disease.

Occupational airway disease

Occupational asthma

Occupational asthma is asthma that results from specific workplace sensitisers and not asthma exacerbated by occupational irritants. It is responsible for 10% of adult-onset asthma and should be considered in any individual of working age who develops new-onset asthma, particularly if the individual reports improvement in asthma symptoms during periods away from work, such as at weekends and on holidays. Workers in certain occupations appear to be at particularly high risk (Box 17.80), and the condition is more common in smokers and atopic individuals. Depending on the intensity of exposure, asthmatic symptoms usually develop within the first few years of employment but are classically preceded by a latent period. Symptoms of rhinoconjunctivitis often precede the development of asthma. When occupational asthma follows exposure to high-molecular-weight proteins, sensitisation may be demonstrated by skin testing or measurement of specific IgE to the agent in question. Confirmation of occupational asthma should be sought from lung function tests. This usually involves serial recording of peak flow at work and home at least four times per day for a minimum of 3 weeks and, if possible, including a holiday period away from work (Fig. 17.60). In certain circumstances, specific challenge tests are required to confirm the diagnosis.

It may be possible to remove the worker from the implicated agent, but when this cannot be done, consideration of personal protective equipment and workplace hygiene may allow the worker to retain their job and livelihood. Specialist follow-up in such situations is highly advisable. Where reduction or avoidance of exposure fails to bring about resolution, the management is identical to that of any patient with asthma.

17.80 Occupational asthma

Most frequently reported causative agents

- Isocyanates
- Flour and grain dust
- Colophony and fluxes
- Latex
- Animals
- Aldehydes
- Wood dust

Workers most commonly reported to occupational asthma schemes

- Paint sprayers
- Bakers and pastry-makers
- Nurses
- Chemical workers

17.79 Rare interstitial lung diseases

Disease	Presentation	CXR	Course
Idiopathic pulmonary haemosiderosis	Haemoptysis, breathlessness, anaemia	Bilateral infiltrates, often perihilar Diffuse pulmonary fibrosis	Rapidly progressive in children Slow progression or remission in adults Death from massive pulmonary haemorrhage or cor pulmonale and respiratory failure
Alveolar proteinosis	Breathlessness and cough Occasionally fever, chest pain and haemoptysis	Diffuse bilateral shadowing, often more pronounced in the hilar regions Air bronchogram	Spontaneous remission in one-third Whole-lung lavage or granulocyte–macrophage colony-stimulating factor (GM–CSF) therapy may be effective
Langerhans cell histiocytosis (histiocytosis X)	Breathlessness, cough, pneumothorax	Diffuse interstitial shadowing progressing to honeycombing	Course unpredictable but may progress to respiratory failure Smoking cessation may be followed by significant improvement Poor response to immunosuppressive treatment
Neurofibromatosis	Breathlessness and cough in a patient with multiple organ involvement with neurofibromas, including skin	Bilateral reticulonodular shadowing of diffuse interstitial fibrosis	Slow progression to death from respiratory failure Poor response to corticosteroid therapy
Alveolar microlithiasis	May be asymptomatic Breathlessness and cough	Diffuse calcified micronodular shadowing more pronounced in the lower zones	Slowly progressive to cor pulmonale and respiratory failure May stabilise in some
Lymphangioleiomyomatosis (LAM)	Haemoptysis, breathlessness, pneumothorax and chylous effusion in females	Diffuse bilateral shadowing CT shows characteristic thin-walled cysts with well-defined walls throughout both lungs	Progressive to death within 10 years Oestrogen ablation and progesterone therapy of doubtful value Consider lung transplantation
Pulmonary tuberous sclerosis	Very similar to lymphangioleiomyomatosis, except occasionally occurs in men		

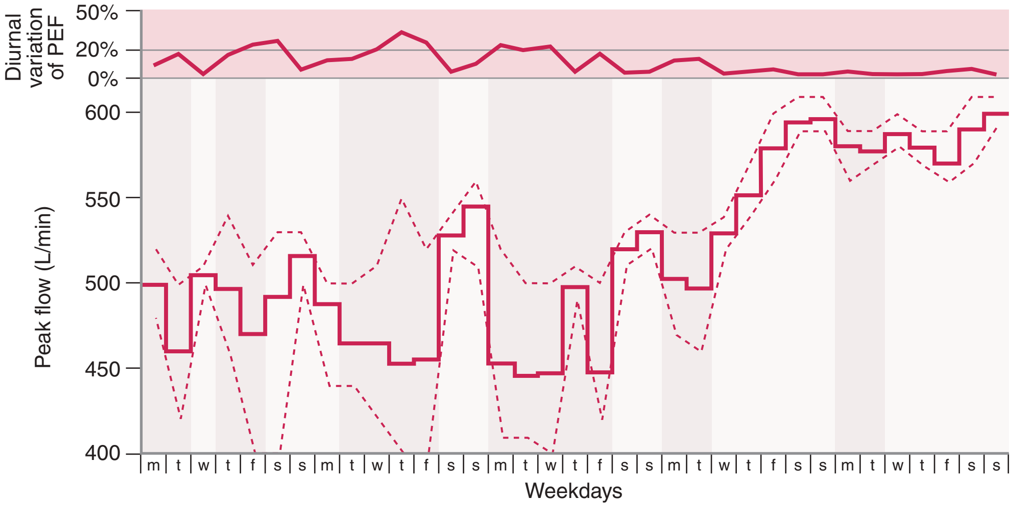

Fig. 17.60 **Peak flow readings in occupational asthma**. In this example, an individual with suspected occupational asthma has performed serial peak flow recording both at and away from work. The maximum, mean and minimum values are plotted daily. Days at work are indicated by the shaded areas. The diurnal variation is displayed at the top. Here, a period away from work is followed by a marked improvement in peak flow readings and a reduction in diurnal variation. (PEF = peak expiratory flow)

Irritant-induced asthma

Irritant-induced asthma (previously called reactive airways dysfunction syndrome) refers to the development of a persistent asthma-like syndrome following the inhalation of an airway irritant: typically, a single, specific exposure to a gas, smoke, fume or vapour in very high concentrations. Pulmonary function tests show airflow obstruction and airway hyper-reactivity, and the management is similar to that of asthma. Once developed, the condition often persists, but it is common for symptoms to improve over years.

Chronic obstructive pulmonary disease

While tobacco smoking remains the most important preventable cause of COPD, there is increasing recognition that other noxious particles and gases can cause, or aggravate, the condition. Occupational COPD is recognised in workers exposed to coal dust, crystalline silica and cadmium. In many low-income countries, indoor air pollution from the burning of biomass fuels in confined spaces used for cooking contributes to the development of COPD.

Byssinosis

Byssinosis occurs in workers of cotton and flax mills exposed to cotton brack (dried leaf and plant debris). An acute form of the disease may occur, but more typically, byssinosis develops after 20–30 years' exposure. Typical symptoms include chest tightness or breathlessness accompanied by a drop in lung function; classically, these are most severe on the first day of the working week ('Monday fever') or on return to work following a period away. As the week progresses, symptoms improve and the fall in lung function becomes less dramatic. Continued exposure leads to the development of persistent symptoms and a progressive decline in FEV_1, similar to that observed in COPD.

Pneumoconiosis

Pneumoconiosis may be defined as a permanent alteration of lung structure due to the inhalation of mineral dust and the tissue reactions of the lung to its presence, excluding bronchitis and emphysema (Box 17.81). Not all dusts are pathogenic. For example, silica is highly fibrogenic, whereas iron (siderosis), tin (stannosis) and barium (baritosis) are almost inert. Beryllium causes an interstitial granulomatous disease similar to sarcoidosis. In many types of pneumoconiosis, a long period of dust exposure is required before radiological changes appear, and these may precede clinical symptoms. The most important pneumoconioses include coal worker's pneumoconiosis, silicosis and asbestosis. Treatment for pneumoconiosis is generally supportive, but for those with progressive fibrosis then nintedanib can be indicated.

Coal worker's pneumoconiosis

Coal worker's pneumoconiosis (CWP) follows prolonged inhalation of coal dust. Dust-laden alveolar macrophages aggregate to form macules in or near the centre of the secondary pulmonary lobule, and a fibrotic reaction ensues, resulting in the appearance of scattered discrete fibrotic lesions. Classification is based on the size and extent of radiographic nodularity. Simple coal worker's pneumoconiosis (SCWP) refers to the appearance of small radiographic nodules in an otherwise asymptomatic individual. SCWP does not impair lung function and, once exposure ceases, will seldom progress. Progressive massive fibrosis (PMF) refers to the formation of one or more conglomerate masses more than 1 cm in diameter (mainly in the upper lobes), which may calcify, cavitate, or undergo necrosis. The development of PMF is usually associated with cough, sputum that may be black (melanoptysis) and breathlessness. Despite the term fibrosis, examination is unremarkable, and the identification of clubbing or crepitations suggests an alternative diagnosis. The CXR appearances may be confused with lung cancer, TB and granulomatosis with polyangiitis (GPA). Management involves removing or reducing coal dust exposure, coupled with supportive treatment. PMF may progress, even after coal dust exposure ceases, and in extreme cases leads to respiratory failure and right ventricular failure. CWP is not associated with increased risk of lung cancer.

Caplan syndrome describes the coexistence of rheumatoid arthritis and rounded fibrotic nodules 0.5–5 cm in diameter. They show pathological features similar to a rheumatoid nodule, including central necrosis, palisading histiocytes, and a peripheral rim of lymphocytes and plasma cells. This syndrome may also occur in other types of pneumoconiosis.

Silicosis

Silicosis results from the inhalation of crystalline silica, usually in the form of quartz, by workers cutting, grinding and polishing stone. Patients experience dry cough and breathlessness, with the sensation of chest restriction replicated on spirometry. Classic or sub-acute silicosis is most common and usually manifests after 10–20 years of continuous silica exposure, during which time the patient remains asymptomatic. Accelerated silicosis is associated with a much shorter duration of dust exposure (typically 5–10 years), may present as early as after 1 year of

17.81 Lung diseases caused by exposure to inorganic dusts

Cause	Occupation	Description	Characteristic pathological features
Coal dust	Coal mining	Coal worker's pneumoconiosis	Focal and interstitial fibrosis, centrilobular emphysema, progressive massive fibrosis
Silica	Mining, quarrying, stone dressing, metal grinding, pottery, boiler scaling	Silicosis	Hyalinised nodule core surrounded by concentric rings of collagen with dust laden histiocytes peripherally
Asbestos	Demolition, ship breaking, manufacture of fireproof insulating materials, pipe and boiler lagging	Asbestos-related disease	Pleural plaques, diffuse pleural thickening, acute benign pleurisy, carcinoma of lung, interstitial fibrosis, mesothelioma
Iron oxide	Arc welding	Siderosis	Mineral deposition only
Tin oxide	Tin mining	Stannosis	Tin-laden macrophages
Beryllium	Aircraft, atomic energy and electronics industries	Berylliosis	Granulomas, interstitial fibrosis

exposure and, as the name suggests, follows a more aggressive course. Intense exposure to very fine crystalline silica dust can cause a more acute disease: silicoproteinosis, similar to alveolar proteinosis (see Box 17.79). Chronic silicosis can develop after 10–30 years of continuous exposure to lower concentrations of silica dust.

Radiological features are similar to those of CWP, with multiple well-circumscribed 3–5 mm nodular opacities predominantly in the mid- and upper zones. As the disease progresses, PMF may develop (Fig. 17.61), and often does so more rapidly than in CWP and with larger opacities. Enlargement of the hilar glands with an 'egg-shell' pattern of calcification is said to be characteristic but is non-specific. Silica is highly fibrogenic and the disease is usually progressive, even when exposure ceases; hence the affected worker should invariably be removed from further exposure. Individuals with silicosis are at increased risk of TB (silicotuberculosis), non-tuberculous mycobacterial infection, lung cancer and COPD; associations with renal and connective tissue disease have also been described.

Berylliosis

Exposure to beryllium is encountered in the aerospace, engineering, telecommunications and biomedical industries. The presence of cough, progressive breathlessness, night sweats and arthralgia in a worker exposed to dusts, fumes or vapours containing beryllium should raise suspicion of berylliosis. Berylliosis is a delayed hypersensitivity-type reaction with a symptom latency ranging from months to more than 10 years. The radiographic appearances are similar in type and distribution to those of sarcoidosis, with nodules and then progression to interstitial fibrosis predominantly in the upper lobes. Bronchoalveolar lavage reveals lymphocytes, biopsy shows sarcoid-like granulomas, and spirometry is restrictive. The diagnosis may be confirmed by the beryllium lymphocyte proliferation test, which indicates sensitisation to beryllium. Treatment is with long-term steroids to delay or prevent progression to fibrosis. As with sarcoidosis, complications can occur as a result of hypercalcaemia.

Less common pneumoconioses

Siderosis refers to the development of a benign iron oxide pneumoconiosis in welders and other iron foundry workers. Baritosis may be seen in barium process workers and stannosis in tin refining. Haematite lung occurs in iron ore miners and resembles silicosis but stains the lung red. Diamond polishers may develop hard metal disease, which is similar to UIP but the pathology shows a giant-cell interstitial pneumonia. Workers exposed to aluminium oxide develop bauxite pneumoconiosis, sometimes referred to as Shaver disease. Popcorn worker's lung is a form of obliterative bronchiolitis following ingestion of diacetyl, used in butter flavouring.

Lung diseases due to organic dusts

A wide range of organic agents may cause respiratory disorders (Box 17.82). The lung disease results from a local immune response to animal proteins or fungal antigens in mouldy vegetable matter. Hypersensitivity pneumonitis is the most common of these conditions.

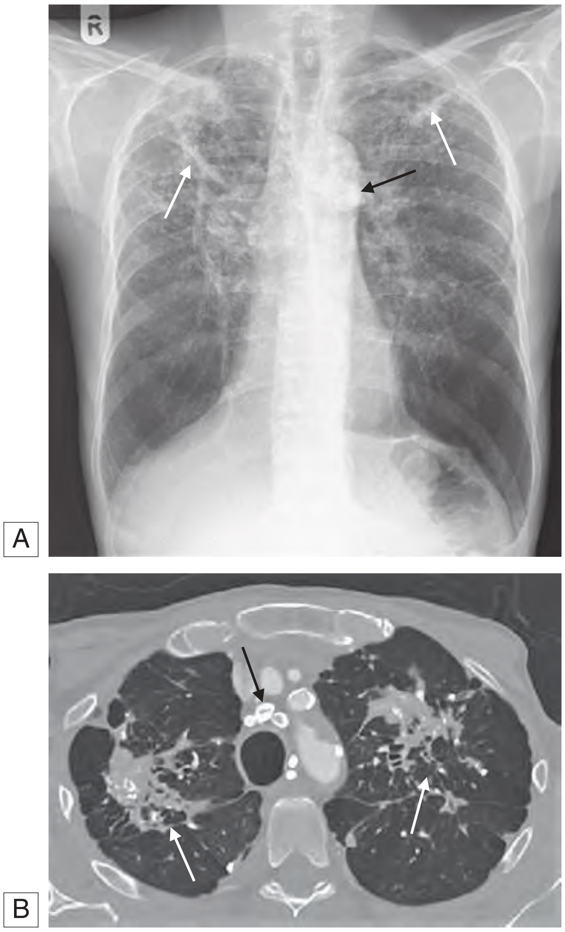

Fig. 17.61 **Silicosis.** **A** Chest X-ray from a patient with silicosis demonstrating bilateral upper lobe calcified nodules and soft tissue opacities (white arrows) with associated volume loss and calcified mediastinal lymph nodes (black arrow). **B** High-resolution CT scan from the same patient demonstrating the presence of nodules (white arrows), with calcified mediastinal lymph nodes (black arrow).

Hypersensitivity pneumonitis

Hypersensitivity pneumonitis (HP; previously called extrinsic allergic alveolitis) results from the inhalation of a wide variety of organic antigens that give rise to a diffuse immune complex reaction in the walls of alveoli and bronchioles. Common causes include farmer's lung and bird fancier's lung. Other examples are shown in Box 17.82. The condition is not

17.82 Examples of lung diseases caused by organic dusts

Disorder	Source	Antigen/agent
Farmer's lung*	Mouldy hay, straw, grain	*Saccharopolyspora rectivirgula* (formerly *Micropolyspora faeni*) *Aspergillus fumigatus*
Bird fancier's lung*	Avian excreta, proteins and feathers	Avian serum proteins
Malt worker's lung*	Mouldy maltings	*Aspergillus clavatus*
Cheese worker's lung*	Mouldy cheese	*Aspergillus clavatus* *Penicillium casei*
Maple bark stripper's lung*	Bark from stored maple	*Cryptostroma corticale*
Saxophone player's lung*	Reed of any wind instrument	*Fusarium* spp. *Penicillium* spp. *Cladosporium* spp.
Byssinosis	Textile industries	Cotton, flax, hemp dust
Inhalation ('humidifier') fever	Contamination of air conditioning	Thermophilic actinomycetes

*Presents as hypersensitivity pneumonitis.

exclusively occupational or due to environmental exposures, and other important causes include medications (see Box 17.78).

The pathology of HP is consistent with both type III and type IV hypersensitivity reactions (Ch. 4). Precipitating IgG antibodies may be detected in the serum and a type III hypersensitivity reaction is believed to occur in the lung, where the precipitation of immune complexes results in activation of complement and an inflammatory response in the alveolar walls, characterised by the influx of mononuclear cells and foamy histiocytes. The presence of poorly formed non-caseating granulomas in the alveolar walls suggests that type IV hypersensitivity responses are also important. The distribution of the inflammatory infiltrate is predominantly peribronchiolar. Chronic forms of the disease may be accompanied by fibrosis. For reasons that remain uncertain, there is a lower incidence of HP in smokers compared to non-smokers.

Clinical features

The presentation of HP varies from an acute form to a more indolent pattern in accordance with the antigen load. For example, the farmer exposed to mouldy hay, as occurs when the hay is gathered and stored damp during a wet summer, or the pigeon fancier cleaning a large pigeon loft, will, within a few hours, report influenza-like symptoms accompanied by cough, breathlessness and wheeze. The individual with low-level antigen exposure, however, such as the owner of an indoor pet bird, will typically present in a more indolent fashion with slowly progressive breathlessness; in some cases, established fibrosis may be present by the time the disease is recognised. Chest auscultation typically reveals widespread end-inspiratory crackles and squeaks.

Investigations

In cases of acute HP, the CXR typically shows ill-defined patchy airspace shadowing, which, given the systemic features, may be confused with pneumonia. HRCT is more likely to show bilateral ground-glass shadowing and areas of consolidation superimposed on small centrilobar nodular opacities with an upper and middle lobe predominance and mosaicism (areas of increased lucency due to air-trapping) (Fig. 17.62). In more chronic disease, features of fibrosis, such as volume loss, traction bronchiectasis and honeycombing, appear. In common with other fibrotic diseases, pulmonary function tests show a restrictive ventilatory defect with reduced lung volumes and impaired gas transfer, dynamic tests may detect oxygen desaturation and, in more advanced disease, type I respiratory failure is present at rest.

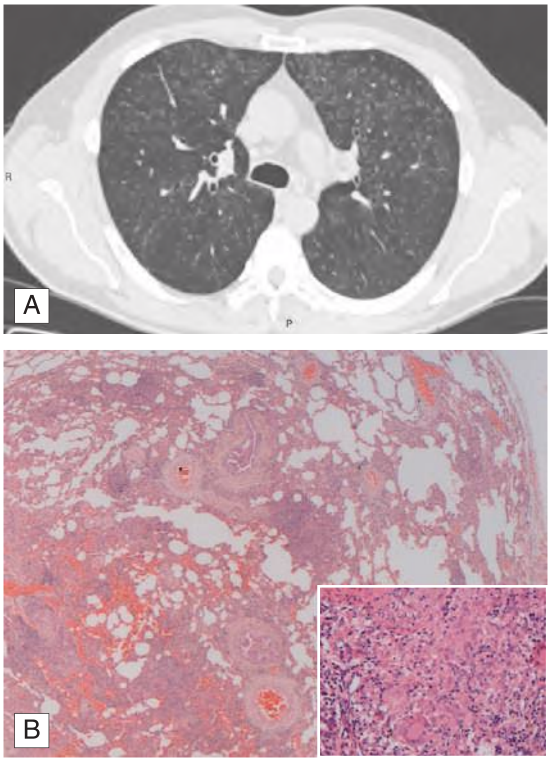

Fig. 17.62 Hypersensitivity pneumonitis. **A** High-resolution CT showing typical patchy ground-glass opacification throughout both lungs. **B** Histology shows evidence of an interstitial inflammatory infiltrate in the lung, and expanding alveolar walls, with a peribronchial distribution. Within the infiltrate, there are foci of small, poorly defined non-caseating granulomas *(inset)*, which often lie adjacent to the airways. In this case, there is little in the way of established lung fibrosis, but this can be marked. *(A) Courtesy of Dr S. Jackson, Western General Hospital, Edinburgh. (B) Courtesy of Dr William Wallace, Department of Pathology, Royal Infirmary of Edinburgh.*

Diagnosis

The diagnosis of HP is usually based on the characteristic clinical and radiological features, together with the identification of a potential source of antigen at the patient's home or place of work (Box 17.83). It may be supported by a positive serum antibody (IgG) or precipitin test or by more sensitive serological investigations. It is important, however, to be aware that the presence of antibodies in the absence of other features does not make the diagnosis; the great majority of farmers with positive precipitins do not have farmer's lung, and up to 15% of pigeon breeders may have positive serum precipitins yet remain healthy.

Where HP is suspected but the cause is not readily apparent, a visit to the patient's home or workplace should be arranged. Occasionally, such as when an agent previously unrecognised as causing HP is suspected, provocation testing may be necessary to prove the diagnosis; if positive, inhalation of the relevant antigen is followed after 3–6 hours by pyrexia and a reduction in vital capacity and gas transfer factor. BAL fluid usually shows an increase in the number of CD8$^+$ T lymphocytes and transbronchial biopsy can occasionally provide sufficient tissue for a confident diagnosis; however, open lung biopsy may be necessary. In up to 40% of patients with HP, the causative antigen remains unknown despite extensive investigation.

Management

If it is practical, the patient should cease exposure to the precipitating agent. In some cases, however, this may be difficult because of either implications for livelihood (such as farmers) or addiction to hobbies (such as pigeon breeders). Dust masks with appropriate filters may minimise exposure and may be combined with methods of reducing levels of antigen such as drying hay before storage. In acute cases,

i 17.83 Predictive factors in the identification of hypersensitivity pneumonitis

- Exposure to a known offending antigen
- Positive precipitating antibodies to offending antigen
- Recurrent episodes of symptoms
- Inspiratory crackles on examination
- Symptoms occurring 4–8 hours after exposure
- Weight loss

prednisolone 0.5 mg/kg should be given daily until clinical and radiological resolution, before slowly weaning over several months down to 10 mg/day for a further few months. In chronic cases, mycophenolate mofetil or azathioprine may be utilised as steroid sparing agents. For those patients with progressive fibrotic change, nintedanib can be indicated.

Severely hypoxaemic patients may require high-concentration oxygen therapy initially. Most patients recover completely, but if unchecked, fibrosis may progress to cause severe respiratory disability, hypoxaemia, pulmonary hypertension, cor pulmonale and eventually death.

Inhalation (humidifier) fever

Inhalation fever shares similarities with HP. It occurs as a result of contaminated humidifiers or air-conditioning units that release a fine spray of microorganisms into the atmosphere. The illness is characterised by self-limiting fever and breathlessness; permanent sequelae are unusual. An identical syndrome can also develop after disturbing an accumulation of mouldy hay, compost or mulch. So-called ‘hot tub lung’ appears to be attributable to *Mycobacterium avium*. Outbreaks of HP in workers using metalworking fluids appear to be linked to *Acinetobacter* or *Ochrobactrum*.

Asbestos-related lung and pleural diseases

Asbestos is a naturally occurring silicate. Asbestos fibres may be classified as either serpentine (chrysotile or white asbestos), which accounts for 95% of the world’s production, or amphibole serpentine (crocidolite or blue asbestos, and amosite or brown asbestos). The favourable thermal and chemical insulation properties led to its extensive use by the shipbuilding and construction industries throughout the latter part of the 20th century. Exposure to asbestos may be followed, after a lengthy latent period, by the development of both pleural and pulmonary disease. With the exception of an increased risk of lung cancer in asbestosis, benign asbestos-related diseases do not increase the risk of malignancy beyond that already resulting from exposure to asbestos.

Pleural plaques

Pleural plaques are the most common manifestation of previous asbestos exposure, being discrete circumscribed areas of hyaline fibrosis situated on the parietal pleura of the chest wall, diaphragm, pericardium or mediastinum. They are virtually always asymptomatic, usually being identified as an incidental finding on a CXR (Fig. 17.63) or thoracic CT scan, particularly when partially calcified. They do not cause impairment of lung function and are benign.

Acute benign asbestos pleurisy

Benign asbestos pleurisy is estimated to occur in around 20% of asbestos workers but many episodes are subclinical and pass unreported. When symptomatic, patients present with features of pleurisy, including mild fever and systemic disturbance. The diagnosis requires the exclusion of other causes of pleurisy, and treatment is with NSAIDs. Repeated episodes may be followed by the development of diffuse (visceral) pleural thickening.

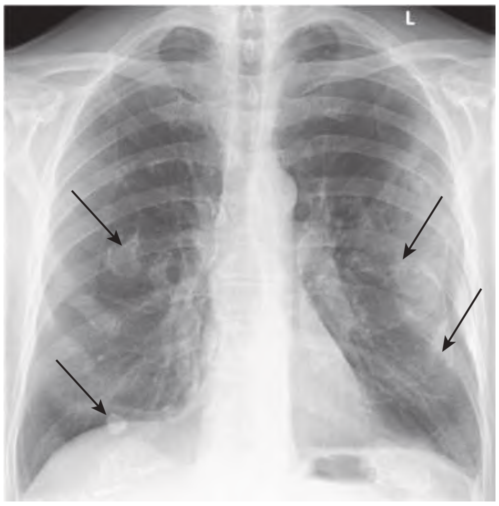

Fig. 17.63 Asbestos-related benign pleural plaques. The CXR shows extensive calcified pleural plaques (‘candle wax’ appearance – arrows), particularly marked on the diaphragm and lateral pleural surfaces.

Benign asbestos-related pleural effusion

Benign asbestos-related pleural effusions are usually small and unilateral. The patient is commonly asymptomatic, though some have symptoms of pleurisy or breathlessness, especially if the effusion is moderate to large. Diagnosis requires the exclusion of mesothelioma, usually by thoracoscopy. Pleural fluid analysis demonstrates an exudate that is often haemorrhagic. Treatment is with drainage if symptomatic.

Diffuse pleural thickening

Diffuse pleural thickening (DPT) refers to thickening of the visceral pleura. In contrast to pleural plaques, if this is sufficiently extensive, it may cause restrictive lung function impairment, exertional breathlessness and, occasionally, persistent chest pain. The typical appearances of DPT on CXR include thickening of the pleura along the chest wall and obliteration of the costophrenic angles. Earlier manifestations detected by CT scanning include parenchymal bands (Fig. 17.64) and ‘rounded atelectasis’. There is no treatment and the condition may be progressive in around one-third of individuals. A pleural biopsy may be required to exclude mesothelioma.

Asbestosis

Fibrosis of the lung following asbestos exposure generally requires substantial exposure over several years and is rarely associated with low-level or bystander exposure (unlike other asbestos-related diseases). In common with other fibrosing lung diseases, asbestosis usually presents with exertional breathlessness and fine, late inspiratory crackles over the lower zones. Finger clubbing may be present. Pulmonary function tests and HRCT appearances are similar to those of IPF. These features, accompanied by a history of substantial asbestos exposure, are generally sufficient to establish the diagnosis. In some cases, asbestos fibre counts may be performed on lung biopsy material to establish the diagnosis, but this is rarely appropriate pre-mortem. Patients with asbestosis have a 10-fold increased risk of developing lung cancer, with rates even higher amongst those with additional smoking history.

Asbestosis is usually slowly progressive and has a better prognosis than untreated IPF. In advanced cases, respiratory failure, pulmonary hypertension and cor pulmonale may still develop. As well as supportive treatments, nintedanib can slow lung function decline in patients with progressive fibrosis.

Mesothelioma

Mesothelioma is a malignant tumour affecting the pleura or, less commonly, the peritoneum. Its occurrence almost invariably suggests past

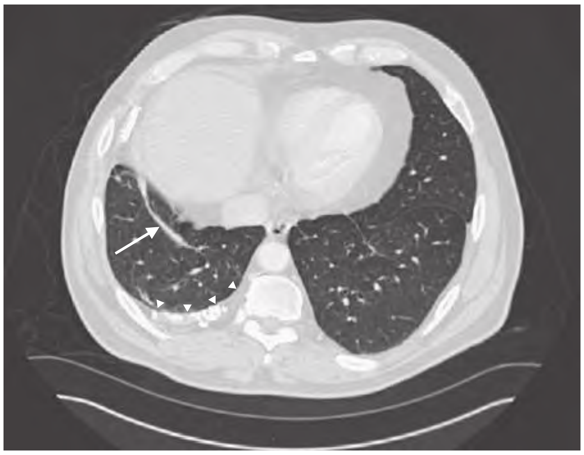

Fig. 17.64 Diffuse pleural thickening. Thoracic CT showing right-sided posterior calcified pleural thickening (white arrowheads) and an associated parenchymal band (white arrow).

asbestos exposure, which may be low-level. There is typically a long latent interval between first exposure and the onset of clinical manifestations, and this accounts for the continued increasing incidence many years after control measures have been implemented. Despite regulations, 125 million people are exposed to asbestos in the workplace. Around 1 in 170 of all British men born in the 1940s will die of mesothelioma.

Pleural mesothelioma typically presents with increasing breathlessness resulting from pleural effusion or unremitting chest pain, reflecting involvement of the chest wall. As the tumour progresses, it encases the underlying lung and may invade the parenchyma, the mediastinum and the pericardium. Metastatic disease, although not often clinically detectable in life, is a common finding on postmortem examination.

Mesothelioma is almost invariably fatal. The use of chemotherapy with agents such as cisplatin and pemetrexed may improve quality of life and can be accompanied by a small survival benefit of around 3 months more than may be expected in patients who are otherwise untreated. Radiotherapy can be used to control pain. A variety of surgical techniques have been used, but to date these have shown no benefit and may even cause harm to patients. Pleural effusions can be managed with drainage (preferably with indwelling pleural catheters) with or without pleurodesis. The typical duration of survival from onset of symptoms is around 16 months for epithelioid tumours, 10 months for sarcomatoid tumours and 15 months for biphasic tumours, with only a minority of patients surviving for longer periods.

Occupational lung cancer

Individuals exposed to substantial quantities of asbestos are at increased risk of lung cancer, particularly if they smoke tobacco. Increased risks of lung cancer have also been reported in workers who develop silicosis and those exposed to radon gas, beryllium, diesel exhaust fumes, cadmium, chromium, and dust and fumes from coke plants.

Occupational pneumonia

Occupational and environmental exposures may be linked to the development of pneumonia. Pneumococcal vaccine is recommended for welders and metal workers. Farm workers, abattoir workers and hide factory workers may be exposed to *Coxiella burnetii*, the causative agent of Q fever. The organisms are excreted from milk, urine, faeces and amniotic fluid; they may be transmitted by cattle ticks or contaminated dust from the milking floor, or by drinking milk that is inadequately pasteurised. Birds (often parrots) or budgerigars infected with *Chlamydophila psittaci* can cause psittacosis. Sewage workers, farmers, animal handlers and vets run an increased risk of leptospirosis and leptospiral pneumonia, due to their exposure to *Leptospira interrogans* in rodent urine. Contact with rabbits, hares, muskrats and ground squirrels is associated with tularaemic pneumonia, caused by *Francisella tularensis*. Anthrax (wool-sorter's disease) may occur in workers exposed to hides, hair, bristle, bonemeal and animal carcasses that are contaminated with *Bacillus anthracis* spores. In some countries, COVID-19 is classified as an occupational disease of people whose occupations cause them to come into close contact with other people (medical staff, taxi drivers, retail workers). This is potentially a contentious issue, however, as the high prevalence of the disease in the community makes it difficult to establish the specific source of a COVID-19 infection.

Pulmonary vascular disease

Pulmonary embolism

The majority of pulmonary emboli arise from the propagation of lower limb deep vein thrombosis (venous thromboembolism, VTE). Rare causes include septic emboli (from endocarditis affecting the tricuspid or pulmonary valves), tumour (especially choriocarcinoma), fat following fracture of long bones (such as the femur), air, and amniotic fluid (which may enter the mother's circulation following delivery).

Clinical features

The diagnosis of pulmonary embolism (PE) may be aided by asking three questions:

- Is the clinical presentation consistent with PE?
- Does the patient have risk factors for PE?
- Are there any alternative diagnoses that can explain the patient's presentation?

Clinical presentation varies, depending on number, size and distribution of emboli and on underlying cardiorespiratory reserve (Box 17.84). A recognised risk factor for VTE is present in 80%–90% (see Box 24.71). The presence of one or more risk factors increases the risk further still.

Investigations

A variety of non-specific radiographic appearances have been described (Fig. 17.65), but the CXR is most useful in excluding key differential diagnoses, such as pneumonia or pneumothorax. Normal appearances in an acutely breathless and hypoxaemic patient should raise the suspicion of PE, as should bilateral changes in anyone presenting with unilateral pleuritic chest pain.

The ECG is often normal but is useful in excluding other important differential diagnoses, such as acute myocardial infarction and pericarditis. The most common findings in PE include sinus tachycardia and anterior T-wave inversion but these are non-specific; larger emboli may cause right heart strain revealed by an $S_1Q_3T_3$ pattern, ST-segment and T-wave changes, or the appearance of right bundle branch block.

Analysis of an ABG typically shows a reduced PaO_2 and a normal or low $PaCO_2$, and an increased alveolar–arterial oxygen gradient, but may be normal in a significant minority. A metabolic acidosis may be seen in acute massive PE with cardiovascular collapse.

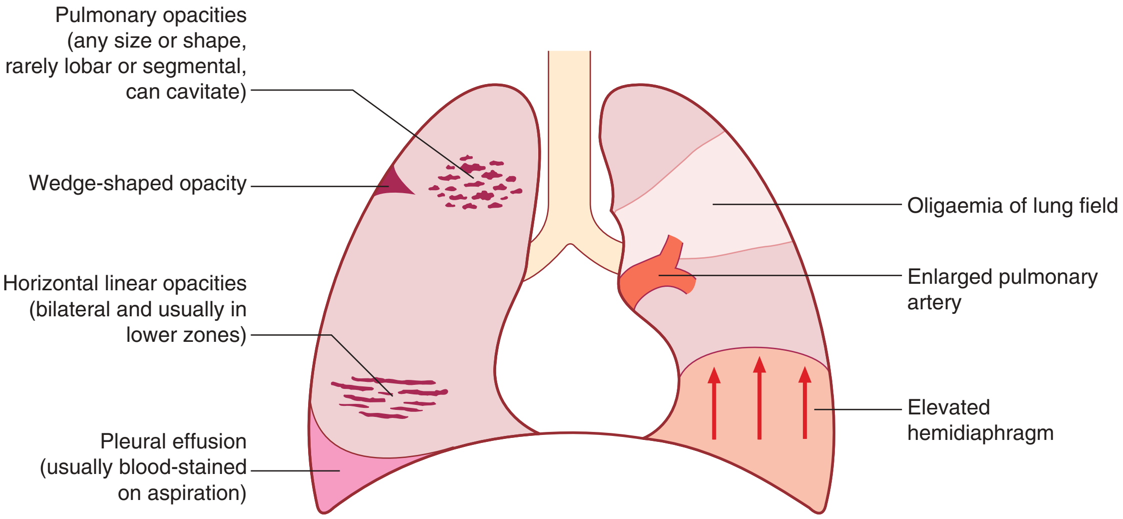
The two-level PE Wells score is used to estimate the likelihood of PE (Fig. 17.66). If a PE is likely, the patient should have definitive imaging (as below). If a PE is unlikely, a D-dimer test is performed. An elevated D-dimer (see Fig. 10.7) is of limited value, as it may be raised in a variety of other conditions, including myocardial infarction, pneumonia and sepsis. However, low levels, particularly in the context of a low clinical risk, have a high negative predictive value and further investigation is usually unnecessary (see Fig. 17.66). The serum troponin I (see Box 10.3) may be elevated, reflecting right heart strain.

The first-line diagnostic test is CTPA (Fig. 17.67). It has the advantage of visualising the distribution and extent of the emboli or highlighting an alternative diagnosis, such as consolidation, pneumothorax or aortic dissection. The sensitivity of CTPA may be increased by simultaneous visualisation of the femoral and popliteal veins, although this is not widely used in clinical practice. Due to potential nephrotoxicity of the contrast

17.84 Features of pulmonary thromboembolic disease

	Acute massive PE	Acute small/medium PE	Chronic PE
Pathophysiology	Major haemodynamic effects: ↓cardiac output; acute right heart failure	Occlusion of segmental pulmonary artery → infarction ± effusion	Chronic occlusion of pulmonary microvasculature, right heart failure
Symptoms	Faintness or collapse, crushing central chest pain, apprehension, severe dyspnoea	Pleuritic chest pain, restricted breathing, haemoptysis	Exertional dyspnoea Late: symptoms of pulmonary hypertension or right heart failure
Signs	Major circulatory collapse: tachycardia, hypotension, ↑JVP, RV gallop rhythm, loud P_2, severe cyanosis, ↓urinary output	Tachycardia, pleural rub, raised hemidiaphragm, crackles, effusion (often blood-stained), low-grade fever	Early: may be minimal Later: RV heave, loud P_2 Terminal: signs of right heart failure
CXR	Usually normal; may be subtle oligaemia	Pleuropulmonary opacities, pleural effusion, linear shadows, raised hemidiaphragm	Enlarged pulmonary artery trunk, enlarged heart, prominent right ventricle
ECG	$S_1Q_3T_3$ anterior T-wave inversion, RBBB	Sinus tachycardia	RV hypertrophy and strain
ABG	Markedly abnormal with ↓PaO_2 and ↓$PaCO_2$, metabolic acidosis	May be normal or ↓PaO_2 or ↓$PaCO_2$	Exertional ↓PaO_2 or desaturation on formal exercise testing
Alternative diagnoses	Myocardial infarction, pericardial tamponade, aortic dissection	Pneumonia, pneumothorax, musculoskeletal chest pain	Other causes of pulmonary hypertension

(JVP = jugular venous pressure; PE = pulmonary embolism; RBBB = right bundle branch block; RV = right ventricular)



Pulmonary opacities (any size or shape, rarely lobar or segmental, can cavitate)
Wedge-shaped opacity
Horizontal linear opacities (bilateral and usually in lower zones)
Pleural effusion (usually blood-stained on aspiration)
Oligaemia of lung field
Enlarged pulmonary artery
Elevated hemidiaphragm

Fig. 17.65 Features of pulmonary thromboembolism or infarction on chest X-ray.

media, care should be taken in patients with renal impairment undergoing CTPA, and the test is contraindicated in those with a history of iodinated contrast media allergy. In these cases, either *V/Q* scanning or ventilation/perfusion single photon emission computed tomography (*V/Q* SPECT) may be considered. *V/Q* scanning is of little benefit in patients with an abnormal CXR, as perfusion abnormalities are likely due to underlying lung disease rather than PE. Specific diagnostic and management considerations for PE in pregnancy are shown in Box 17.85.

Colour Doppler ultrasound of the leg veins may be used in patients with suspected PE, particularly if there are clinical signs in a limb, as many will have identifiable proximal thrombus in the leg veins. This can be a useful strategy in pregnant women, where there is a desire to minimise ionising radiation to the mother and the fetus.

Bedside echocardiography is extremely helpful in the differential diagnosis and assessment of acute circulatory collapse. Acute dilatation of the right heart is usually present in massive PE, and thrombus (embolism in transit) may be visible. Important differential diagnoses, including left ventricular failure, aortic dissection and pericardial tamponade, can also be identified.

In the absence of haemodynamic instability and hypoxia, most patients can have outpatient investigations for PE, providing they receive anticoagulation. The Pulmonary Embolism Severity Index (PESI) predicts 30-day outcome. Those with a low risk of mortality (low PESI score) and no evidence of RV dysfunction on imaging can be considered for outpatient management, whilst those with either high risk of mortality (high PESI) or evidence of RV dysfunction on imaging should be admitted, and furthermore be monitored closely if they have RV dysfunction and a raised troponin.

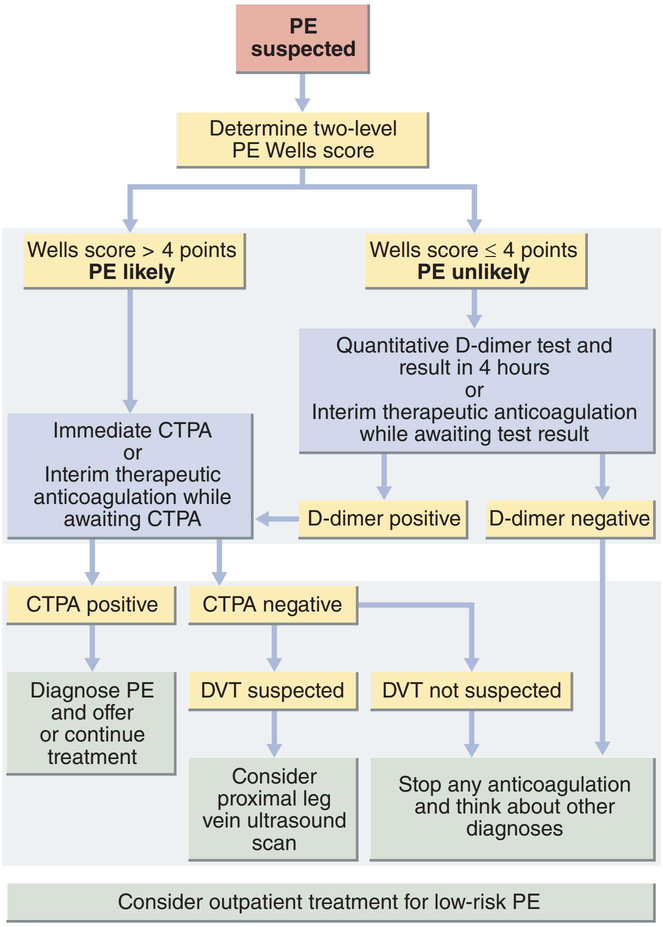
Management

General measures

Prompt recognition and treatment are potentially life-saving. Sufficient oxygen should be given to hypoxaemic patients to maintain the target oxygen saturations specified on. p 229. Opiates may be necessary to relieve pain and distress but should be used with caution in the hypotensive patient.

Anticoagulation

The main principle of treatment for PE is anticoagulation, which is discussed for PE and other forms of venous thromboembolism (VTE) on page 951.



PE suspected
Determine two-level PE Wells score
Wells score > 4 points PE likely
Wells score ≤ 4 points PE unlikely
Quantitative D-dimer test and result in 4 hours or Interim therapeutic anticoagulation while awaiting test result
Immediate CTPA or Interim therapeutic anticoagulation while awaiting CTPA
D-dimer positive
D-dimer negative
CTPA positive
CTPA negative
Diagnose PE and offer or continue treatment
DVT suspected
DVT not suspected
Consider proximal leg vein ultrasound scan
Stop any anticoagulation and think about other diagnoses
Consider outpatient treatment for low-risk PE

Fig. 17.66 Algorithm for the investigation of patients with suspected pulmonary thromboembolism. Clinical risk is based on the presence of risk factors for venous thromboembolism and the probability of another diagnosis. (CTPA = computed tomography pulmonary angiography; DVT = deep vein thrombosis; PE = pulmonary embolism)

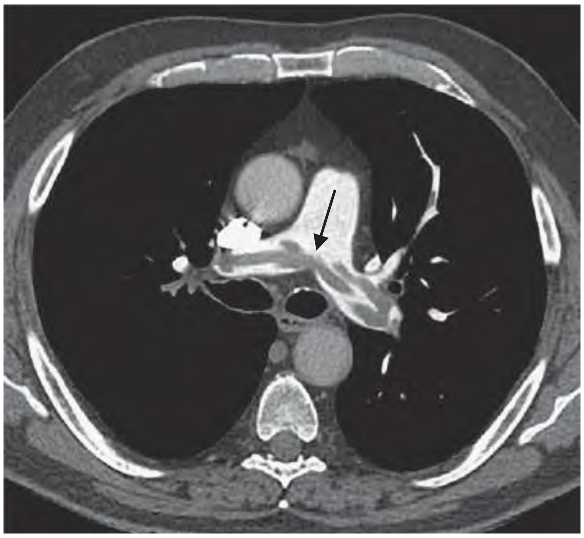


Fig. 17.67 Pulmonary embolism on CT pulmonary angiogram. The arrow points to a saddle embolism at the bifurcation of the pulmonary trunk extending into the right and left pulmonary arteries.

17.85 Pulmonary embolism in pregnancy

- **Maternal mortality**: venous thromboembolism is the leading direct cause in the UK.
- **CT pulmonary angiography**: may be performed safely (0.01–0.06 mGy). It is important to consider the risk of radiation to breast tissue (particularly if there is a family history of breast carcinoma).
- **V/Q scanning**: greater radiation dose to fetus (0.11–0.22 mGy) but significantly less to maternal breast tissue.
- **In utero radiation exposure**: estimated incidence of childhood malignancy is about 1 in 16 000 per mGy.
- **Warfarin**: teratogenic, so pulmonary embolism should be treated with low-molecular-weight heparin during pregnancy.

Thrombolytic and surgical therapy

Thrombolysis is indicated in any patient presenting with acute massive PE accompanied by haemodynamic instability. Patients must be screened carefully for haemorrhage risk, as there is a high risk of intracranial haemorrhage. Surgical or percutaneous pulmonary embolectomy may be considered in patients with an absolute contraindication to thrombolysis but carries a high mortality.

Caval filters

An inferior vena cava filter should be considered in any patient where anticoagulation is contraindicated or in those who have had recurrent VTE despite anticoagulation. Retrievable caval filters are particularly useful in individuals with temporary risk factors. The caval filter should be used only until anticoagulation can be safely initiated, at which time the filter should be removed if possible.

Further investigations

All patients should be clinically assessed for underlying malignancy. A detailed history should elicit any red-flag symptoms and be followed by focused examination (including breast and rectal examination if appropriate) and investigation only if there are any positive findings. Thrombophilia screening is only considered for patients with no identified VTE risk factors and a strong family history of VTE.

Prognosis

Immediate mortality is greatest in those with echocardiographic evidence of right ventricular dysfunction or cardiogenic shock. Once anticoagulation is commenced, however, the risk of mortality falls rapidly. The risk of recurrence is highest in the first 6–12 months after the initial event, and at 10 years around one-third of individuals will have suffered a further event. Patients with right ventricular dysfunction at presentation should have a repeat echocardiogram at 3 months to assess for evidence of chronic thromboembolic pulmonary hypertension (CTEPH).

Pulmonary hypertension

Pulmonary hypertension (PH) is defined as a mean pulmonary artery pressure (PAP) of at least 25 mmHg at rest, as measured by right heart catheterisation. The definition may be further refined by consideration of the pulmonary wedge pressure (PWP), the cardiac output and the transpulmonary pressure gradient (mean PAP – mean PWP). The clinical classification of PH is shown in Box 17.86. Further classification is based on the degree of functional disturbance, assessed using the New York Heart Association (NYHA) grades I–IV. Although respiratory failure due to intrinsic pulmonary disease is the most common cause of PH, severe PH may occur as a primary disorder, as a complication of connective tissue disease such as systemic sclerosis, left heart disease, or as a result of CTEPH.

Primary pulmonary hypertension (PPH) is a rare but important disease that predominantly affects women aged between 20 and 30 years. Familial disease is rarer still but is known to be associated with pathogenic variants in the gene encoding type II bone morphogenetic protein receptor (*BMPR2*),

i 17.86 Classification of pulmonary hypertension

Pulmonary arterial hypertension

- Idiopathic
- Heritable
- Drugs
- Connective tissue disease
- HIV
- Portal hypertension
- Congenital heart disease
- Schistosomiasis
- Pulmonary veno-occlusive disease
- Pulmonary capillary haemaglomatosis

Pulmonary hypertension owing to left heart disease

- Systolic dysfunction
- Diastolic dysfunction
- Valvular disease

Pulmonary hypertension owing to lung disease/hypoxia

- Chronic obstructive pulmonary disease
- Interstitial lung disease
- Sleep-disordered breathing

Adapted from Kiely DG, Elliot CA, Sabroe I, Condliffe R. Pulmonary hypertension: diagnosis and management. BMJ 2013;346:f2028.

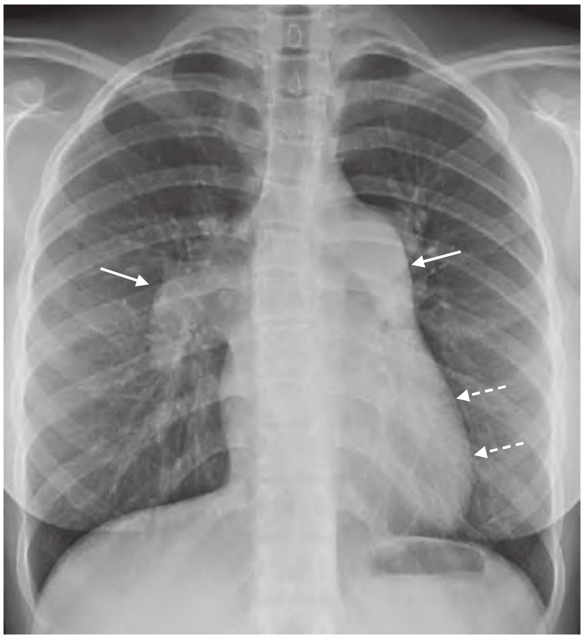

Fig. 17.68 Appearances of pulmonary hypertension on chest X-ray. There is evidence of enlarged pulmonary arteries (white arrows), right ventricle enlargement (interrupted white arrows) and a paucity of peripheral pulmonary blood vessels.

a member of the transforming growth factor beta (TGF-β) superfamily. Variants in this gene have been identified in some patients with sporadic PH. Pathological features include hypertrophy of both the media and the intima of the vessel wall and a clonal expansion of endothelial cells, which take on the appearance of plexiform lesions. There is marked narrowing of the vessel lumen and this, together with the frequently observed in situ thrombosis, leads to an increase in pulmonary vascular resistance and PH.

Clinical features

The presentation of PH is often insidious and the condition is frequently diagnosed at an advanced stage. Typical symptoms include breathlessness, chest pain, fatigue, palpitations, exertional dizziness and syncope. Important signs include elevation of the JVP (with a prominent 'a' wave if in sinus rhythm), a parasternal heave (right ventricular hypertrophy), accentuation of the pulmonary component of the second heart sound, a right ventricular third heart sound, peripheral oedema and ascites. Signs of interstitial lung disease or cardiac, liver or connective tissue disease may suggest the underlying cause.

Investigations

The diagnosis of PH should be suspected if an ECG shows a right ventricular 'strain' pattern or a CXR shows enlarged pulmonary arteries, peripheral pruning and right ventricle enlargement (Fig. 17.68). Doppler assessment of the tricuspid regurgitant jet by transthoracic echocardiography provides a non-invasive estimate of the PAP, which is equal to 4 × (tricuspid regurgitation velocity)^2. Further assessment should be by right heart catheterisation to assess pulmonary haemodynamics, measure vasodilator responsiveness and guide further therapy. Additional investigations should be performed to identify the cause of PH, including pulmonary function tests, V/Q scan, CT thorax, CTPA, MRI, overnight oximetry and exercise testing.

Management

Specialist centres should direct the management of PH. Diuretic therapy should be prescribed for patients with right heart failure. Supplemental oxygen should be given to maintain resting PaO_2 above 8 kPa (60 mmHg). Anticoagulation should be considered unless there is an increased risk of bleeding. Digoxin may be useful in patients who develop atrial tachyarrhythmias. Pregnancy carries a very high risk of death, and women of child-bearing age should be counselled appropriately. Excessive physical activity that leads to distressing symptoms should be avoided, but otherwise patients should be encouraged to remain active. Pneumococcal and influenza vaccination should be offered. Nitrates should be avoided owing to the risk of hypotension, and β-blockers are poorly tolerated. Cyclizine can aggravate PH and should also be avoided.

Disease-targeted strategies have focused on replacing endogenous prostacyclins with epoprostenol, treprostinil or iloprost; blocking endothelin-mediated vasoconstriction with agents such as bosentan, ambrisentan or macitentan; or enhancing endogenous nitric oxide-mediated vasodilatation with phosphodiesterase V inhibitors such as sildenafil 20 mg 3 times daily or tadalafil 40 mg once daily, or the guanylate cyclase stimulator riociguat titrated up to 2.5 mg 3 times daily. High-dose calcium channel blockers such as amlodipine 20 mg once daily may be appropriate in those with an acute pulmonary vasodilator response as assessed at right heart catheterisation.

Selected patients can be referred for double-lung transplantation, and pulmonary thrombo-endarterectomy may be contemplated in those with chronic thromboembolic pulmonary hypertension (CTEPH). Atrial septostomy (the creation of a right-to-left shunt) decompresses the right ventricle and improves haemodynamic performance; it may be used as a bridge to transplantation.

Diseases of the upper airway

Diseases of the nasopharynx

Allergic rhinitis

This is a disorder in which there are episodes of nasal congestion, watery nasal discharge and sneezing. It may be seasonal or perennial and is due to an immediate hypersensitivity reaction in the nasal mucosa. Seasonal antigens include pollens from grasses, flowers, weeds or trees. Grass pollen is responsible for hay fever, the most common type of seasonal allergic rhinitis in northern Europe, which is at its peak between May and July. This is a worldwide problem, however, which may be aggravated during harvest seasons.

Perennial allergic rhinitis may be a specific reaction to antigens derived from house dust, fungal spores or animal dander, but similar symptoms can be caused by physical or chemical irritants, pungent odours or fumes, including strong perfumes, as well as cold air and dry atmospheres. The phrase 'vasomotor rhinitis' is often used in this context, as the term 'allergic' is a misnomer.

Clinical features

In the seasonal type, there are frequent sudden attacks of sneezing, with profuse watery nasal discharge and nasal obstruction. These attacks last for a few hours and are often accompanied by pruritus, watering of the eyes and conjunctival irritation. In perennial rhinitis, the symptoms are similar but more continuous and usually less severe. Skin hypersensitivity tests with the relevant antigen are usually positive in seasonal allergic rhinitis but are less useful in perennial rhinitis.

Management

In those sensitised to house dust, simple measures, such as thorough dust removal from the bed area, leaving a window open and washing all bedding once weekly, are often helpful. Avoidance of pollen and antigens from domestic pets, however desirable and beneficial, may be impractical.

The following medications, singly or in combination, are usually effective in both seasonal and perennial allergic rhinitis:

- an antihistamine (such as loratadine or cetirizine)
- sodium cromoglicate nasal spray
- corticosteroid nasal spray, such as beclometasone dipropionate, fluticasone, mometasone or budesonide.

When symptoms are very severe, resistant to usual treatments and seriously interfering with school, business or social activities, immunotherapy (desensitisation) is also used but carries the risk of anaphylaxis and must be managed in specialist centres. Vasomotor rhinitis is often difficult to treat but may respond to ipratropium bromide, administered into each nostril 3 times daily.

Sleep-disordered breathing

A variety of respiratory disorders affect sleep or are affected by sleep. Cough and wheeze disturbing sleep are characteristic of asthma, while the hypoventilation that accompanies normal sleep can precipitate respiratory failure in patients with disordered ventilation due to chest wall restrictive diseases, neuromuscular diseases or diaphragmatic paralysis.

In contrast, a small but important group of disorders cause problems only during sleep. Patients may have normal lungs and daytime respiratory function, but during sleep have either abnormalities of ventilatory drive (central sleep apnoea) or upper airway obstruction (obstructive sleep apnoea). Of these, the obstructive sleep apnoea/hypopnoea syndrome is by far the most common and important. When this coexists with COPD (overlap syndrome), severe respiratory failure can result, even if the COPD is mild.

The obstructive sleep apnoea/hypopnoea syndrome

Recurrent upper airway obstruction during sleep, sufficient to cause sleep fragmentation and daytime sleepiness, is thought to affect 2% of women and 4% of men aged 30–60 in populations of predominantly European descent. Daytime sleepiness, especially in monotonous situations, results in a threefold increased risk of road traffic accidents and a ninefold increased risk of single-vehicle accidents.

Aetiology

Sleep apnoea results from recurrent occlusion of the pharynx during sleep, usually at the level of the soft palate. Inspiration results in negative pressure within the pharynx. During wakefulness, upper airway dilating muscles, including palatoglossus and genioglossus, contract actively during inspiration to preserve airway patency. During sleep, muscle tone declines, impairing the ability of these muscles to maintain pharyngeal patency. In a minority of people, a combination of an anatomically narrow palatopharynx and under-activity of the dilating muscles during sleep results in inspiratory airway obstruction. Incomplete obstruction causes turbulent flow, resulting in snoring (44% of men and 28% of women aged 30–60 snore). More severe obstruction triggers increased inspiratory effort and transiently wakes the patient, allowing the dilating muscles to re-open the airway. These awakenings are so brief that patients have no recollection of them. After a series of loud deep breaths that may wake their bed partner, the patient rapidly returns to sleep, snores and becomes apnoeic once more. This cycle of apnoea and awakening may repeat itself many hundreds of times per night and results in severe sleep fragmentation and secondary variations in blood pressure, which may predispose over time to cardiovascular disease.

Factors that predispose to the obstructive sleep apnoea/hypopnoea syndrome (OSAHS) include male gender, which doubles the risk, and obesity, which is found in about 70% because parapharyngeal fat deposits tend to narrow the pharynx. Nasal obstruction or a recessed mandible can further exacerbate the problem. Acromegaly and hypothyroidism also predispose by causing submucosal infiltration and narrowing of the upper airway. Sleep apnoea is often familial, where the maxilla and mandible are back-set, narrowing the upper airway. Alcohol and sedatives predispose to snoring and apnoea by relaxing the upper airway dilating muscles. As a result of marked sympathetic activation during apnoea, sleep-disordered breathing is associated over time with sustained hypertension and an increased risk of coronary events and stroke. Associations have also been described with insulin resistance, the metabolic syndrome and type 2 diabetes. In addition to improving symptoms and reducing vehicular risk, treatment of sleep apnoea reduces sympathetic drive and blood pressure and may also improve these associated metabolic disorders.

Clinical features

Excessive daytime sleepiness is the principal symptom and snoring is virtually universal. The patient usually feels that he or she has been asleep all night but wakes unrefreshed, though may recall waking with choking/gasping episodes. Bed partners report loud snoring in all body positions and often have noticed multiple breathing pauses (apnoeas). Difficulty with concentration, impaired cognitive function and work performance, depression, irritability and nocturia are other features. Early morning headaches may be a sign of more severe OSAHS.

Investigations

Provided that the sleepiness does not result from inadequate time in bed or from shift work, anyone who repeatedly falls asleep during the day when not in bed, who complains that their work is impaired by sleepiness, or who is a habitual snorer with multiple witnessed apnoeas should be referred for a sleep assessment. A more quantitative assessment of daytime tendency to fall asleep can be obtained by using the Epworth questionnaire (Box 17.87).

Overnight studies of breathing, oxygenation and sleep quality are diagnostic (Fig. 17.69), but the level of investigation depends on local resources and the probability of the diagnosis. The severity of OSAHS is determined by the number of apnoeas/hypopnoeas per hour of sleep (apnoea/hypopnoea index, AHI). An apnoea is defined as a 10-second or longer breathing pause and a hypopnoea is a 10-second or longer 50% reduction in ventilation that results in a 4% drop in arterial oxygen saturation. An AHI of 5–14 indicates mild OSAHS, 15–30 is moderate and more than 30 is severe.

Several other conditions can cause daytime sleepiness but can usually be excluded by a careful history (Box 17.88). Narcolepsy is a rare cause of sudden-onset sleepiness, occurring in 0.05% of the population. Idiopathic hypersomnolence occurs in younger individuals and is characterised by long nocturnal sleeps.

Management

The major hazard to patients and those around them is traffic accidents. Drivers must be strongly advised not to drive until treatment has relieved their sleepiness, and they have a responsibility to inform their driving licence authority if there is sleepiness sufficient to impair driving.

17.87 Epworth sleepiness scale

How likely are you to doze off or fall asleep in the situations described below? Choose the most appropriate number for each situation from the following scale:

0 = would never doze
1 = slight chance of dozing
2 = moderate chance of dozing
3 = high chance of dozing

- Sitting and reading
- Watching TV
- Sitting inactive in a public place (such as a theatre or a meeting)
- As a passenger in a car for an hour without a break
- Lying down to rest in the afternoon when circumstances permit
- Sitting and talking to someone
- Sitting quietly after a lunch without alcohol
- In a car, while stopped for a few minutes in the traffic

The maximum score is 24 points. Normal subjects average 5.9 (SD 2.2) and patients with severe obstructive sleep apnoea average 16.0 (SD 4.4).

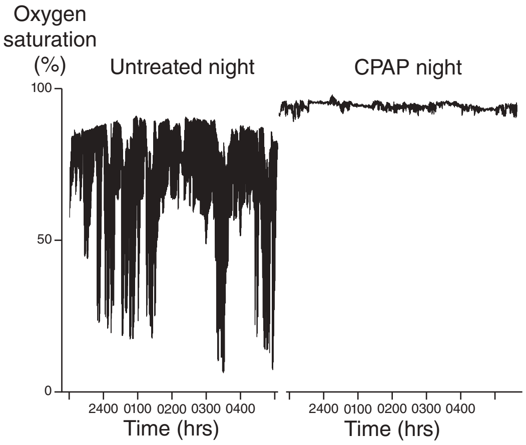

Fig. 17.69 Overnight oxygen saturation trace in sleep apnoea/hypopnoea syndrome. The left-hand panel shows the trace of a patient who had 53 apnoeas plus hypopnoeas/hour, 55 brief awakenings/hour and marked oxygen desaturation. The right-hand panel shows the effect of continuous positive airway pressure (CPAP) of 10 cm H_2O delivered through a tight-fitting nasal mask: it abolished his breathing irregularity and awakenings, and improved oxygenation. *Courtesy of Professor N.J. Douglas.*

Overweight or obese patients should be encouraged to lose weight and be considered for drug therapy or bariatric surgery if appropriate. Though weight loss rarely results in complete remission of OSAHS, it decreases the AHI and blood pressure and improves overall health and quality of life. In a minority, relief of nasal obstruction or the avoidance of alcohol or sedating medication may prevent obstruction. Mandibular advancement devices that fit over the teeth and hold the mandible forward, thus opening the pharynx, are an alternative that is effective in some patients. There is no evidence that palatal surgery is of benefit. The gold standard therapy for the majority of patients is continuous positive airway pressure (CPAP) delivered by a mask every night to splint the upper airway open. When CPAP is tolerated, the effect is often dramatic (see Fig. 17.69), with relief of somnolence and improved daytime performance, quality of life and survival. Unfortunately, 30%–50% of patients do not tolerate CPAP or have poor adherence. Increasing use of telemedicine to remotely monitor CPAP use and overnight oximetry will enable non-adherers to be identified and supported to improve adherence. Interventions to promote adherence include improving mask fit, pressure modification and humidification, education and behavioural therapy.

17.88 Differential diagnosis of persistent sleepiness

Lack of sleep

- Inadequate time in bed
- Extraneous sleep disruption
- Shift work
- Excessive caffeine intake
- Physical illness

Sleep disruption

- Sleep apnoea/hypopnoea syndrome
- Periodic limb movement disorder (recurrent limb movements during non-REM sleep, frequent nocturnal awakenings)

Sleepiness with relatively normal sleep

- Narcolepsy
- Idiopathic hypersomnolence (rare)
- Neurological lesions (hypothalamic or upper brainstem infarcts or tumours)
- Drugs

Psychological/psychiatric

- Depression

Central sleep apnoea and nocturnal hypoventilation

Episodic reduced ventilation during sleep in the absence of upper airway obstruction is called central sleep apnoea (CSA) or nocturnal hypoventilation. CSA is much less prevalent than OSAHS.

Aetiology

Central sleep apnoea or nocturnal hypoventilation occur when there is an altered ventilatory drive and/or an inability to adequately expand the chest. Loss of drive can be a result of brainstem abnormality, such as in post-polio syndrome and brainstem stroke, or ventilatory suppression, such as by opiates and alcohol. Cheyne–Stokes breathing is a sinusoidal cycling between hypoventilation and compensatory hyperventilation, which occurs most often when left ventricular failure influences ventilatory drive. The normal ventilatory mechanism can be impaired by neurological conditions, including myopathies such as Duchenne muscular dystrophy and myotonic dystrophy; neuropathies such as motor neuron disease and Guillain–Barré syndrome; and neuromuscular junction abnormalities such as myasthenia gravis. The condition can also occur when chest wall expansion is reduced by severe kyphoscoliosis and severe ankylosing spondylitis. Severe obstructive airways disease also impairs ventilation, and the effect is exacerbated by coexisting OSA, obesity and/or muscle weakness.

Clinical features

Patients may present with the same signs and symptoms as those with OSAHS, in addition to features of the condition that has caused their CSA or hypoventilation. Patients can also present in acute type II respiratory failure or with features of cor pulmonale (fluid retention due to chronic hypoxia). Early morning headaches are common.

Investigations

Sleep studies are used to differentiate between OSAHS, CSA and nocturnal hypoventilation. Blood gases can demonstrate the presence of type II respiratory failure, and pulmonary function tests can assess ventilatory muscle strength. History and examination will often reveal the underlying cause for CSA or hypoventilation, but further targeted investigations may also be necessary, such as CT or MRI brain imaging if there is concern for brain stem pathology such as stroke, tumour or Chiari malformations.

Management

Overnight home NIV improves symptoms and, in many conditions, prognosis. Sedating medications (unless palliative) and excessive alcohol should be stopped. Optimising heart failure treatment can reduce Cheyne–Stokes breathing, but patients who remain symptomatic may benefit from CPAP or nocturnal oxygen.

Laryngeal disorders

The larynx is commonly affected by acute self-limiting infections. Other disorders include chronic laryngitis, laryngeal tuberculosis, laryngeal paralysis and laryngeal obstruction. Tumours of the larynx are relatively common, particularly in smokers. For further details, the reader should refer to an otolaryngology text.

Chronic laryngitis

The common causes are listed in Box 17.89. The chief symptoms are hoarseness or loss of voice (aphonia). There is irritation of the throat and a spasmodic cough. The disease pursues a chronic course, frequently uninfluenced by treatment, and the voice may become permanently impaired. Other causes of chronic hoarseness include use of inhaled glucocorticoid treatment, tuberculosis, laryngeal paralysis or tumour.

In some patients, a CXR may reveal an unsuspected lung cancer or pulmonary tuberculosis. If these are not found, laryngoscopy should be performed to exclude a local structural cause.

When no specific treatable cause is found, the voice must be rested completely. This is particularly important for public speakers and singers. Smoking should be avoided. Some benefit may be obtained from frequent inhalations of steam.

17.89 Causes of chronic laryngitis

- Excessive use of the voice
- Heavy tobacco smoking
- Heavy alcohol intake
- Gastroesophageal reflux disease
- Repeated attacks of acute laryngitis
- Chronic sinusitis with post-nasal drip
- Occupational exposure to irritating chemicals or dusts
- Sarcoidosis

Laryngeal paralysis

Interruption of the motor nerve supply of the larynx is nearly always unilateral and, because of the intrathoracic course of the left recurrent laryngeal nerve, usually left-sided. One or both recurrent laryngeal nerves may be damaged by thyroidectomy, carcinoma of the thyroid or anterior neck injury. Rarely, the vagal trunk itself is involved by tumour, aneurysm or trauma.

Clinical features and management

Hoarseness always accompanies laryngeal paralysis, whatever its cause. Paralysis of organic origin is seldom reversible, but when only one vocal cord is affected, hoarseness may improve or even disappear after a few weeks, as the normal cord compensates by crossing the midline to approximate with the paralysed cord on phonation.

Bovine cough is a characteristic feature of organic laryngeal paralysis and lacks the explosive quality of normal coughing because the cords fail to close the glottis. Sputum clearance may also be impaired. A normal cough in patients with partial loss of voice or aphonia virtually excludes laryngeal paralysis. Stridor is occasionally present but seldom severe, except when laryngeal paralysis is bilateral.

Laryngoscopy is required to establish the diagnosis of laryngeal paralysis. The paralysed cord lies in a paramedian position, midway between abduction and adduction.

The cause of laryngeal paralysis should be treated, if possible, and speech and language therapy offered. In unilateral paralysis, persistent dysphonia may be improved by the injection of bulking agents into the affected vocal cord. In bilateral organic paralysis, tracheal intubation, tracheostomy or surgery to reposition and/or reshape the larynx may be necessary.

Psychogenic hoarseness and aphonia

Psychogenic causes of hoarseness or aphonia may be suggested by associated symptoms in the history (p. 1275). Laryngoscopy may be necessary, however, to exclude a physical cause. In psychogenic aphonia, only the voluntary movement of adduction of the vocal cords is seen to be impaired. Speech therapy may be helpful.

Laryngeal obstruction

Laryngeal obstruction is more liable to occur in children than in adults because of the smaller size of the glottis. Important causes are listed in Box 17.90. Sudden complete laryngeal obstruction by a foreign body produces the clinical picture of acute asphyxia: violent but ineffective inspiratory efforts with indrawing of the intercostal spaces and the unsupported lower ribs, accompanied by cyanosis. Unrelieved, the condition progresses to coma and death within a few minutes. When, as in most cases, the obstruction is incomplete at first, the main clinical features are progressive breathlessness accompanied by stridor and cyanosis. Urgent treatment to prevent complete obstruction is needed.

Management

Laryngeal obstruction carries a high mortality and demands prompt treatment. When a foreign body causes laryngeal obstruction, give up to five sharp back blows using the heel of the hand between the scapulae. If this is ineffective, use abdominal thrusts, or, in those aged under 12 months old or pregnant, give chest thrusts. Tracheostomy must be performed without delay if these procedures fail to relieve complete obstruction. If the adult patient is stable with only partial obstruction, direct laryngoscopy can be used to remove the foreign body or insert a tube past the obstruction into the trachea to maintain the airway.

In diphtheria, antitoxin should be administered, and for other infections the appropriate antibiotic should be given. In angioedema, complete laryngeal occlusion can usually be prevented by treatment with adrenaline (epinephrine; 0.5–1 mg (0.5–1 mL of 1:1000) intramuscularly), chlorphenamine (10 mg by slow intravenous injection) and intravenous hydrocortisone sodium succinate (200 mg).

Tracheal disorders

Tracheal obstruction

External compression by lymph nodes containing metastases, usually due to lung cancer, is a more frequent cause of tracheal obstruction than primary benign or malignant tumours. The trachea may also be compressed by a retrosternal goitre (see Fig. 20.12). Rare causes include an aneurysm of the aortic arch and (in children) tuberculous mediastinal lymph nodes. Tracheal stenosis is an occasional complication of tracheostomy, prolonged intubation, granulomatosis with polyangiitis (GPA) or trauma.

17.90 Causes of laryngeal obstruction

- Inflammatory or allergic oedema, or exudate
- Spasm of laryngeal muscles
- Inhaled foreign body
- Inhaled blood clot or vomitus in an unconscious patient
- Tumours of the larynx
- Bilateral vocal cord paralysis
- Fixation of both cords in rheumatoid disease

Clinical features and management

Stridor can be detected in every patient with severe tracheal narrowing. CT will usually enable the cause to be identified, and bronchoscopic examination (if safe) can determine the degree and nature of the obstruction and enable biopsy.

Localised tumours of the trachea can be resected, but reconstruction after resection may be technically difficult. Endobronchial laser therapy, bronchoscopically placed tracheal stents, chemotherapy and radiotherapy are alternatives to surgery. The choice of treatment depends on the nature of the tumour and the general health of the patient. Benign tracheal strictures can sometimes be dilated but may require resection.

Tracheo-oesophageal fistula

Tracheo-oesophageal fistula may be present in newborn infants as a congenital abnormality. In adults, it is usually due to malignant lesions in the mediastinum, such as carcinoma or lymphoma, eroding both the trachea and oesophagus to produce a communication between them. Swallowed liquids enter the trachea and bronchi through the fistula and provoke coughing.

Surgical closure of a congenital fistula, if undertaken promptly, is usually successful. There is usually no curative treatment for malignant fistulae, and death from overwhelming pulmonary infection rapidly supervenes.

Pleural disease

Pleurisy, pleural effusion, empyema and asbestos-associated pleural disease have been described above. Specific features of pleural disease in old age are shown in Box 17.91.

Pneumothorax

Pneumothorax is the presence of air in the pleural space, which can either occur spontaneously, or result from iatrogenic injury or trauma to the lung or chest wall (Box 17.92). Pneumothorax has a bimodal age distribution (Fig. 17.70). Primary spontaneous pneumothorax (PSP) occurs in patients with no history of lung disease. Smoking, tall stature and the presence of apical subpleural blebs are risk factors. Secondary spontaneous pneumothorax (SSP) affects patients with pre-existing lung disease and is associated with higher mortality rates.

Where the communication between the airway and the pleural space seals off as the lung deflates and does not re-open, the pneumothorax is referred to as 'closed' (Fig. 17.71A). The mean pleural pressure remains negative, spontaneous re-absorption of air and re-expansion of the lung occur over a few days or weeks, and infection is uncommon. This contrasts with an 'open' pneumothorax, where the communication fails to seal and air continues to pass freely between the bronchial tree and pleural space (Fig. 17.71B). An example of the latter is a bronchopleural fistula, which can facilitate the transmission of infection from the airways into the pleural space, leading to empyema. An open pneumothorax is commonly seen following rupture of an emphysematous bulla, tuberculous cavity or lung abscess into the pleural space.

17.91 Pleural disease in old age

- **Spontaneous pneumothorax**: invariably associated with underlying lung disease in old age and has significant mortality.
- **Rib fracture**: common cause of pleural-type pain; may be spontaneous (due to coughing), traumatic or pathological. Underlying osteomalacia may contribute to poor healing, especially in the housebound with no exposure to sunlight.
- **Tuberculosis**: should always be considered and actively excluded in older patients presenting with a unilateral pleural effusion.
- **Mesothelioma**: more common in older individuals than younger people due to a long latency period between asbestos exposure (often more than 20 years) and the development of disease.
- **Analgesia**: frail older people are particularly sensitive to the respiratory depressant effects of opiate-based analgesia and careful monitoring is required when using these agents for pleural pain.

Occasionally, the communication between the airway and the pleural space acts as a one-way valve, allowing air to enter the pleural space during inspiration but not to escape on expiration. This is a tension pneumothorax. Large amounts of trapped air accumulate progressively in the pleural space and the intrapleural pressure rises to well above atmospheric levels. This causes mediastinal displacement towards the opposite side, with compression of the opposite normal lung and impairment of systemic venous return, causing cardiovascular compromise (Fig. 17.71C).

Clinical features

The most common symptoms are sudden-onset unilateral pleuritic chest pain and/or breathlessness. In those individuals with underlying lung disease, breathlessness can be severe and may not resolve spontaneously. In patients with a small pneumothorax, physical examination may be normal. A larger pneumothorax (> 15% of the hemithorax) results in decreased or absent breath sounds. The combination of absent breath sounds and a hyper-resonant percussion note is diagnostic of pneumothorax.

By contrast, in tension pneumothorax there is rapidly progressive breathlessness, associated with a marked tachycardia, hypotension, cyanosis and tracheal displacement away from the side of the silent hemithorax. Occasionally, tension pneumothorax may occur without mediastinal shift, if malignant disease or scarring has splinted the mediastinum.

Investigations

The CXR shows the sharply defined edge of the deflated lung with complete translucency (no lung markings) between this and the chest wall. Care must be taken to differentiate between a large pre-existing emphysematous bulla and a pneumothorax. In general, the lung edge is convex in a pneumothorax, whereas the edge of a bulla is concave. Radiological findings should be correlated with the patient's clinical condition. Imaging with CT is indicated in complex pneumothoraces to identify pleural adhesions and

17.92 Classification of pneumothorax

Spontaneous

Primary

- No evidence of overt lung disease; air escapes from the lung into the pleural space through rupture of a small pleural bleb, or the pulmonary end of a pleural adhesion

Secondary

- Underlying lung disease, most commonly chronic obstructive pulmonary disease and tuberculosis; also seen in asthma, lung abscess, pulmonary infarcts, lung cancer and all forms of fibrotic and cystic lung disease

Traumatic

- Iatrogenic (following thoracic surgery or biopsy)
- Chest wall injury

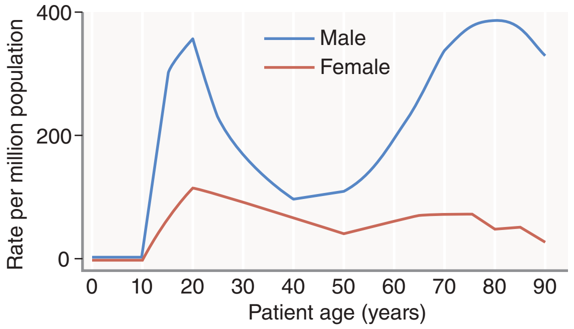

Fig. 17.70 Bimodal age distribution for hospital admissions for pneumothorax in England. The incidence of primary spontaneous pneumothorax peaks in males aged 15–30 years. Secondary spontaneous pneumothorax occurs mainly in males over 55 years.

avoid iatrogenic bronchopleural fistula during subsequent attempts at aspiration. CXRs may also show the extent of any mediastinal displacement and reveal any pleural fluid or underlying pulmonary disease.

Management

Asymptomatic spontaneous pneumothoraces can be managed conservatively, irrespective of their size. Those with an asymptomatic SSP should be admitted for observation, whilst those with an asymptomatic PSP can be discharged with regular outpatient review. Symptomatic patients should be assessed for high-risk characteristics (haemodynamic compromise, hypoxia, bilateral pneumothorax, underlying lung disease, > 50 years old with significant smoking history, haemopneumothorax) and if present and safe to intervene, should undergo insertion of an intercostal chest drain. Symptomatic patients without high-risk characteristics can be managed with percutaneous needle aspiration of air, an ambulatory device or conservatively, depending on patient preference and local availability. Percutaneous needle aspiration of air is a simple and well-tolerated alternative to intercostal tube drainage, with a 60%–80% chance of avoiding the need for a chest drain (Fig. 17.72). Patients who have a persistent symptomatic pneumothorax despite aspiration will require a chest drain. Ambulatory devices are purpose-made and contain a one-way valve to drain the pneumothorax under outpatient monitoring. If there is a tension pneumothorax, life-saving immediate release of the positive pressure by insertion of a cannula into the pleural space should be performed, allowing time to prepare for chest drain insertion.

When needed, intercostal drains are inserted in the triangle of safety (Fig. 17.73), connected to an underwater seal or one-way Heimlich valve, and secured firmly to the chest wall with stitches. Clamping of an intercostal drain is potentially dangerous and rarely indicated. The drain should be removed the morning after the lung has fully re-inflated and bubbling has stopped. Continued bubbling after 48 hours is an indication for consideration of CT scanning and referral to thoracic surgery for surgical intervention to repair the air leak. If bubbling in the drainage bottle stops before full re-inflation, the tube is either blocked, kinked or displaced. Supplemental oxygen may speed up resolution, as it accelerates the rate at which nitrogen is reabsorbed by the pleura.

Patients with a closed pneumothorax should be advised not to fly, as the trapped gas expands at altitude. After complete resolution, there is no clear evidence to indicate how long patients should avoid flying. British Thoracic Society guidelines suggest that flying should be delayed until 7 days after CXR confirmation of full inflation. Patients should also be advised to stop smoking and informed about the risks of a recurrent pneumothorax, which is significantly reduced by smoking cessation. Diving is contraindicated following a pneumothorax, unless a surgical pleurodesis has sealed the lung to the chest wall.

Recurrent spontaneous pneumothorax

After primary spontaneous pneumothorax, recurrence occurs within a year of either aspiration or tube drainage in approximately 25% of patients and should prompt definitive treatment. Surgical pleurodesis is recommended in all patients following a second pneumothorax and should be considered following the first episode of secondary pneumothorax if low respiratory reserve makes recurrence hazardous. Pleurodesis can be achieved by pleural abrasion or parietal pleurectomy at thoracotomy or thoracoscopy.

Fig. 17.72 **Management of spontaneous pneumothorax.** [1]Immediate decompression prior to insertion of the intercostal drain. [2]Aspirate in the second intercostal space anteriorly in the mid-clavicular line using a 16F cannula; discontinue if resistance is felt, the patient coughs excessively, or more than 2.5L of air is removed. [3]The post-aspiration CXR is not a reliable indicator of whether a pleural leak remains, and all patients should be told to attend again immediately in the event of deterioration.

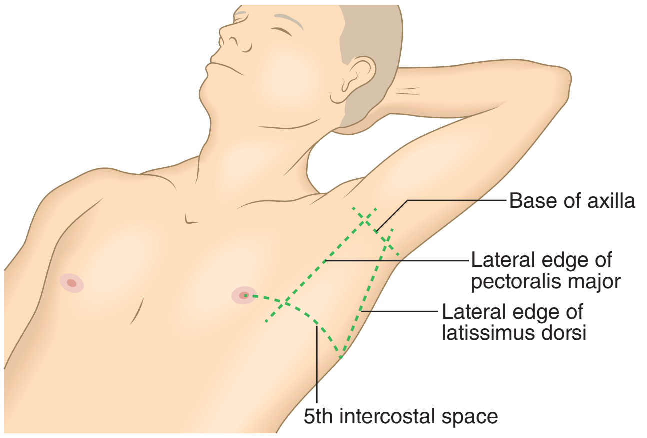
Diseases of the diaphragm and chest wall

Disorders of the diaphragm

Congenital disorders

Diaphragmatic hernias

Congenital defects of the diaphragm can allow herniation of abdominal viscera. Posteriorly situated hernias through the foramen of Bochdalek are more common than anterior hernias through the foramen of Morgagni.



Base of axilla
Lateral edge of pectoralis major
Lateral edge of latissimus dorsi
5th intercostal space

Fig. 17.73 **The triangle of safety**. The triangle of safety is the anatomical region that has the axilla as the apex, the lateral border of the pectoralis major anteriorly, the lateral border of the latissimus dorsi posteriorly and, inferiorly, the 5th intercostal space.

Eventration of the diaphragm

Abnormal elevation or bulging of one hemidiaphragm, more often the left, results from total or partial absence of muscular development of the septum transversum. Most eventrations are asymptomatic and are detected by chance on CXR in adult life, but severe respiratory distress can be caused in infancy if the diaphragmatic muscular defect is extensive.

Acquired disorders

Elevation of a hemidiaphragm may result from paralysis or other structural causes (Box 17.93). The phrenic nerve may be damaged by lung cancer, disease of cervical vertebrae, tumours of the cervical cord, shingles, trauma (including road traffic and birth injuries), surgery, and stretching of the nerve by mediastinal masses and aortic aneurysms. Idiopathic diaphragmatic paralysis occasionally occurs in otherwise fit patients. Paralysis of one hemidiaphragm results in loss of around 20% of ventilatory capacity but may not be noticed by otherwise healthy individuals. Supine vital capacity is significantly reduced compared to erect. Diaphragm fluoroscopy can be used to demonstrate paradoxical upward movement of the paralysed hemidiaphragm on sniffing. CT of the chest and neck is the best way to exclude occult disease affecting the phrenic nerve.

Bilateral diaphragmatic weakness occurs in peripheral neuropathies of any type, including Guillain–Barré syndrome; in disorders affecting the anterior horn cells, such as poliomyelitis; in muscular dystrophies; and in connective tissue disorders, such as SLE and polymyositis.

Hiatus hernia is common. Diaphragmatic rupture is usually caused by a crush injury and may not be detected until years later. Respiratory disorders that cause pulmonary hyperinflation like emphysema, and those that result in small stiff lungs like diffuse pulmonary fibrosis, compromise diaphragmatic function and predispose to fatigue.

Deformities of the chest wall

Thoracic kyphoscoliosis

Abnormalities of alignment of the dorsal spine and their consequent effects on thoracic shape may be caused by:

- congenital abnormality
- vertebral disease, including tuberculosis, osteoporosis and ankylosing spondylitis
- trauma
- neuromuscular disease, such as poliomyelitis.

Simple kyphosis (increased anterior curvature of the thoracic spine) causes less pulmonary impairment than kyphoscoliosis (anteroposterior and lateral curvature). Kyphoscoliosis, if severe, restricts and distorts expansion of the chest wall and impairs diaphragmatic function, causing ventilation–perfusion mismatch in the lungs. Patients with severe deformity may develop type II respiratory failure (initially manifest during sleep), pulmonary hypertension and right ventricular failure. They can often be successfully treated with non-invasive ventilatory support.

17.93 Causes of elevation of a hemidiaphragm

- Phrenic nerve paralysis
- Eventration of the diaphragm
- Decrease in volume of one lung (lobectomy, unilateral pulmonary fibrosis)
- Severe pleuritic pain
- Pulmonary infarction
- Subphrenic abscess
- Large volume of gas in the stomach or colon
- Large tumours or cysts of the liver

Pectus

Pectus is the result of abnormal costal cartilage growth, causing the sternum to protrude (carinatum) or, more commonly, to be depressed (excavatum). In patients with pectus excavatum, the heart is displaced to the left and may be compressed between the sternum and the vertebral column, but only rarely is there associated disturbance of cardiac function. The deformity may restrict chest expansion and reduce vital capacity. Operative correction is rarely performed, and then only for cosmetic reasons. Although no associated gene has yet been identified, pectus is likely genetic, and a quarter of those affected have a family history of chest wall deformity. Pectus can be associated with kyphoscoliosis and is a feature of certain syndromes (including Marfan and Poland syndromes).

Multiple Choice Questions

17.1. A 24-year-old woman presents to the emergency department with sudden onset of left-sided chest pain and breathlessness over the preceding 4 hours. The pain is worse on inspiration. She smokes 10 cigarettes per day. She has no significant past medical history, and her only regular medication is the oral contraceptive pill. She has a temperature of 37.4°C, BP of 95/60 mmHg and pulse rate 120 bpm. Her oxygen saturation is 89% breathing air and improves to 96% with oxygen at 40% FiO_2. Chest examination is normal. Which is the most likely diagnosis?

A. Left lower lobe pneumonia
B. Myocardial infarction
C. Pneumothorax
D. Hyperventilation
E. Pulmonary embolism

Answer: E.

Pulmonary embolism is the most likely diagnosis. She has two risk factors for pulmonary embolism – tobacco exposure and oral contraceptive pill use. Clinically, she has presented with an acute history that would be compatible with pulmonary embolism but could also be compatible with other diagnoses such as pneumonia or pneumothorax. Normal examination findings would make the diagnosis of pulmonary embolism much more likely. It would be anticipated that there would be abnormal examination findings if she was presenting with pneumonia or pneumothorax. Patients with hyperventilation can have normal examination findings, but are not hypoxic on air and conversely have normal or potentially supra-normal oxygen saturations, which would again make this diagnosis unlikely. The clinical history is not suggestive of myocardial infarctions, and it would be very unusual for a patient of this age to present with a myocardial infarction.

17.2. A 76-year-old woman has presented to the emergency department with community-acquired pneumonia. She has a past medical history of hypertension and hypercholesterolaemia. She is disorientated, with an Abbreviated Mental Test Score (AMTS) of 6/10. On examination, her temperature is 38.3°C, pulse rate 120 bpm, BP 90/61 mmHg, respiratory rate 28 breaths per minute and oxygen saturation of 94% on room air. She has bronchial breathing at the left base. She has a number of investigations (numbers in parentheses represent reference ranges):

Chest X-ray	Right lower lobe consolidation
Leukocyte count	13×10^9/L (4.0–11.0)
Urea	9.9 mmol/L (2.5–6.6)
Creatinine	170 µmol/L (50–98)
CRP	60 mg/L (<5)

What is her CURB-65 score?

A. 1
B. 2
C. 3
D. 4
E. 5

Answer: C.

CURB-65, also known as the CURB criteria, is a clinical scoring tool that has been validated for predicting mortality in people with community-acquired pneumonia. The score is an acronym for the risk factors measured. Each risk factor scores one point, for a maximum score of 5:

Confusion of new onset (defined as an AMTS of 8 or less)
Blood **U**rea nitrogen greater than 7 mmol/L (19 mg/dL)
Respiratory rate of 30 breaths per minute or greater
Blood pressure less than 90 mmHg systolic or diastolic blood pressure 60 mmHg or less
Age **65** or older

The scoring system is used to predict 30-day mortality (see below), and can be used to guide the need for inpatient or outpatient treatment of people with pneumonia as well the appropriate use of treatments such as broad-spectrum intravenous antibiotics.

CURB-65 score	30-day mortality	Treatment guidance
0	0.7%	Treat as outpatient
1	3.2%	
2	13.0%	Consider a short stay in hospital or watch very closely as an outpatient
3	17.0%	Requires hospitalisation with consideration for referral for critical care
4	41.5%	
5	57.0%	

17.3. A 78-year-old attends the respiratory outpatient clinic with 1 month of increasing shortness of breath, persistent chest wall pain and 5 kg weight loss. He has no past medical history and is not taking any regular medication. He has a 60 pack-year smoking history and is a retired dock worker. He is apyrexial and haemodynamically stable. There are no clinical features to suggest cardiac failure. On examination of his thorax, there is a stony dull percussion note at the left base, with absent breath sounds. Chest X-ray confirms the presence of a large left pleural effusion and numerous bilateral pleural plaques. Which is the most appropriate initial investigation?

A. Bronchoscopy
B. CT pulmonary angiography
C. Sputum for microscopy and culture
D. Ultrasound-guided pleural fluid aspiration
E. Pulmonary function tests

Answer: D.

The clinical concern for this man would be the possibility of thoracic malignancy and specifically mesothelioma. He has a heavy smoking history, and the occupational history of dock working with the presence of pleural plaques on chest X-ray would raise a concern with regards to possible asbestos exposure.

Diagnostic pleural fluid aspiration would be recommended as the first investigation. This should be done under ultrasound guidance to confirm the presence of the effusion, and ensure minimisation of risk of complications of pleural aspiration such as pneumothorax or perforation of other organs. Analysis of the fluid using Light's criteria will provide guidance as to whether the fluid is a transudate or exudate. Samples should also be sent for cytological examination – the detection of malignant cells in the fluid may provide the diagnosis. Samples should also be sent for both standard and acid-fast bacilli (AFB) microscopy and culture.

Pulmonary function tests are not going to help in this situation, as the chest X-ray has already identified that the cause of the breathlessness is due to the pleural effusion. As this is a pleural-based pathology, sputum analysis and bronchoscopy are not going to be helpful. CT scanning may need to be undertaken, particularly in view of the suspicion of malignancy; however, this should not be a CT pulmonary angiogram. A staging CT with contrast would be the appropriate form of CT imaging in this clinical situation.

17.4. A 34-year-old man presents to the respiratory clinic with a 4-year history of cough and sputum production. He has had three episodes in the last 12 months of worsening symptoms with increased sputum volume and purulence. He has never smoked and works in an office. There are no animals in the house. These episodes have responded to short courses of oral antibiotics. He does not recall any childhood illness and was born on time with no issues in the neonatal period. On examination, he has finger clubbing and bilateral crackles at both apices on auscultation of the chest. The most likely diagnosis is:

A. Asthma
B. COPD
C. Interstitial lung disease
D. Bronchiectasis
E. Sarcoidosis

Answer: D.

In view of the history of chronic sputum production and response to antibiotics, the most likely diagnosis is one of bronchiectasis. Initial investigations would be a CXR, followed by CT scanning. If bronchiectasis was confirmed on CT scan, then he would need extensive investigation for an underlying cause. In view of his age, this would include a sweat test for the possibility of cystic fibrosis.

17.5. A 65-year-old man attends for his annual asthma review with his family doctor. He is currently prescribed beclomethasone/formoterol 100/6 2 puffs twice a day. He has intermittent symptoms of wheeze, breathlessness and cough. He is currently using his salbutamol reliever inhaler 4 times per week. He has attended the local emergency department twice in the last 12 months for acutely worsening symptoms of asthma and received oral steroids each time. What would be the appropriate initial next step?

A. Increase his inhaler to beclomethasone/formoterol 200/6 2 puffs twice a day
B. Add montelukast 10 mg at night
C. Assess inhaler technique and concordance with therapy
D. Add tiotropium 2.5 mg 2 puffs once daily
E. Advise him to continue on current inhaled therapy

Answer: C.

This man has evidence of poorly controlled asthma with excessive use of his reliever inhaler, but also exacerbations of asthma requiring emergency department review. Prior to any increase in asthma therapy, all patients should have a review of inhaler technique and concordance with their current therapy. Only if this is satisfactory should there be a consideration of increasing asthma therapy.

This chapter describes the disorders of the kidneys and urinary tract that are commonly encountered in clinical practice, as well as giving an overview of the highly specialised field of kidney replacement therapy. Disorders of renal tubular function, which may cause alterations in electrolyte and acid–base balance, are described in Chapter 19.

Kidney disease is common, with chronic kidney disease (CKD) affecting 7%–10% of the population and prevalence increasing exponentially with age. In addition, acute kidney injury (AKI) occurs in approximately 10% of hospital admissions. Both AKI and CKD typically occur in the context of other systemic diseases, including diabetes, hypertension, vascular disease or autoimmune diseases such as systemic lupus erythematosus (SLE) or small vessel vasculitis. Less commonly, kidney injury is due to conditions that primarily affect the kidneys, including autoimmune diseases such as immunoglobulin A (IgA) or membranous nephropathy, or genetic disorders such as polycystic kidney disease. The prevalence of each aetiology varies globally, with diabetic kidney disease being particularly prevalent in North and Central America but also increasingly in Asia and in indigenous populations in America and Oceania. IgA nephropathy is more common in east Asia, whereas focal and segmental glomerulosclerosis (FSGS) is far more common in Black people with recent West African descent. Kidney disease due to infection has marked geographic variation, with membranous nephropathy due to hepatitis B being more common in Asia, whereas obstructive nephropathy due to schistosomiasis is more common in Africa.

History taking in kidney disease

Many diseases of the kidney and urinary tract are clinically silent, at least in the early stages. Accordingly, it is common for these conditions to be detected first by routine blood tests, on dipstick testing of the urine or incidentally on scanning. However, it is important to take a history focused on the causes and consequences of kidney disease. This should include enquiring about oral fluid intake, vomiting, diarrhoea or fever, particularly in patients with AKI. Comorbidities such as diabetes mellitus, hypertension, and cardiovascular disease should be documented, including how well they have been controlled. Consider symptoms of undiagnosed systemic disease such as SLE/small vessel vasculitis, including arthralgia, deafness, haemoptysis, nasal congestion, paraesthesia, rash or red eyes. It is necessary to enquire about urinary symptoms, such as visible haematuria (most commonly occurs in urological disease), frothy urine (nephrotic syndrome), urine concentration, reduced urine output or bladder outlet symptoms (p. 650). In addition, document new medications/dose change of drugs such as diuretics/renin–angiotensin–aldosterone system (RAAS) inhibitors, toxins, including gentamicin, or common drugs that cause interstitial nephritis (e.g. proton pump inhibitors, non-steroidal anti-inflammatories, antibiotics). Symptoms in more advanced kidney disease may include itch, lethargy, loss of appetite/weight, oedema, shortness of breath and reduced urine output.

Functional anatomy and physiology

The kidneys

The kidneys play a central role in excretion of many metabolic breakdown products, including ammonia and urea from protein, creatinine from muscle, uric acid from nucleic acids, drugs and toxins. They achieve this by making large volumes of an ultrafiltrate of plasma (125 mL/min, 180 L/24 h) at the glomerulus, and selectively reabsorbing components of this ultrafiltrate at points along the nephron. The rates of filtration and reabsorption are controlled by many hormonal and haemodynamic signals to regulate fluid and electrolyte balance, blood pressure, and acid–base and calcium–phosphate homeostasis (all discussed in Ch. 19). In addition, the kidneys activate vitamin D and control the synthesis of red blood cells by producing erythropoietin. Strategies to replace each of these important functions are required when managing patients with kidney failure.

Each kidney is approximately 10–13 cm in length in healthy adults; they are located retroperitoneally on either side of the aorta and inferior vena cava between the 12th thoracic and 3rd lumbar vertebrae (Fig. 18.1A). The right kidney is usually a few centimetres lower because the liver lies above it. Both kidneys rise and descend several centimetres with respiration.

In keeping with their role as efficient blood filters, the kidneys have a rich blood supply and receive approximately 20%–25% of cardiac output through the renal arteries, which arise from the abdominal aorta. The renal arteries undergo various subdivisions within the kidney, eventually forming interlobular arteries that run through the renal cortex. These eventually give rise to afferent glomerular arterioles that supply the glomeruli. The efferent arteriole, leading from the glomerulus, supplies the distal nephron and medulla (Fig. 18.1B). This unique arrangement of two serial capillary beds reflects the role of the afferent and efferent arterioles in autoregulation of glomerular filtration.

The nephron

Each kidney contains approximately 1 million individual functional units, called nephrons. Each nephron consists of a glomerulus, which is responsible for ultrafiltration of blood, a proximal renal tubule, a loop of Henle, a distal renal tubule and a collecting duct, which together are responsible for selective reabsorption of water and electrolytes that have been filtered at the glomerulus (see Fig. 19.2 and Fig. 18.1B). Under normal circumstances, approximately 99% of the 180 L of glomerular filtrate that is produced each day is reabsorbed in the tubules. The remainder passes through the collecting ducts of each nephron and drains into the renal pelvis and ureters.

The glomerulus

The glomerulus comprises a tightly packed loop of capillaries supplied by an afferent arteriole and drained by an efferent arteriole. It is surrounded by a cup-shaped extension of the proximal tubule termed Bowman capsule, which is composed of epithelial cells. The glomerular capillary endothelial cells contain pores (fenestrae), through which circulating molecules can pass to reach the underlying glomerular basement membrane (GBM), which is formed by fusion of the basement membranes of tubular epithelial and vascular endothelial cells (Fig. 18.1C and D). Glomerular epithelial cells (podocytes) have multiple long foot processes that interdigitate with those of the adjacent epithelial cells, thereby maintaining a selective barrier to filtration (Fig. 18.1E). Mesangial cells lie in the central region of the glomerulus. They have contractile properties similar to those of vascular smooth muscle cells and play a role in regulating glomerular filtration rate (GFR).

Under normal circumstances, the glomerulus is impermeable to proteins the size of albumin (67 kDa) or larger, while proteins of 20 kDa or smaller are filtered freely. The ability of molecules between 20 and 67 kDa to pass through the GBM is variable and depends on the size (smaller molecules are filtered more easily) and charge (positively charged molecules are filtered more easily). Very little lipid is filtered by the glomerulus.

Filtration pressure in the glomerulus is normally maintained at a constant level in the face of wide variations in systemic blood pressure and cardiac output, by alterations in muscle tone within the afferent and efferent arterioles and mesangial cells. This is known as autoregulation. Reduced renal perfusion pressure increases local production of prostaglandins that mediate vasodilatation of the afferent arteriole, thereby increasing the intraglomerular pressure (see Fig. 18.1D). In addition, renin is released by specialised smooth muscle cells in the juxtaglomerular apparatus in response to reduced perfusion pressure, stimulation of sympathetic nerves or low sodium concentration in the fluid in the distal convoluted tubule at the macula densa. Renin cleaves angiotensinogen to release angiotensin I, which is further cleaved by angiotensin-converting enzyme (ACE) to produce angiotensin II. This restores glomerular perfusion pressure in

the short term by causing vasoconstriction of the efferent arterioles within the kidney to raise intraglomerular pressure (see Fig. 18.1D), and by inducing systemic vasoconstriction to increase blood pressure and thus renal perfusion pressure. In the medium term, angiotensin II increases plasma volume by stimulating aldosterone release, which enhances sodium reabsorption by the renal tubules (see Fig. 20.19). Consumption of non-steroidal anti-inflammatory preparations and RAAS inhibitors in the context of volume depletion may impair the ability of the kidney to maintain glomerular filtration and hence exacerbate pre-renal failure (see Fig. 18.20).

Renal tubules, loop of Henle and collecting ducts

The proximal renal tubule, loop of Henle, distal renal tubule and collecting ducts are responsible for reabsorption of water, electrolytes and other solutes, as well as regulating acid–base balance, as described in detail on page 660 and in Figure 19.2. They also play a key role in regulating calcium homeostasis by converting 25-hydroxyvitamin D to the active metabolite 1,25-dihydroxyvitamin D (see Fig. 18.25). Failure of this process contributes to the pathogenesis of hypocalcaemia and hyperparathyroidism that occurs in CKD. Fibroblast-like cells that lie in the interstitium of the renal cortex are responsible for production of erythropoietin, which is required for production of red blood cells. Erythropoietin synthesis is regulated by oxygen tension; anaemia and hypoxia increase production, whereas polycythaemia and hyperoxia inhibit it. Failure of erythropoietin production plays an important role in the pathogenesis of anaemia in CKD.

The ureters and bladder

The ureters drain urine from the renal pelvis (see Fig. 18.1A) and deliver it to the bladder, a muscular organ that lies anteriorly in the lower part of the pelvis, just behind the pubic bone. The function of the bladder is to store and then release urine during micturition. The bladder is richly innervated. Sympathetic nerves arising from T10–L2 relay in the pelvic ganglia to cause relaxation of the detrusor muscle and contraction of the bladder neck (both via α-adrenoceptors), thereby preventing release of urine from the bladder. The distal sphincter mechanism is innervated by somatic motor fibres from sacral segments S2–S4, which reach the sphincter either by the pelvic plexus or via the pudendal nerves. Afferent sensory impulses pass to the cerebral cortex, from where reflex-increased sphincter tone and suppression of detrusor contraction inhibit micturition until it is appropriate. Conversely, parasympathetic nerves arising from S2–S4 stimulate detrusor contraction, promoting micturition.

The micturition cycle has a storage (filling) phase and a voiding (micturition) phase. During the filling phase, the high compliance of the detrusor muscle allows the bladder to fill steadily without a rise in intravesical pressure. As bladder volume increases, stretch receptors in its wall cause reflex bladder relaxation and increased sphincter tone. The act of micturition is initiated first by voluntary and then by reflex relaxation of the pelvic floor and distal sphincter mechanism, followed by reflex detrusor contraction. These actions are coordinated by the pontine micturition centre. Intravesical pressure remains greater than urethral pressure until the bladder is empty.

The prostate gland

The prostate gland is situated at the base of the bladder, surrounding the proximal urethra (p. 599). Exocrine glands within the prostate produce fluid, which comprises about 20% of the volume of ejaculated seminal fluid and is rich in zinc and proteolytic enzymes. The remainder of the ejaculate is formed in the seminal vesicles and bulbo-urethral glands, with spermatozoa arising from the testes.

Smooth muscle fibres within the prostate, which are under sympathetic control, play a role in controlling urine flow through the bulbar urethra, and also contract at orgasm to move seminal fluid through ejaculatory ducts into the bulbar urethra (emission). Contraction of the bulbocavernosus muscle (via a spinal muscle reflex) then ejaculates the semen out of the urethra.

The penis

Blood flow into the corpus cavernosum of the penis is controlled by sympathetic nerves from the thoracolumbar plexus, which maintain smooth muscle contraction (p. 599). In response to afferent input from the glans penis and from higher centres, pelvic splanchnic parasympathetic nerves actively relax the cavernosal smooth muscle via neurotransmitters such as nitric oxide, acetylcholine, vasoactive intestinal polypeptide (VIP) and prostacyclin, with consequent dilatation of the lacunar space. At the same time, draining venules are compressed, trapping blood in the lacunar space with consequent elevation of pressure and erection (tumescence) of the penis.

Investigation of renal and urinary tract disease

Glomerular filtration rate

GFR is the sum of the ultrafiltration rates from plasma into the Bowman space in each nephron and is a measure of renal excretory function. It is proportionate to body size, and the reference value is usually expressed after correction for body surface area (e.g. 150 ± 25 mL/min/1.73 m^2). GFR may be measured directly by injecting and measuring the clearance of compounds such as inulin or radiolabelled ethylenediamine-tetra-acetic acid (EDTA), which are completely filtered at the glomerulus and are not secreted or reabsorbed by the renal tubules (Box 18.1). This is usually reserved for special circumstances when very accurate measurement of renal function is required, for example in assessment of potential living kidney donors. In clinical practice GFR is usually assessed indirectly by measuring serum levels of endogenously produced compounds that are excreted by the kidney, such as creatinine or cystatin C. The most widely used is serum creatinine, which is almost completely filtered at the glomerulus and is not reabsorbed, though it is excreted to a minor degree in the proximal tubule. Changes in serum creatinine concentrations closely reflect changes in GFR; however, the relationship between serum creatinine and GFR is not linear, and a modest elevation in serum creatinine above the normal range may therefore reflect a

18.1 How to quantify glomerular filtration rate (GFR)

Measuring GFR

- Direct measurement using labelled ethylenediamine-tetra-acetic acid (EDTA) or inulin
- Creatinine clearance (CrCl):
    - Minor tubular secretion of creatinine causes CrCl to exaggerate GFR when renal function is poor
    - Can be affected by drugs (e.g. trimethoprim, cimetidine)
    - Needs 24-hour urine collection (inconvenient and often unreliable)

$$\text{CrCl(mL/min)} = \frac{\text{urine creatinine concentration (micromol/L)} \times \text{urine volume (mL)}}{\text{serum creatinine (micromol/L)} \times \text{duration of collection (mins)}}$$

Estimating GFR with equations

These require knowledge of age and sex only; therefore they can be reported automatically by laboratories

- The Chronic Kidney Disease Epidemiology Collaboration (CKD-EPI) 2021 equation:

$$\text{eGFR}_{\text{cr}} = 142 \times \min(S_{\text{cr}}/\kappa,\ 1)^{\alpha} \times \max(S_{\text{cr}}/\kappa,\ 1)^{-1.200} \times 0.9938^{\text{Age}} \times 1.012\,[\text{if female}]$$

  Where S_{cr} = serum creatinine in micromol/L.
  κ = 61.9 if female and 79.6 if male
  α = −0.329 if female and −0.411 if male
  min = whichever is the minimum of serum creatinine/κ or 1
  max = whichever is the maximum of serum creatinine/κ or 1
  For limitations, see Box 18.2.

- CKD-EPI Cystatin C (2012) equation:

$$\text{eGFR}_{\text{cr}} = 133 \times \min(S_{\text{cys}}/0.8,\ 1)^{-0.499} \times \max(S_{\text{cys}}/0.8,\ 1)^{-1.328} \times 0.996^{\text{Age}} \times 0.932\,[\text{if female}]$$

  Where, S_{cys} = serum cystatin C in mg/L
  min = whichever is the minimum of serum cystatin C/0.8 or 1
  max = whichever is the maximum of serum cystatin C/0.8 or 1

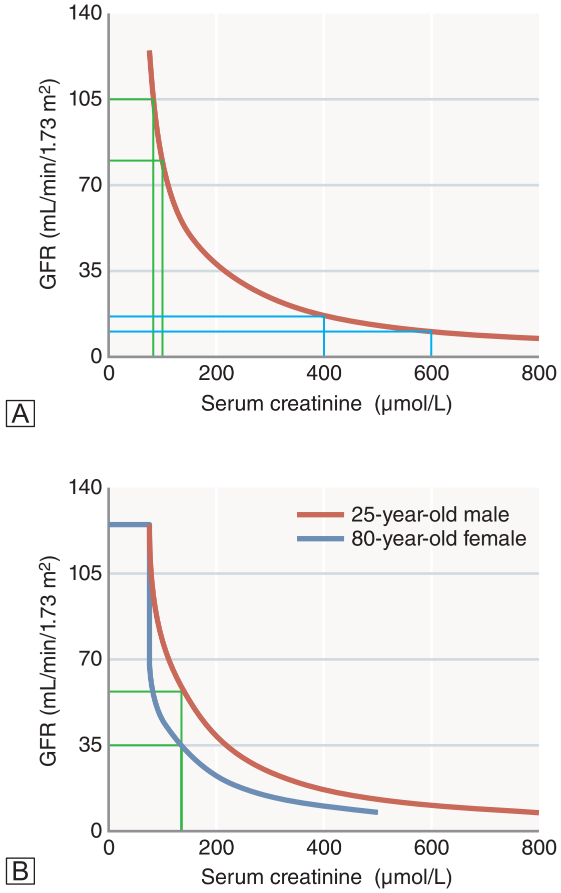

Fig. 18.2 Serum creatinine and the glomerular filtration rate (GFR). A The relationship between serum creatinine and estimated GFR (eGFR) is non-linear: small increases above the normal range (e.g. 80–100 µmol/L; green lines) can indicate a substantial decline in renal function (e.g. 105–80 mL/min/1.73 m^2); conversely, in the high range, large changes in creatinine (e.g. 400–600 µmol/L; blue lines) can occur with only small declines in renal function (e.g. 20–15 mL/min/1.73 m^2). B Creatinine is dependent on muscle mass; the same creatinine value may therefore reflect very different levels of renal function depending on the age and sex of the individual. To convert creatinine in mg/dL to µmol/L, multiply by 88.4.

substantial decline in GFR (Fig. 18.2A). Furthermore, creatinine is derived from muscle and hence the serum creatinine level will be higher in those with greater muscle mass, such as males and younger patients, compared to those with less muscle, even if their kidney function is identical (Fig. 18.2B). For these reasons, several methods have been developed to estimate GFR (eGFR) from serum creatinine measurements. The most widely used is the Chronic Kidney Disease Epidemiology Collaboration (CKD-EPI) equation (see Box 18.1). The CKD-EPI equation only corrects for differences in muscle mass due to age and sex; therefore, it may be misleading in individuals whose muscle bulk is outside the normal range for their age and sex (Box 18.2). In this context, measurement of other endogenous metabolites, such as cystatin C, may provide a more accurate eGFR as cystatin C is produced by all nucleated cells in the body and hence less influenced by muscle mass (see Box 18.1). However, this test is not yet widely available in routine clinical practice. Routine reporting of eGFR is used in the staging of CKD (Box 18.3), which is helpful in predicting the risk of end-stage renal disease and cardiovascular disease (Fig. 18.3). Indeed, eGFR results can be incorporated into calculators to predict the likelihood of progressing to end-stage renal disease (ESRD) (e.g. the Kidney Failure Risk Equation, kidneyfailurerisk.com).

Direct measurement of creatinine clearance by collecting a 24-hour urine sample and relating serum creatinine levels to urinary creatinine excretion (see Box 18.1) is now less commonly performed due to the difficulty in obtaining accurate 24-hour urine collections. It may still have a role in assessing renal function in patients at extremes of muscle mass, where the creatinine-based eGFR equations perform poorly.

18.2 Limitations of estimated glomerular filtration rate (eGFR)

- It is only an estimate, with wide confidence intervals (90% of patients will have eGFR within 30% of their measured GFR, and 98% within 50%)
- Equations based on serum creatinine (CKI-EPI) may overestimate actual GFR in patients with low muscle mass (e.g. those with cachexia, amputees) and underestimate actual GFR in individuals with high muscle mass (e.g. body builders, people of West African ancestry), those taking creatine supplements (creatinine is a metabolite of creatine) or trimethoprim (inhibits tubular secretion of creatinine)
- Requires serum creatinine or cystatin C to be stable over days; therefore, eGFR is **not** valid in assessing acute kidney injury
- In older adults, who constitute the majority of those with low eGFR, there is controversy about categorising people as having chronic kidney disease (see Box 18.3) on the basis of eGFR alone, particularly at stage 3A, since there is little evidence of adverse outcomes when eGFR is $>$ 45 mL/min/1.73 m^2 unless there is also proteinuria
- eGFR is not valid in under-18s or during pregnancy
- Few patients will understand eGFR in terms of mL/min/1.73 m^2; it may therefore be helpful to assume that a GFR of 100 mL/min/1.73 m^2 is approximately normal and to discuss eGFR values in terms of a percentage of normal, e.g. 25 mL/min/1.73 m^2 = 25% of normal kidney function

Urine investigations

Screening for the presence of blood (p. 609), protein (p. 610), glucose, ketones, nitrates and leucocytes, and assessment of urinary pH and osmolality can be achieved by dipstick testing. While the presence of glucose often indicates poor glycaemic control in persons with diabetes mellitus, it can be observed in the presence of normal serum glucose levels where there is dysfunction of the proximal tubule (Fanconi syndrome) or in patients who are prescribed sodium-glucose transporter-2 (SGLT2) inhibitors. The presence of leucocytes and nitrites in urine is indicative of renal tract infection; however, if leucocytes alone are detected, this may indicate inflammation in the kidney (e.g. in the setting of tubulo-interstitial nephritis). Urine pH can provide diagnostic information in the assessment of renal tubular acidosis and urinary tract stones (p. 672). High urine specific gravity indicates that the urine is very concentrated and hence the patient may be dehydrated.

Urine microscopy (Fig. 18.4) may detect dysmorphic erythrocytes or red cell casts, which suggest the presence of glomerular disease. White cell casts are strongly suggestive of pyelonephritis but may also occur in other forms of inflammation, such as interstitial nephritis. Microscopy may also detect the presence of bacteria in those with urinary infection and crystals in patients with renal stone disease. It should be noted that calcium oxalate and urate crystals can sometimes be found in normal urine that has been left to stand, due to crystal formation ex vivo.

Urine collection over a 24-hour period may be performed to measure excretion of solutes, such as calcium, oxalate and urate, in patients with recurrent renal stone disease (p. 644). Proteinuria can also be measured on 24-hour collections but is usually now quantified by protein:creatinine ratio on single urine samples.

Other dynamic tests of tubular function are usually performed in very specific contexts, including concentrating ability (p. 742), ability to excrete a water load (p. 666), ability to excrete acid (p. 629) and calculation of fractional calcium, phosphate or sodium excretion. The fractional excretion of these ions can be calculated by the general formula: $100 \times (\text{urine concentration of analyte} \times \text{serum creatinine}) / (\text{serum concentration of analyte} \times \text{urinary creatinine})$. Calculation of fractional excretion of sodium (FENa) can help in the setting of AKI to differentiate pre-renal failure, when the intact tubules are avidly conserving sodium in response to volume depletion (FENa typically $<1.0\%$), from acute tubular necrosis, when the tubules are damaged and are less able to conserve sodium (FENa typically $>1.0\%$). In clinical practice this is seldom required.

18.3 Stages of chronic kidney disease (CKD)

Stage[1]	Definition[2]	Description	Prevalence[4]	Clinical presentation[5]
1	Kidney damage[3] with normal or high GFR (> 90)	Normal function	3.5%	Asymptomatic
2	Kidney damage and GFR 60–89	Mild CKD	3.9%	Asymptomatic
3A	GFR 45–59	Mild to moderate CKD	7.6% (3A and 3B combined)	Usually asymptomatic
3B	GFR 30–44	Moderate to severe CKD		Anaemia in some patients at 3B Most are non-progressive or progress very slowly
4	GFR 15–29	Severe CKD	0.4%	First symptoms often at GFR < 20 Electrolyte problems and anaemia likely as GFR falls
5	GFR < 15 or on dialysis	Kidney failure	0.1%	Significant symptoms and complications usually present Dialysis initiation varies but usually at GFR < 10

[1] Stages of CKD 1–5 were originally defined by the US National Kidney Foundation Kidney Disease Outcomes Quality Initiative 2002. In the 2013 Kidney Disease Outcomes Quality Initiative (K/DOQI) CKD guideline update, the suffices A1, A2 and A3 are recommended, indicating the presence of albuminuria of < 30, 30–300 and > 300 mg/24 hrs, respectively, in view of the prognostic importance of albuminuria.
[2] Two glomerular filtration rate (GFR) values 3 months apart are required to assign a stage. All GFR values are in mL/min/1.73 m^2.
[3] Kidney damage means pathological abnormalities or markers of damage, including abnormalities in urine tests or imaging studies.
[4] From Hill NR, Fatoba ST, Oke JL, et al. Global prevalence of chronic kidney disease – a systematic review and meta-analysis. PLoS One 2016;11:e0158765.

Blood tests

Haematology

A normochromic normocytic anaemia is common in CKD and is due in part to deficiency of erythropoietin and bone marrow suppression secondary to toxins retained in CKD. Other causes of anaemia include iron deficiency from urinary tract bleeding and haemolytic anaemia secondary to disorders such as haemolytic uraemic syndrome (HUS) and thrombotic thrombocytopenic purpura (TTP). Other abnormalities may be observed that reflect underlying disease processes, such as neutrophilia and raised erythrocyte sedimentation rate (ESR) in vasculitis or sepsis, and lymphopenia and raised ESR in SLE. Fragmented red cells on blood film and low platelets may be observed in thrombotic microangiopathies such as HUS/TTP and malignant hypertension. Pancytopenia may occur in SLE or bone marrow suppression due to myeloma.

Biochemistry

Abnormalities of routine biochemistry are common in renal disease. Serum levels of creatinine may be raised, reflecting reduced GFR (see above), as may serum potassium. Serum levels of urea are often increased in kidney disease, but this analyte has limited value as a measure of GFR since levels are dependent on factors other than renal function. Serum urea increases with high protein intake, following gastrointestinal haemorrhage and in catabolic states. Conversely, urea levels may be reduced in patients with chronic liver disease and in patients who are anorexic or malnourished. In the absence of the other causes mentioned above, an elevated urea:creatinine ratio is indicative of volume depletion and pre-renal failure (see AKI section). Serum calcium tends to be reduced and phosphate increased in CKD, in association with high parathyroid hormone (PTH) levels (secondary hyperparathyroidism, p. 632). In some patients, this may be accompanied by a raised serum alkaline phosphatase level, which is indicative of renal osteodystrophy. Serum bicarbonate may be low in renal failure and also in renal tubular acidosis independent of renal function. Serum albumin may be low in malnutrition/malabsorption, in liver disease, or as a negative acute phase response; however, if it is a new finding, it should prompt urinalysis to exclude nephrotic syndrome. Other biochemical abnormalities that may reflect underlying disease processes include raised glucose and HbA$_{1c}$ in diabetes mellitus (p. 754), raised serum C-reactive protein (CRP) in sepsis and vasculitis and the presence of a paraprotein band or free light chains in the serum in myeloma (p. 1001).

Immunology

Antinuclear antibodies, antibodies to extractable nuclear antigens and anti-double-stranded DNA antibodies may be detected in patients with renal disease secondary to SLE (Ch. 25). Anti-neutrophil cytoplasm antibodies (ANCAs) may be detected in patients with glomerulonephritis secondary to systemic vasculitis (Ch. 25), as may antibodies to GBM in patients with Goodpasture disease, and low levels of complement may be observed in several kidney diseases (see Box 18.17). Antibodies directed against M-type phospholipase A$_2$ receptor (anti-PLA2R) are positive in about 70%–80% of cases of primary membranous nephropathy.

Imaging

Ultrasound

Renal ultrasound is a valuable non-invasive technique that may be performed to assess renal size and to investigate patients suspected of having urinary tract obstruction (Fig. 18.5), renal tumours, cysts or stones. Ultrasound can also be used to provide images of the prostate gland and bladder, and to estimate the completeness of bladder emptying in patients with suspected bladder outflow obstruction. Increased echogenic signal in the renal cortex on ultrasonography with loss of distinction between cortex and medulla is characteristic of intrinsic renal disease, but not specific for any particular pathology. Doppler imaging can be used to study blood flow in extrarenal and larger intrarenal vessels, and to assess the resistivity index (peak systolic velocity – end-diastolic velocity/peak systolic velocity in the intrarenal arteries), which may be elevated (> 0.7) in various diseases, including acute tubular necrosis and rejection of a renal transplant. However, renal ultrasound is operator-dependent, and the results are often less clear in obese patients.

Computed tomography

Computed tomography urography (CTU) is used to evaluate cysts and mass lesions in the kidney or filling defects within the collecting system. It usually entails an initial scan without contrast medium, and subsequent scans following injection of contrast to obtain a nephrogram image and images during the excretory phases. CTU has largely replaced the previous gold-standard investigation of intravenous urography (IVU) for investigation of the upper urinary tract, having the advantage of providing complete staging information and details of surrounding organs. Contrast enhancement is particularly useful for characterising mass lesions within the kidney and differentiating benign from malignant lesions (see Fig. 18.33B). CT without contrast gives clear definition of retroperitoneal anatomy regardless of obesity and is superior to ultrasound in this respect. Non-contrast CT of kidneys, ureters and bladder (CT KUB) is the method of choice for demonstrating stones within the kidney or ureter (see Fig. 18.29). For investigation of patients with renal trauma, a

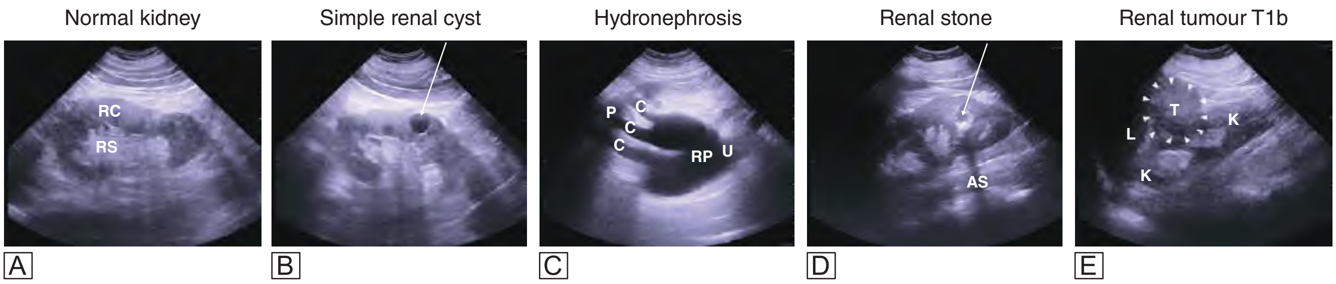

Fig. 18.5 Renal ultrasound. **A** Normal kidney. The normal cortex is less echo-dense (blacker) than the adjacent liver. **B** Simple renal cyst: round, echo-free fluid content, no septa, posterior acoustic enhancement. **C** The renal pelvis and calyces are dilated due to obstruction. The thinness of the parenchyma (P) indicates chronic obstruction. **D** A typical renal stone with posterior shadowing. **E** A T1b renal tumour arising from the renal cortex. 18.4 Renal complications of radiological investigations

Contrast nephrotoxicity

- Acute deterioration in renal function commencing <48 hrs after administration of IV radiographic contrast media. Typically modest and reversible AKI

Risk factors

- Pre-existing renal impairment (eGFR <45 mL/min/1.73 m^2)
- Use of ionic contrast media and repetitive dosing in short time periods
- Diabetes mellitus and myeloma

Prevention

- Hydration with free oral fluids plus consider IV isotonic saline 500 mL, then 250 mL/hr during procedure
- Withhold NSAIDs. Omit metformin for 48 hrs after the procedure, in moderate or high-risk patients
- If the risks are high (eGFR <30 mL/min/1.73 m^2), consider alternative methods of imaging, but proceed if benefit of imaging exceeds risk of nephropathy, which is often the case

Cholesterol atheroembolism

- Typically follows days to weeks after intra-arterial investigations or interventions

Nephrogenic sclerosing fibrosis after MRI contrast agents

- Chronic progressive sclerosis of skin, deeper tissues and other organs, associated with gadolinium-based contrast agents
- Only reported in patients with renal impairment, typically on dialysis or with GFR <15 mL/min/1.73 m^2, but caution is advised in patients with GFR <30 mL/min/1.73 m^2
- Rare since switch to more stable gadolinium-based agents

(AKI = acute kidney injury; eGFR = estimated glomerular filtration rate; IV = intravenous; NSAIDs = non-steroidal anti-inflammatory drugs)

triple-phase CT scan with a delayed phase, to assess the integrity of the collecting system, is performed. Drawbacks of contrast-enhanced CT scans include the significant radiation dose required and the fact that contrast medium may cause AKI. The incidence of contrast nephropathy is probably lower than previously thought, and the AKI is typically mild and reversible; therefore, this potential risk should not preclude CT scanning when indicated (Box 18.4).

Magnetic resonance imaging

Magnetic resonance imaging (MRI) offers excellent resolution and distinction between different tissue types (see Fig. 18.16). It is very useful for local staging of prostate, bladder and penile cancers. Magnetic resonance angiography (MRA) provides an alternative to CT for imaging renal vessels but involves administration of gadolinium-based contrast media, which may carry risks for patients with impaired renal function (see Box 18.4). Whilst MRA provides good images of the main renal vessels, stenosis of small branch arteries may be missed.

Renal arteriography

Renal arteriography involves obtaining X-rays following an injection of contrast medium directly into the renal artery via a catheter that is usually inserted into the femoral artery. The main indication is to investigate renal artery stenosis (p. 621) or haemorrhage following renal trauma. Renal angiography can be combined with therapeutic balloon dilatation or stenting of the renal artery. It can be used to occlude bleeding vessels and arteriovenous fistulae by the insertion of thin platinum wires (coils), which promote thrombosis, thereby securing haemostasis.

Pyelography

Pyelography involves direct injection of contrast medium into the collecting system from above (antegrade) or below (retrograde). It offers the best views of the collecting system and upper tract and is often used to identify the cause of urinary tract obstruction. Antegrade pyelography requires the insertion of a fine needle into the pelvicalyceal system under ultrasound or radiographic control. In addition to visualising the cause of obstruction, percutaneous nephrostomy drainage can be established, and an antegrade stent can be passed through any obstruction. Retrograde pyelography can be performed by inserting a ureteric catheter into the ureteric orifice at cystoscopy (Fig. 18.6), and again a stent can be inserted to bypass any obstruction.

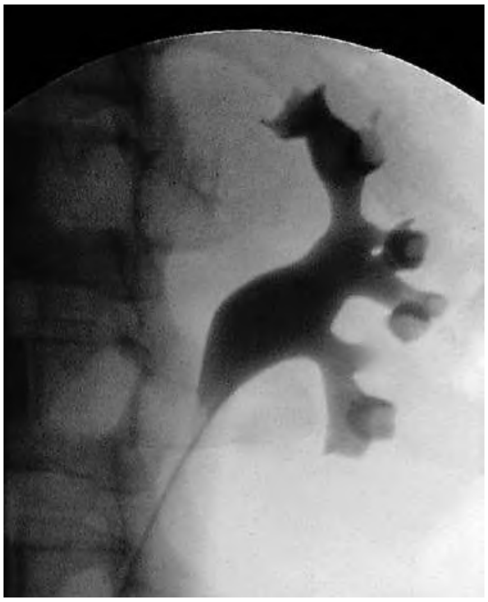

Fig. 18.6 Retrograde pyelography. The best views of the collecting system are obtained by pyelography. A catheter has been passed into the left renal pelvis at cystoscopy. In the image shown, the calyces are sharp-edged and normal. *Courtesy of Dr A.P. Bayliss and Dr P. Thorpe, Aberdeen Royal Infirmary.*

Radionuclide studies

These are functional studies requiring the injection of gamma ray–emitting radiopharmaceuticals that are taken up and excreted by the kidney, a process that can be monitored by an external gamma camera.

Dynamic radionuclide studies are performed with technetium (^{99m}Tc-MAG3), cleared almost entirely by proximal tubular secretion and provides a measure of effective renal plasma flow. Imaging following ^{99m}Tc-MAG3 injection can provide valuable information about the perfusion of each kidney but is not a reliable method for identifying renal artery stenosis. In patients with significant obstruction of the outflow tract, ^{99m}Tc-MAG3 persists in the renal pelvis and a loop diuretic fails to accelerate its disappearance. This study can be useful in determining the functional significance of a collecting system that appears obstructed on imaging.

Formal measurements of GFR can be made by radionuclide studies following the injection of diethylenetriamine penta-acetic acid (^{99m}Tc-DPTA) or ^{51}Cr-EDTA.

Static radionuclide studies are performed with dimercaptosuccinic acid labelled with technetium (^{99m}Tc-DMSA), which is taken up by proximal tubular cells. Following intravenous injection, images of the renal cortex are obtained to show the shape, size and relative function of each kidney (Fig. 18.7). This is a sensitive method for demonstrating cortical scarring in reflux nephropathy.

Renal biopsy

Renal biopsy is used to establish the diagnosis and severity of renal disease to judge the prognosis and need for treatment (Box 18.5). A biopsy may be performed to determine the aetiology of a renal mass. The procedure is performed percutaneously under local anaesthetic with

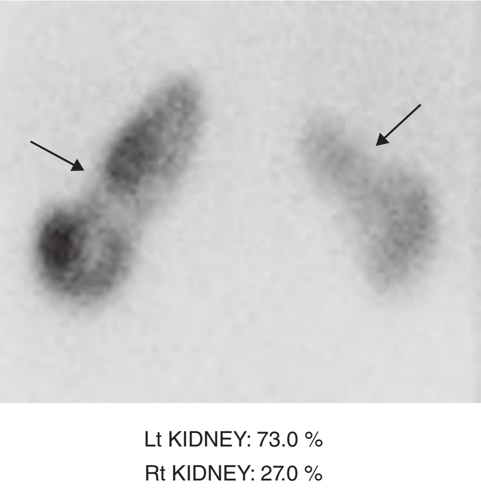

Fig. 18.7 **^{99m}Tc-DMSA scan.** Posterior view demonstrating bilateral cortical scarring (arrows) and impaired relative renal function with the right kidney contributing 73% of total renal function (normal range 45%–55%) in a patient with reflux nephropathy.

18.5 Renal biopsy

Indications

- Acute kidney injury and chronic kidney disease of uncertain aetiology
- Nephrotic syndrome or glomerular proteinuria (protein:creatinine ratio > 100 mg/mol) in adults
- Nephrotic syndrome in children that has atypical features or is not responding to treatment
- Nephritic syndrome
- Renal transplant dysfunction
- Rarely performed for isolated haematuria or isolated low-grade proteinuria in the absence of impaired renal function or evidence of a multisystem disorder

Contraindications

- Disordered coagulation or thrombocytopenia. Aspirin and other antiplatelet agents increase bleeding risk
- Uncontrolled hypertension
- Kidneys <60% predicted size
- Solitary kidney* (except transplants)

Complications

- Pain, usually mild
- Bleeding into urine, usually minor but may produce clot colic and obstruction
- Bleeding around the kidney, occasionally massive and requiring angiography with intervention, or surgery
- Arteriovenous fistula, rarely significant clinically

*Relative contraindication.

ultrasound guidance to ensure accurate needle placement into a renal pole. Light microscopy, electron microscopy and immunohistological assessment of the specimen may all be required.

Presenting problems in renal and urinary tract disease

It is important to recognise that many forms of kidney disease and urological diseases are asymptomatic. For example, most causes of CKD do not present with symptoms until kidney function is severely impaired (GFR < 20 mL/min/1.73 m^2), and even then the symptoms are non-specific, such as lethargy, swelling and loss of appetite and weight. Hence, kidney disease is often detected in asymptomatic patients through investigations such as serum creatinine, urinalysis or urinary albumin:creatinine ratio. People at high risk of disease, for example those with diabetes mellitus, hypertension or SLE, should therefore be screened regularly using these tests, as should people presenting with symptoms such as oedema. Patients with renal or prostate cancer often have no relevant symptoms and the diagnosis is made serendipitously.

18.6 Causes of anuria (<100 mL urine output per day)

Condition	Examples
Urinary obstruction (complete)	Urinary retention due to prostatic enlargement, urethral stenosis, bladder tumour Bilateral ureteric obstruction due to retroperitoneal fibrosis, cancer, bilateral ureteric stones, radiation injury Bilateral renal stones (usually staghorn calculi) Massive crystalluria obstruction of tubules (rare)
Lack of renal perfusion (bilateral)	Aortic dissection involving renal arteries Severe acute tubular necrosis Severe functional hypoperfusion (cardiorenal, hepatorenal)
Rapidly progressive glomerulonephritis	Anti-glomerular basement membrane disease, severe antineutrophil cytoplasmic antibody (ANCA) vasculitis (100% glomerular crescents on biopsy)

Oliguria/anuria

Oliguria and anuria are defined as a urine output of less than 400 mL/day or 100 mL/day, respectively. The volume of urine produced represents a balance between the amount of fluid filtered at the glomerulus and that reabsorbed by the renal tubules. When GFR is low, urine volumes may still be normal if tubular reabsorption is also reduced; hence patients with advanced kidney disease may not report a reduction in urinary output, particularly in diseases where the tubular injury predominates (e.g. tubulo-interstitial nephritis). Complete anuria, particularly when sudden in onset, may indicate a structural problem such as complete urinary obstruction or vascular occlusion, though it may occur with severe renal disease of any cause (Box 18.6).

Oliguria is common in pre-renal AKI, as the intravascular volume depletion activates the renin–angiotensin–aldosterone system to promote sodium retention and stimulates release of vasopressin (antidiuretic hormone, ADH) to promote water retention. Indeed, oliguria may precede and predict the onset of AKI and hence urinary output < 0.5 mL/kg/hr should prompt assessment of fluid status and correction of volume depletion where present. Urine volume may remain normal in pre-renal failure when there is an osmotic diuresis as occurs in diabetic ketoacidosis with marked glycosuria or in hypercalcaemia.

Urine volumes are variable in AKI due to intrinsic renal disease, but a rapid decline in urine volume may be observed. Marked oliguria predicts poor renal outcome in those with glomerulonephritis and poor patient survival in those with acute tubular necrosis in ICU.

Obstruction of the renal tract can result in oliguria and anuria; however, for this to occur, the obstruction must be complete and affect both kidneys, unless the patient has a single functioning kidney. Hence, the obstruction is most likely to occur at the level of the bladder outlet, for example in benign prostatic hypertrophy (see Fig. 18.19). It is less common for both ureters to become obstructed simultaneously, though this can occur with retroperitoneal fibrosis or bilateral renal calculi. Partial obstruction can be associated with normal or even high urine volume due to chronic tubular injury, which causes loss of tubular concentrating ability.

Polyuria

Polyuria is defined as a urine volume in excess of 3 L/24 hrs. Various underlying conditions, both renal and extrarenal, may be responsible, as outlined in Box 18.7.

Investigation of polyuria includes measurement of urea, creatinine, sodium, potassium, osmolarity, glucose and calcium. A 24-hour urine collection may be helpful to confirm the severity of polyuria. The presence of nocturnal polyuria suggests a pathological cause. Investigation

18.7 Causes of polyuria

- Excess fluid intake (characterised by low serum osmolarity)
- Osmotic diuresis: hyperglycaemia, hypercalcaemia, sodium-glucose transporter inhibitors
- Cranial diabetes insipidus
- Arginine vasopressin (AVP) hormone resistance:
- Rare inherited mutations in vasopressin receptor or aquaporin 2 genes
- Vasopressin receptor antagonists (tolvaptan)
- Lithium
- Interstitial nephritis
- Hypokalaemia
- Transiently following recovery from acute tubular necrosis (ATN) or relief of urinary obstruction

and management of suspected arginine vasopressin (AVP) deficiency or resistance (previously termed cranial/nephrogenic diabetes insipidus) are described in Chapter 20.

Frequency

Frequency describes daytime micturition more often than a patient would expect. It may be a consequence of polyuria, when urine volume is high, but is also found in patients with urinary infection and prostatic diseases, when small amounts of urine are passed each time, and the total daily urine volume is normal.

Nocturia

Nocturia is defined as waking to pass urine during the main sleep period. Nocturia occurs in the recovery phase of AKI and in many patients with CKD due to loss of urine-concentrating ability due to tubular injury. It may also be due to prostatic enlargement, when it is associated with other lower urinary tract symptoms such as poor stream, hesitancy, incomplete bladder emptying, terminal dribbling and urinary frequency due to partial urethral obstruction (p. 650). Nocturia may be exacerbated by increased fluid intake or diuretic use in the late evening (including caffeine). It may also occur due to sleep disturbance without any functional abnormalities of the urinary tract.

Urinary incontinence

Urinary incontinence is defined as any involuntary leakage of urine. It may occur in patients with a normal urinary tract, as the result of dementia or poor mobility, or transiently during an acute illness or hospitalisation, especially in older people (see Box 18.52). The pathophysiology, investigation and management of urinary incontinence are discussed in detail later in the chapter.

Abdominal pain

Loin pain is more often musculoskeletal in origin but can be a manifestation of urinary tract disease; in the latter case, it may arise from renal stones, ureteric stones, renal tumours, acute pyelonephritis and urinary tract obstruction. Acute loin pain radiating to the groin is termed renal colic. This is typical of ureteric obstruction due to calculi and is often accompanied by haematuria. Precipitation of dull loin pain by a large fluid intake (Dietl crisis) suggests upper urinary tract obstruction such as caused by a congenital pelvi-ureteric junction obstruction (p. 645). Obstruction at the bladder neck is associated with lower midline abdominal discomfort. Chronic obstruction rarely produces pain but may give rise to a dull ache.

Dysuria

Dysuria refers to painful urination, often described as burning or stinging, and is commonly accompanied by suprapubic pain. It is often associated with frequency of micturition and a feeling of incomplete emptying of the bladder. By far the most common cause is urinary tract infection, as described on page 640. Other diagnoses that need to be considered in patients with dysuria include sexually transmitted infections (Ch. 15) and bladder stones (p. 644).

18.8 Causes of oedema

Increased total extracellular fluid

- Congestive heart failure
- Renal failure
- Liver disease

Low plasma oncotic pressure/serum albumin

- Nephrotic syndrome
- Liver failure
- Malnutrition/malabsorption

Increased capillary permeability

- Local infection/inflammation
- Severe sepsis
- Calcium channel blockers

High local venous pressure

- Deep venous thrombosis or venous insufficiency*
- Pregnancy
- Pelvic tumour

Lymphatic obstruction*

- Infection: filariasis, lymphogranuloma venereum
- Malignancy
- Radiation injury
- Congenital abnormality

*Typically unilateral

Oedema

Oedema is caused by an excessive accumulation of fluid within the interstitial space. Clinically, this can be detected by persistence of an indentation in tissue following pressure on the affected area (pitting oedema). Non-pitting oedema is typical of lymphatic obstruction and may also occur as the result of excessive matrix deposition in tissues: for example, in hypothyroidism (Ch. 20) or systemic sclerosis (Ch. 25). Oedema may be due to several causes (Box 18.8).

Clinical assessment

Dependent areas, such as the ankles and lower legs, are typically affected first, but oedema can be restricted to the sacrum in bed-bound patients. Pitting oedema tends to accumulate in the ankles during the day and improves overnight as the interstitial fluid is reabsorbed. Conversely, facial oedema on waking is common. With increasing severity, oedema spreads to affect the upper parts of the legs, the genitalia and abdomen. Ascites is common and often an earlier feature in children or young adults, and in liver disease. Pleural effusions are common, particularly on the right side. Raised jugular venous pressure (JVP) and pulmonary oedema are uncommon in patients with low oncotic pressure such as in nephrotic syndrome, but common in the context of increased total extracellular fluid such as in cardiac and renal failure. Hence, the absence of raised JVP in patients with extensive peripheral oedema should prompt consideration of nephrotic syndrome or other cause of hypoalbuminaemia. Features of intravascular volume depletion (tachycardia, postural hypotension) may occur when oedema is due to decreased oncotic pressure or increased capillary permeability. If oedema is localised – for example, to one ankle but not the other – then local inflammation, venous thrombosis or lymphatic disease should be suspected.

Investigations

Blood should be taken for measurement of creatinine and electrolytes, liver function and serum albumin, and the urine tested for protein. Further imaging of the liver, heart or kidneys may be indicated, based on history and clinical examination. Where ascites or pleural effusions occur in isolation, measurement of protein, glucose and lactate dehydrogenase (LDH), and microscopy for cells in the aspirate will usually differentiate a transudate (typical of oedema) from an exudate (more suggestive of local pathology, p. 531).

Management

Mild oedema usually responds to elevation of the legs, compression stockings, or a thiazide or a low dose of a loop diuretic. In nephrotic syndrome, renal failure and severe cardiac failure, very large doses of diuretics, sometimes in combination, may be required to achieve a negative sodium and fluid balance. Restriction of sodium and fluid intake may be required. Monitoring of daily weight is helpful to determine response to treatment. Diuretics are not helpful in the treatment of oedema caused by increased capillary permeability or by venous or lymphatic obstruction. Specific causes of oedema, such as venous thrombosis, should be treated.

Hypertension

Hypertension is a very common feature of renal disease. Additionally, the presence of hypertension identifies a population at risk of developing CKD and current recommendations are that patients with hypertension should have renal function checked annually. Control of blood pressure is very important in patients with renal impairment because of its close relationship with further decline of renal function (p. 634) and increased cardiovascular risk. Pathophysiology and management are discussed in Chapter 16.

Haematuria

Healthy individuals may have occasional red blood cells in the urine (<3 red blood cells/high power field), but the presence of visible (macroscopic) haematuria or non-visible (microscopic, only detectable on dipstick testing) haematuria is indicative of bleeding from somewhere in the urinary tract (Fig. 18.8). Once infection, menstruation and causes of a positive urinary dipstick in the absence of red cells (haemoglobinuria/myoglobinuria) have been excluded (Box 18.9), both visible and persistent non-visible haematuria require investigation, as they may be caused by malignancy or indicate glomerulonephritis.

Importantly, urothelial malignancy is the cause in approximately 14% of those presenting with visible haematuria (see Fig. 18.8). Patients with visible haematuria must therefore be referred to urology for imaging (ultrasound or CT scan) and cystoscopy. Non-visible haematuria may also indicate an underlying cancer and, although guidelines vary, current UK guidelines suggest that patients aged 60 years and over with unexplained non-visible haematuria and either dysuria or a raised white cell count on a blood test should undergo imaging and cystoscopy (Fig. 18.9). For those under 60, the risk of underlying cancer is low; as such, management is centre-specific. Other common causes of visible haematuria are urine infection and stones. Visible haematuria may also be encountered in patients with IgA nephropathy, typically during an upper respiratory tract infection.

Non-visible haematuria may also indicate an underlying cancer, and although guidelines vary, current UK guidelines are that patients ages 60 years and over who have unexplained non-visible haematuria and either dysuria or a raised white cell count on a blood test should therefore undergo imaging and cystoscopy. In younger patients, an underlying tumour is much less likely, and if a glomerular cause is not suspected (see below), it may be appropriate to manage them by periodic observation in primary care, although occasionally these individuals develop significant overt renal disease during follow-up.

Glomerular bleeding occurs when inflammatory, destructive or degenerative processes disrupt the GBM, permitting passage of red blood cells into the urine. A characteristic feature of glomerular bleeding is an 'active urinary sediment' (the presence of dysmorphic red blood cells or red cell casts on microscopy); however, this is not always present. Patients with visible and non-visible haematuria should also be assessed for hypertension, proteinuria, reduced/declining renal function, family history of renal disease or features of systemic disease (see Fig. 18.9). The presence of any of these features raises the possibility of intrinsic renal pathology and warrants referral to nephrology for further investigation, including consideration of renal biopsy.

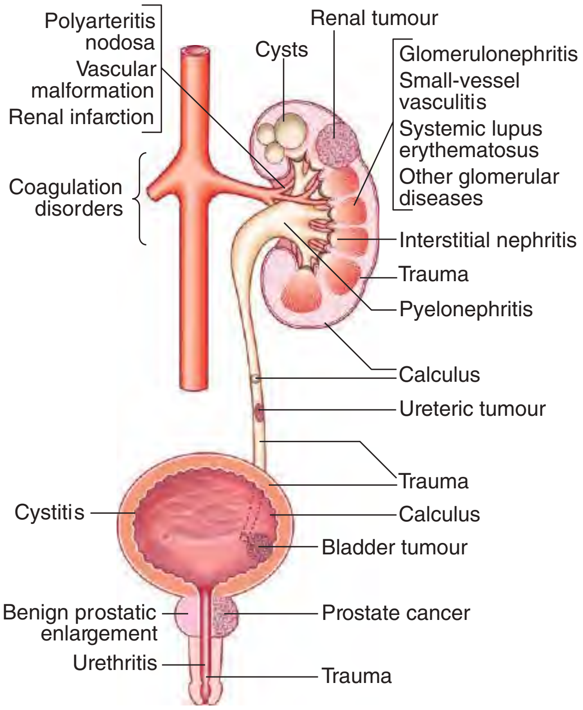

Fig. 18.8 Causes of haematuria.

18.9 Interpretation of non-visible haematuria

Dipstick test positive	Urine microscopy	Suggested cause
Haematuria	White blood cells Abnormal epithelial cells Red cell casts Dysmorphic erythrocytes (phase contrast microscopy)	Infection Tumour Glomerular bleeding*
Haemoglobinuria	No red cells	Intravascular haemolysis
Myoglobinuria (brown urine)	No red cells	Rhabdomyolysis

*Glomerular bleeding implies that the glomerular basement membrane (GBM) is ruptured. It can occur physiologically following very strenuous exertion but usually indicates intrinsic renal disease and is an important feature of the nephritic syndrome.

Nephritic syndrome

The nephritic syndrome is characterised by the presence of haematuria in association with hypertension, oliguria, fluid retention and reduced/declining renal function and the combination of these features warrants urgent investigation. Many patients with glomerulonephritis, particularly those with milder disease, do not exhibit all of these features. In many cases, investigation will include a renal biopsy to confirm diagnosis and guide management, but less invasive investigations may also be useful (Box 18.10).

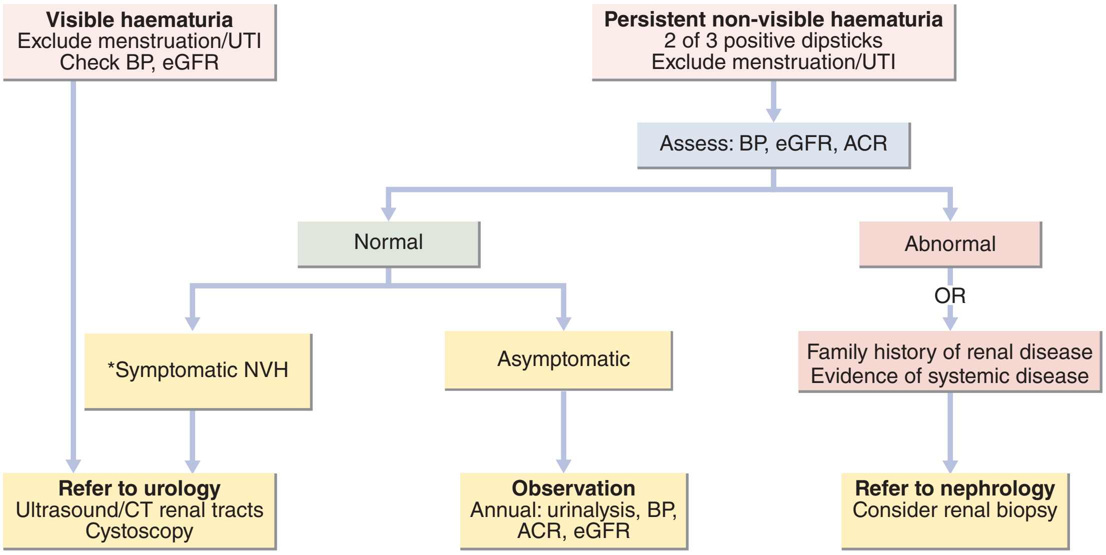

Fig. 18.9 Investigation of haematuria. *Symptomatic: ≥ 60 yrs – dysuria or raised blood white cell count. For those under 60, the risk of underlying cancer is low; as such, management is centre-specific. (ACR = albumin:creatinine ratio; BP = blood pressure; CT = computed tomography; eGFR = estimated glomerular filtration rate; NVH = non-visible haematuria; UTI = urinary tract infection)

i 18.10 Investigation of nephritic syndrome

Cause	Investigations
Rapidly progressive glomerulonephritis (RPGN)	
Post-infectious glomerulonephritis	ASOT, C3, C4
Anti-GBM disease	Anti-GBM antibody
Small-vessel vasculitis	PR3 and MPO ANCA
Lupus nephritis	ANA, dsDNA, C3, C4
Mild glomerulonephritic presentation	
IgA nephropathy	Serum IgA (polyclonal rise in 50% of patients)
Mesangioproliferative glomerulonephritis	C3, C4, hepatitis B, C + HIV serology, ANA, dsDNA, immunoglobulins, PPE
Alport syndrome*	Genetic screening, hearing test

*Not a glomerulonephritis but may present in a similar manner with haematuria, variable proteinuria, hypertension and slowly declining renal function. (ANA = antinuclear antibody; ANCA = antineutrophil cytoplasmic antibody; ASOT = anti-streptolysin O titre; C3, C4 = complement proteins 3, 4; dsDNA = double-stranded DNA; GBM = glomerular basement membrane; HIV = human immunodeficiency virus; IgA = immunoglobulin A; PPE = plasma protein electrophoresis)

Patients with nephritic syndrome may also exhibit varying degrees of proteinuria, including nephrotic-range proteinuria; the prominence of haematuria on dipstick should, however, alert the physician to the possibility of a glomerulonephritis. Indeed, it is important to recognise that the characteristic features of nephritic syndrome and nephrotic syndrome do not always present in isolation but should be considered to be the extreme phenotypes at either end of a spectrum of presentations (Fig. 18.10).

Proteinuria

While small amounts of high-molecular-weight proteins and moderate amounts of low-molecular-weight proteins pass through the healthy GBM, these proteins normally are completely reabsorbed by tubular cells. Hence, in healthy individuals, less than 150 mg of protein is excreted in the urine each day, much of which is derived from tubular cells. This includes Tamm–Horsfall protein (uromodulin), encoded by the *UMOD* gene, mutations in which have been linked to tubulo-interstitial disease (see Box 18.20). The presence of larger amounts of proteinuria indicates significant renal disease, with greater than 1 g/day indicative of glomerular pathology.

Proteinuria is usually asymptomatic and is often picked up by urinalysis, although large amounts of protein may make the urine frothy and cause oedema in nephrotic syndrome. Transient proteinuria can occur after vigorous exercise, during fever, in heart failure and in people with urinary tract infection. Patients should be assessed for the presence of these conditions and urine testing repeated once the potential trigger has been treated or resolved.

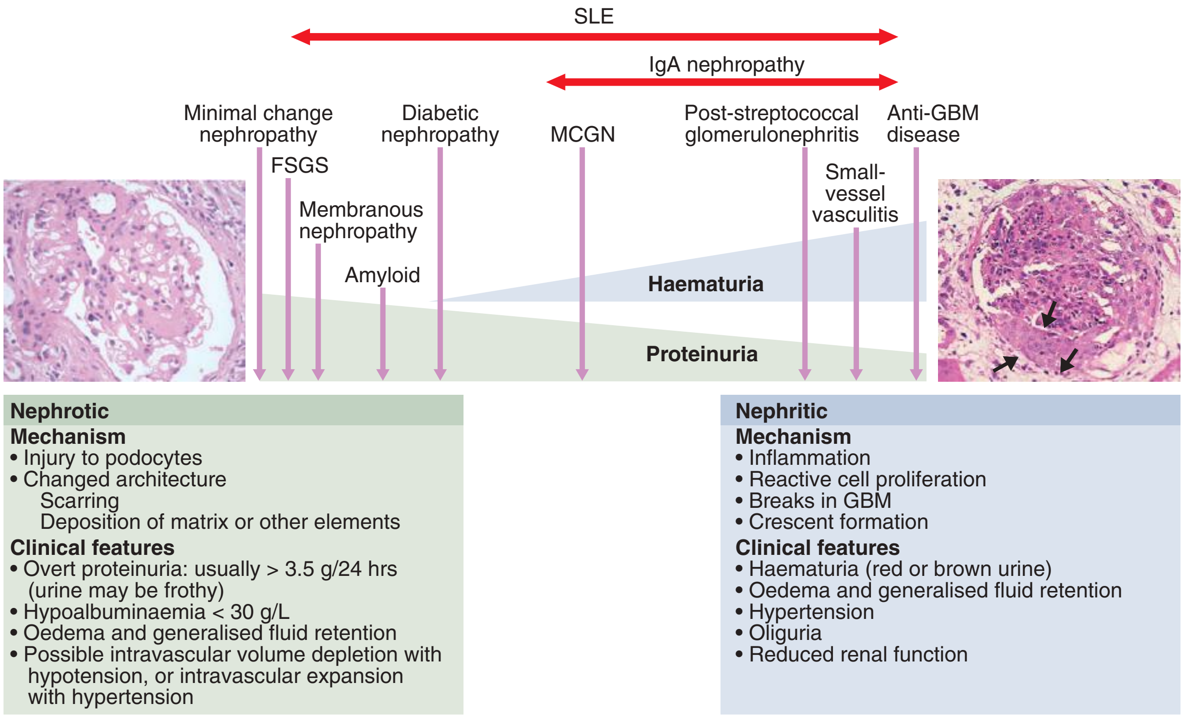
Testing for proteinuria is best done on an early morning sample, as some individuals exhibit orthostatic proteinuria, with urinary dipstick being positive only when upright. Orthostatic proteinuria is regarded as a benign disorder that does not require treatment.

Moderately elevated albuminuria (microalbuminuria)

In healthy individuals, there is virtually no urinary excretion of large-molecular-weight serum proteins, such as albumin. The presence of even moderate amounts of albuminuria (previously referred to as microalbuminuria) is therefore abnormal and is the most sensitive marker of early glomerular pathology, when the standard dipstick test remains negative (Box 18.11). Screening for moderately elevated albuminuria should be performed regularly in patients with diabetes mellitus, as persistently high levels warrant therapy with inhibitors of the renin–angiotensin–aldosterone system, even in normotensive individuals (see Box 21.31). The presence of increasing levels of albuminuria predicts poor renal outcomes and has also been associated with increased cardiovascular mortality (see Fig. 18.3).

Overt (dipstick-positive) proteinuria

Urinary dipstick testing is a valuable screening tool for the detection of proteinuria; it is only semi-quantitative, however, as it is highly dependent on the concentration of the urine. Typically, standard dipsticks test positive for protein once the urinary protein exceeds approximately 0.5 g/24 hrs; however, trace to 1+ may be observed on dipstick in very concentrated urine from healthy individuals. After urinary tract infection has been excluded, all patients with persistent proteinuria on dipstick (two or more positives in three consecutive samples) should have the amount of protein quantified to guide further investigations (Fig. 18.11). When more than 1 g of protein per day is excreted, glomerular disease



Nephrotic

Mechanism

- Injury to podocytes
- Changed architecture
  Scarring
  Deposition of matrix or other elements

Clinical features

- Overt proteinuria: usually > 3.5 g/24 hrs (urine may be frothy)
- Hypoalbuminaemia < 30 g/L
- Oedema and generalised fluid retention
- Possible intravascular volume depletion with hypotension, or intravascular expansion with hypertension

Nephritic

Mechanism

- Inflammation
- Reactive cell proliferation
- Breaks in GBM
- Crescent formation

Clinical features

- Haematuria (red or brown urine)
- Oedema and generalised fluid retention
- Hypertension
- Oliguria
- Reduced renal function

Fig. 18.10 Nephritic and nephrotic syndrome. At one extreme, specific injury to podocytes causes proteinuria and nephrotic syndrome. The histology to the left shows diabetic nephropathy. At the other end of the spectrum, inflammation leads to cell damage and proliferation, breaks form in the glomerular basement membrane (GBM) and blood leaks into urine. In its extreme form, with acute sodium retention and hypertension, such disease is labelled nephritic syndrome. The histology to the right shows a glomerulus with many extra nuclei from proliferating intrinsic cells, and influx of inflammatory cells leading to crescent formation (arrows) in response to severe post-infectious glomerulonephritis. (FSGS = focal and segmental glomerulosclerosis; IgA = immunoglobulin A; MCGN = mesangiocapillary glomerulonephritis; SLE = systemic lupus erythematosus)

i 18.11 Quantifying proteinuria in random urine samples

ACR[1] mg/mmol	PCR[1] mg/mmol	Typical dipstick results[2]	Significance
< 3.5 (female) < 2.5 (male)	< 25	–	Normal
3.5–30	25–50	–	Moderately elevated
30–70	50–100	+ to ++	Dipstick positive
70–300	100–350	++ to +++	Glomerular disease more likely; equivalent to > 1 g/24 hrs
> 300	> 350	+++ to ++++	Nephrotic range: almost always glomerular disease, equivalent to > 3.5 g/24 hrs

[1] Values are given for mg/mmol; if urine creatinine is measured in mg/dL, reference values for PCR and ACR can be derived by dividing by 11.31.
[2] Dipstick results are affected by urine concentration and are occasionally weakly positive on concentrated samples from healthy individuals.

is likely, and this is an indication for renal biopsy. Since 24-hour urine collection is often inaccurate, the protein:creatinine ratio (PCR) in a single sample of urine is preferred. This makes an allowance for the variable degree of urinary dilution and can be used to extrapolate to 24-hour values (see Box 18.11). Changes in PCR also give valuable information about the progression of renal disease and response to therapy in CKD. Albumin:creatinine ratio (ACR), requires a more expensive immunoassay and is usually reserved for situations when high sensitivity is required, such as detection of moderately elevated albuminuria in the early stages of diabetic nephropathy (p. 792).

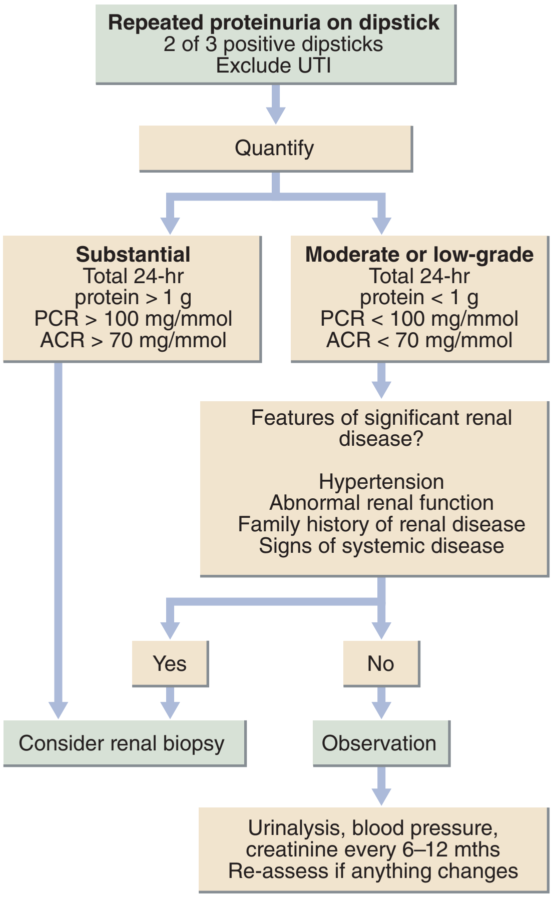
It is sometimes helpful to identify the type of protein in the urine. Large amounts of low-molecular-weight proteins, such as β_2-microglobulin (molecular weight 12 kDa), in the urine suggest renal tubular damage and are referred to as tubular proteinuria. This rarely exceeds 1.5–2 g/24 hrs (maximum PCR 150–200 mg/mmol; see Box 18.11 for conversion of mg/mmol to mg/dL).

Free immunoglobulin light chains (molecular weight 25 kDa) are filtered freely at the glomerulus but are poorly identified by dipstick tests. Their presence may also be indicated by a 'protein gap', where the PCR is markedly greater than the ACR (i.e. by more than the normal gap of 30 mg/mmol, see Box 18.11). In this context, electrophoresis of the urine and specific immunodetection methods are required to detect immunoglobulin light chains, known as 'Bence Jones protein'. This may occur in AL amyloidosis (Ch. 4) and in plasma-cell dyscrasias such as myeloma (Ch. 24).

Nephrotic syndrome

Nephrotic syndrome is characterised by very heavy proteinuria (> 3.5 g/24 hrs), hypoalbuminaemia and oedema. Blood volume may be normal, reduced or increased. Renal sodium retention is an early and universal feature; the mechanisms of this are shown in Figure 19.4. The diseases that cause nephrotic syndrome injure the podocytes directly (see Fig. 18.10) or indirectly, by causing scarring or deposition of exogenous material such as amyloid into the glomerulus.

Investigation of nephrotic syndrome usually involves renal biopsy, although non-invasive tests may also be helpful in suggesting the underlying cause, which may be infectious or malignant in nature (Box 18.12). In children, minimal change disease is by far the most common cause



Repeated proteinuria on dipstick
2 of 3 positive dipsticks
Exclude UTI
Quantify
Substantial
Total 24-hr protein > 1 g
PCR > 100 mg/mmol
ACR > 70 mg/mmol
Moderate or low-grade

No
Consider renal biopsy
Observation
Urinalysis, blood pressure, creatinine every 6–12 mths
Re-assess if anything changes

Fig. 18.11 Investigation of proteinuria. (ACR = albumin:creatinine ratio; PCR = protein:creatinine ratio; UTI = urinary tract infection)

18.12 Investigation of nephrotic syndrome

Cause	Typical age group	Investigations
Minimal change disease	Children, young adults, occasionally seen in older patients	None specific (consider investigations for malignancy in older patients). Anti-nephrin antibodies may be present in serum, but a diagnostic test is not yet available
Primary focal segmental glomerulosclerosis	Young adults	None specific
Membranous nephropathy	Middle-aged to older patients	Anti-phospholipase A_2 receptor antibody (primary disease) Hepatitis B, C & HIV testing, ANA, dsDNA (lupus) Consider investigations for malignancy
Amyloid	Older patients	Immunoglobulins, PPE, Bence Jones protein, serum free light chains
Diabetic nephropathy	Any age, but rarely < 10 years from diagnosis of type 1 diabetes	Glucose, glycosylated haemoglobin

(ANA = antinuclear antibody; dsDNA = double-stranded DNA; HIV = human immunodeficiency virus; PPE = plasma protein electrophoresis)

of nephrotic syndrome and therefore renal biopsy is not usually required unless the patient fails to respond to high-dose glucocorticoid therapy. Similarly, most patients with diabetes presenting with nephrotic syndrome will have diabetic nephropathy, and so renal biopsy is usually not performed unless the course of the disease is atypical (rapidly increasing proteinuria or rapid decline in renal function; p. 792).

Management of nephrotic syndrome should be directed at the underlying cause. In addition, nephrotic syndrome is associated with several complications (Box 18.13), which may require supportive management unless the nephrosis is expected to resolve rapidly, such as in glucocorticoid-responsive minimal change disease. Diuretics are often required to reduce oedema. ACE inhibitors/angiotensin receptor blockers or SGLT2 inhibitors are indicated to reduce intraglomerular pressure and proteinuria, which may lead to an increase in serum albumin concentration.

Glomerular diseases

Glomerular diseases account for a significant proportion of acute and chronic kidney disease. Most patients with glomerular disease do not present acutely and are asymptomatic until abnormalities are detected on routine screening of blood or urine samples.

There are many causes of glomerular damage, including immunological injury, genetic diseases such as Alport syndrome (p. 616), metabolic diseases such as diabetes mellitus (Ch. 21), and deposition of abnormal proteins such as amyloid in the glomeruli (Ch. 4). Several prognostic indicators are common to all causes of glomerulonephritis (Box 18.14) and may be helpful in assessing the need for immunosuppressive therapy. The glomerular cell types that may be the target of injury are shown in Figure 18.12. Proteinuria is the hallmark of glomerular disease; however, the response of the glomerulus to injury and hence the predominant clinical features vary according to the nature of the insult, ranging from fulminant nephrotic syndrome, when the primary target is usually the podocyte, to rapidly progressive glomerulonephritis (see Fig. 18.10). It is therefore helpful to classify the glomerular pathologies according to their clinical presentation (Box 18.15).

Glomerulonephritis

While glomerulonephritis literally means 'inflammation of glomeruli', the term is often used more broadly to describe all types of glomerular disease, even though some of these are not associated with inflammation (e.g. minimal change nephropathy).

Most types of glomerulonephritis are immunologically mediated and several respond to immunosuppressive drugs. Deposition of antibody occurs in many types of glomerulonephritis, and testing for circulating or glomerular deposition of antibodies may aid diagnosis (see Fig. 18.12 and Boxes 18.10 and 18.12). In small-vessel vasculitis, no glomerular antibody deposition is observed (pauci-immune), but the antibodies may be indirectly pathogenic by activating neutrophils to promote endothelial injury (see Fig. 18.12).

Glomerulonephritis is generally classified in terms of the histopathological appearances on renal biopsy, as summarised in Box 18.15 and Figure 18.13. Many non-specialists find the terminology used in describing glomerulonephritis confusing; therefore, some definitions are provided in Box 18.16. It is important to stress that the histological appearance rarely confirms a specific renal disease but rather suggests a limited range of diagnoses, which may be confirmed by further investigation. Conversely, some diseases, such as lupus nephritis, are associated with more than one histological pattern of injury. The most common histological subtypes may be categorised according to their typical clinical presentation, as discussed below.

Diseases typically presenting with nephrotic syndrome

In these diseases, the injury is focused on the podocyte and there is little histological evidence of inflammation or cell proliferation in the

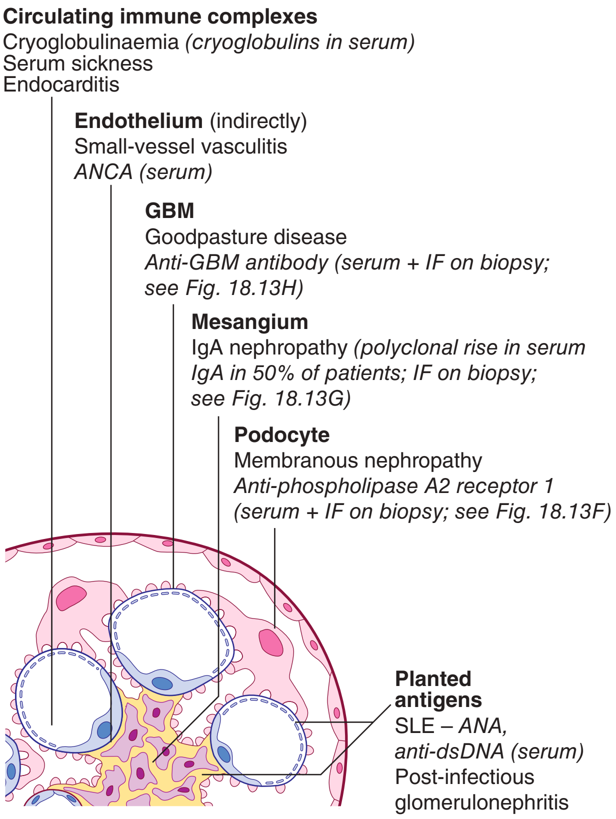
18.13 Consequences of the nephrotic syndrome and their management

Feature	Mechanism	Consequence	Management
Hypoalbuminaemia	Urinary protein losses exceed synthetic capacity of liver	Reduced oncotic pressure Oedema	ACE inhibitors/angiotensin receptor blockade/ SGLT2 inhibitors reduce proteinuria
Avid sodium retention	Secondary hyperaldosteronism Additional poorly characterised intrarenal mechanisms	Oedema	Diuretics and a low-sodium diet*
Hypercholesterolaemia	Non-specific increase in lipoprotein synthesis by liver in response to low oncotic pressure	High rate of atherosclerosis	Statins, ezetimibe if nephrotic syndrome likely to be chronic
Hypercoagulability	Relative loss of inhibitors of coagulation (antithrombin III, protein C and S) and increase in liver synthesis of procoagulant factors	Venous thromboembolism	Consideration of anticoagulation especially when severe hypoalbuminaemia and in membranous nephropathy
Infection	Hypogammaglobulinaemia due to urinary loss of immunoglobulins	Pneumococcal and meningococcal infection	Vaccination

*Severe nephrotic syndrome may need very large doses of combinations of diuretics acting on different parts of the nephron (e.g. loop diuretic plus thiazide plus amiloride). Over-diuresis risks secondary impairment of renal function through hypovolaemia.
(ACE = angiotensin-converting enzyme; MN = membranous nephropathy; SGLT2 = sodium-glucose transporter-2)

18.14 Poor prognostic indicators in glomerular disease

- Male sex
- Hypertension
- Persistent and severe proteinuria
- Elevated creatinine at time of presentation
- Rapid rate of decline in renal function
- Tubulo-interstitial fibrosis observed on renal biopsy



Circulating immune complexes
Cryoglobulinaemia *(cryoglobulins in serum)*
Serum sickness
Endocarditis
Endothelium (indirectly)
Small-vessel vasculitis
ANCA (serum)
GBM
Goodpasture disease
Anti-GBM antibody (serum + IF on biopsy; see Fig. 18.13H)
Mesangium
IgA nephropathy *(polyclonal rise in serum IgA in 50% of patients; IF on biopsy; see Fig. 18.13G)*
Podocyte
Membranous nephropathy

Post-infectious glomerulonephritis

Fig. 18.12 Glomerulonephritis associated with antibody production. Antibodies and antigen–antibody (immune) complexes may target or be deposited in specific components of the glomerulus, resulting in different patterns of histological injury and clinical presentation. Testing for antibody deposition in the glomerulus by immunofluorescence (IF) on renal biopsy tissue or for antibodies in the serum may aid diagnosis. Diagnostic tests are shown in italics. (ANA = antinuclear antibody; ANCA = antineutrophil cytoplasmic antibody; dsDNA = double-stranded DNA; GBM = glomerular basement membrane; IgA = immunoglobulin A; SLE = systemic lupus erythematosus)

glomerulus (non-proliferative, see Fig. 18.13). Minimal change and primary focal segmental glomerulosclerosis (FSGS) typically present with fulminant nephrotic syndrome, whereas in membranous nephropathy and secondary FSGS, the nephrosis tends to be more indolent. Other causes of nephrotic syndrome due to systemic disease are discussed elsewhere, including diabetic nephropathy (p. 792) and amyloid (p. 75).

Hereditary nephrotic syndrome (and steroid-resistant nephrotic syndrome)

Many genes have been discovered that cause early-onset nephrotic syndrome, often with an FSGS pattern of injury on histology. Inheritance may be autosomal dominant or recessive, the former having a less severe and later-onset phenotype, and often exhibiting incomplete penetrance. The genes involved almost all code for podocyte proteins, including nephrin ('Finnish-type' nephropathy) and podocin, which both cause early congenital nephrotic syndrome. Mutations causing nephrotic syndrome and FSGS are unresponsive to treatment (often termed '*steroid-resistant nephrotic syndrome*' (SRNS)). Autosomal dominant mutations in various genes may cause SRNS in isolation or as part of systemic syndromes; the genes include *INF2* (which may also cause Charcot–Marie–Tooth disease), *LMX1B* (nail–patella syndrome) and *WT1* (abnormal genitalia, Wilms tumour, intellectual disability).

Minimal change nephropathy

Minimal change disease can occur at all ages but accounts for most cases of nephrotic syndrome (see Box 18.15) in children and about one-quarter of adult cases. It is caused by reversible dysfunction of podocytes, and antibodies against nephrin protein expressed by podocytes have been found in the circulation in some patients. On light microscopy, the glomeruli appear normal (see Fig. 18.13A), but fusion of podocyte foot processes is observed on electron microscopy. The presentation is with nephrotic syndrome, which typically is severe. High-dose glucocorticoid therapy (1 mg/kg prednisolone for 6 weeks) usually promotes rapid remission of nephrosis, though the response to therapy is often less satisfactory in older patients, who may also develop AKI. Some patients fail to respond or respond incompletely (glucocorticoid resistant), or relapse frequently and need maintenance glucocorticoids (glucocorticoid dependent) and/or additional agents such as cytotoxics or calcineurin inhibitors. Glucocorticoid resistance in children warrants a biopsy to exclude an alternative diagnosis, but if minimal change is confirmed, a genetic cause should be considered (see above). Minimal change disease typically does not progress to CKD but can present with problems related to the nephrotic syndrome (see Box 18.13) and complications of treatment.

Focal segmental glomerulosclerosis

Focal and segmental glomerulosclerosis (FSGS) is a descriptive term, literally meaning there is scarring in some glomeruli (focal) and parts of

18.15 Glomerulonephritis categorised by clinical presentation and histological classification

Histology	Immune deposits	Pathogenesis	Associations	Comments
Nephrotic presentation				
Minimal change				
Normal, except on electron microscopy, where fusion of podocyte foot processes is observed (non-specific finding)	None	Unknown; probable circulating factor promoting podocyte injury; in some cases anti-nephrin antibodies are detected Some cases are genetic	Atopy Drugs, most commonly NSAIDs Haematological malignancies	Acute and often severe nephrotic syndrome Good response to glucocorticoids Dominant cause of idiopathic nephrotic syndrome in childhood
Focal segmental glomerulosclerosis (FSGS)				
Segmental scars in some glomeruli No acute inflammation Podocyte foot process fusion seen in primary FSGS	Non-specific trapping in focal scars	Cause of primary disease is unknown; circulating factors may increase glomerular permeability Injury to podocytes may be common feature Some cases are genetic	*APOL1* variant in people of West African descent Causes of secondary FSGS include: Healing of previous local glomerular injury HIV infection Heroin misuse Morbid obesity Chronic hypertension	*Primary FSGS* presents typically with severe nephrotic syndrome. Less responsive to treatment than minimal change; may progress to renal impairment and can recur after transplantation *Secondary FSGS* presents with variable proteinuria and outcome
Membranous nephropathy				
Thickening of GBM Progressing to increased matrix deposition and glomerulosclerosis	Granular subepithelial IgG, Deposits give rise to 'spikes' in the glomerular basement membrane with silver staining of biopsy	Antibodies to a podocyte surface antigen (commonly phospholipase A_2 receptor 1), with complement-dependent podocyte injury	*HLA-DQA1* (for idiopathic) Drugs: 2.1. Penicillamine, NSAIDs, heavy metals Hepatitis B virus Malignancy Lupus[1]	Common cause of adult idiopathic nephrotic syndrome One-third progress, one-third spontaneously remit and one-third remain stable; may respond to glucocorticoids and immunosuppressants
Mild glomerulonephritic presentation				
IgA nephropathy				
Increased mesangial matrix and cells Focal segmental nephritis in acute disease	Mesangial IgA (and C3)	Unknown Mucosal infections (e.g. helminths) may be involved	Usually idiopathic, flares triggered by upper respiratory infection Liver disease Coeliac disease	Common disease with range of presentations, usually including haematuria and hypertension Henoch–Schönlein purpura is an acute IgA variant common in children
Mesangiocapillary glomerulonephritis				
Immunoglobulin type	Immunoglobulins	Deposition of circulating immune complexes or 'planted' antigens	Infections, autoimmunity or monoclonal gammopathies	Most common pattern found in association with subacute bacterial infection, but also with cryoglobulinaemia ± hepatitis C virus, and others
Complement type	Complement components	Complement abnormalities, inherited or acquired Dense deposit disease is associated with abnormal activation of alternative complement pathway	Complement gene mutations C3 nephritic factor and partial lipodystrophy	In dense deposit disease, intramembranous deposits No proven treatments
Rapidly progressive glomerulonephritis presentation				
Focal necrotising glomerulonephritis				
Segmental inflammation and/or necrosis in some glomeruli ± crescent formation	Variable according to cause but typically negative (or 'pauci-immune')	Small-vessel vasculitis, often ANCA-mediated	Primary or secondary small-vessel vasculitis	Often occurs in systemic disease Responds to treatment with glucocorticoids and immunosuppressants
Diffuse proliferative glomerulonephritis[2]				
Infection-related diffuse proliferative glomerulonephritis[3]				
Diffuse proliferation of endothelial and mesangial cells Infiltration by neutrophils and macrophages ± crescent formation	Subendothelial and subepithelial	Immune complex-mediated (e.g. to streptococcal infection with presumed cross-reactive epitopes)	Post-streptococcal Concurrent infection with staphylococci, endocarditis	Presents with severe sodium and fluid retention, hypertension, haematuria, oliguria Usually resolves spontaneously

i 18.15 Glomerulonephritis categorised by clinical presentation and histological classification—cont'd

Histology	Immune deposits	Pathogenesis	Associations	Comments
Anti-glomerular basement membrane disease				
Usually crescentic nephritis	Linear IgG along GBM	Autoantibodies to α3 chain of type IV collagen in GBM	*HLA-DR15* (previously known as *DR2*)	Associated with lung haemorrhage but renal or lung disease may occur alone Treat with glucocorticoids, cyclophosphamide and plasma exchange

[1] Systemic lupus erythematosus can cause almost any histological injury pattern, most commonly membranous nephropathy or diffuse proliferative glomerulonephritis.
[2] In addition to the association with infection and anti-GBM disease, a diffuse proliferative glomerulonephritis picture may also be seen with lupus and occasionally IgA nephropathy.
[3] Infection may also present with mesangioproliferative glomerulonephritis and membranous nephropathy (HIV).
(ANA = antinuclear antibody; ANCA = antineutrophil cytoplasmic antibody; *APOL1* = apolipoprotein L1; FSGS = focal segmental glomerulosclerosis; GBM = glomerular basement membrane; HLA = human leucocyte antigen; IgA = immunoglobulin A; NSAIDs = non-steroidal anti-inflammatory drugs)

G IgA nephropathy
H Anti-GBM disease

Fig. 18.13 Histopathology of glomerular disease. *(A – E Light microscopy)* A A normal glomerulus. Note the open capillary loops and thinness of their walls. B Focal segmental glomerulosclerosis (GS). The portion of the glomerulus arrowed shows loss of capillary loops and cells, which are replaced by matrix. C Focal necrotising glomerulonephritis (GN). A portion of the glomerulus (focal necrotising lesion, N) is replaced by bright pink material with some 'nuclear dust'. Neutrophils may be seen elsewhere in the glomerulus. There is surrounding interstitial inflammation (I). This is most commonly associated with small-vessel vasculitis and may progress to crescentic nephritis (see E). D Membranous glomerulonephritis. The capillary loops (C) are thickened (compare with the normal glomerulus) and there is expansion of the mesangial regions by matrix deposition (M). However, there is no gross cellular proliferation or excess of inflammatory cells. E Crescentic glomerulonephritis. The lower part of Bowman space is occupied by a semicircular formation ('crescent', Cr) of large pale cells, compressing the glomerular tuft. This is seen in aggressive inflammatory glomerulonephritis. *Antibody deposition in the glomerulus (F – H Direct immunofluorescence).* F Granular deposits of IgG along the basement membrane in a subepithelial pattern, typical of membranous GN. G Immunoglobulin A (IgA) deposits in the mesangium, as seen in IgA nephropathy. H Ribbon-like linear deposits of anti-GBM antibodies along the glomerular basement membrane in Goodpasture disease. The glomerular structure is well preserved in all of these examples. *(A, C, D, E) Courtesy of Dr J.G. Simpson, Aberdeen Royal Infirmary; (F, G, H) Courtesy of Dr R. Herriot.*

these glomeruli are injured (segmental). It is a pattern of injury caused by many diseases or insults (see Box 18.16). Primary FSGS (see Fig. 18.13B) can occur in all age groups and is thought to be due to an as yet undiscovered circulating factor which causes podocyte injury. Primary FSGS typically presents with abrupt onset of severe nephrotic syndrome. Since FSGS is a focal process, abnormal glomeruli may not be detected on renal biopsy if only a few are sampled, leading to an initial diagnosis of minimal change nephropathy. Primary FSGS may respond to high-dose glucocorticoid therapy (0.5–2.0 mg/kg/day), but the response is rarely as rapid as in minimal change disease. Immunosuppressive drugs, such as calcineurin inhibitors, cyclophosphamide, mycophenolate and rituximab, have also been used but their efficacy is uncertain. Progression to CKD is common in patients who do not respond to glucocorticoids and the disease frequently recurs after kidney transplantation.

FSGS may also be secondary to other diseases such as human immunodeficiency virus (HIV), morbid obesity or long-standing hypertension. In addition, it may reflect scarring from previous glomerular injury resulting from other disease processes (e.g. HUS, cholesterol embolism, vasculitis) or from toxic insults (e.g. heroin, bisphosphonates). Patients with secondary FSGS typically present with more modest proteinuria than those with primary disease and rarely exhibit full-blown nephrotic syndrome. Secondary FSGS does not respond to immunosuppression, and management is focused on treating the underlying cause and reducing proteinuria by inhibiting the RAAS system and with SLGT2 inhibitors.

In addition to the genes causing SRNS described above, inherited polymorphisms in the *APOL1* gene (which codes for apolipoprotein L1) lead to a greatly increased risk of kidney disease in adults, usually with an FSGS pattern of injury on histology. These risk variants (termed G1 and G2) have risen to prominence in West Africa over the past few thousand years as they confer resistance to a form of African sleeping sickness. However, the presence of two risk alleles (G1/G1; G2/G2 or G1/G2) leads to a higher risk of kidney disease and likely explains most of the excess risk of ESRD in people of West African origin, including African Americans. It should be noted that the presence of these risk variants does not guarantee kidney disease as additional genetic and environmental modifiers are at play (e.g. viral infections, including HIV).

Membranous nephropathy

Membranous nephropathy is the most common cause of nephrotic syndrome (other than diabetic nephropathy) in people of European descent. It is caused by antibodies directed at antigen(s) expressed on the surface of podocytes, the commonest being the M-type phospholipase A_2 receptor 1, although other antigens have recently been discovered. It is characterised by thickening of the glomerular basement membrane on light microscopy and granular IgG deposition observed by immunofluorescence (see Fig. 18.13). While most cases are autoimmune, a proportion are associated with other causes, such as heavy metal poisoning, drugs, infections, SLE and tumours (see Box 18.15). Approximately one-third of patients with idiopathic membranous nephropathy undergo spontaneous remission, one-third remain in a nephrotic state, and one-third develop progressive CKD. Management includes tight blood pressure control, particularly with RAAS and SGLT2 inhibitors.

In idiopathic disease, immunosuppression treatment may improve both the nephrotic syndrome and the long-term prognosis, and regimens may include glucocorticoids with cyclophosphamide, cyclosporine and increasingly rituximab. However, because of the toxicity of these regimens, many nephrologists reserve such treatment for those with severe or persistent nephrotic syndrome or deteriorating renal function. Treatment of secondary membranous nephropathy is directed at the underlying cause.

i 18.16 Terminology used in glomerulonephritis

Light microscopy

- *Focal*: affecting some but not all glomeruli
- *Diffuse*: affecting > 50% of glomeruli
- *Segmental*: affecting a portion of a glomerulus
- *Global*: affecting all of the glomerulus
- *Necrotising*: severe injury leading to an area of necrosis, usually associated with vasculitis
- *Crescentic*: a crescent-shaped area of inflammatory cells responding to severe glomerular injury

Electron microscopy

- *Subendothelial immune deposits*: found between the endothelial cell and the GBM – often found in nephritic presentations
- *Intramembranous immune deposits*: found within the GBM – found in the dense deposit variant of mesangiocapillary glomerulonephritis
- *Subepithelial immune deposits*: found between the epithelial cell and the GBM – often found in nephrotic presentations, including membranous presentation of lupus

(GBM = glomerular basement membrane)

Diseases typically presenting with nephritic syndrome

Patients with some forms of glomerulonephritis may present with so called 'nephritic syndrome' (see Fig. 18.10). These patients have haematuria (usually but not always non-visible) and modest proteinuria, generally non-nephrotic. IgA nephropathy and mesangiocapillary glomerulonephritis (MCGN) typically fall in this category. Their presentation is highly variable: while often presenting with mild disease, they may occasionally present with rapidly progressive glomerulonephritis or even nephrotic syndrome. Another disease that presents with a similar clinical picture of haematuria, modest proteinuria and slow progression is Alport syndrome; however, this is genetic rather than immunologically mediated.

Alport syndrome

A number of uncommon diseases may involve the glomerulus in childhood, but the most important one affecting adults is Alport syndrome. Most cases arise from a mutation or deletion of the *COL4A5* gene on the X chromosome, which encodes the alpha 5 subunit of type IV collagen, resulting in inheritance as an X-linked recessive disorder (Ch. 3). Mutations in *COL4A3* or *COL4A4* genes are less common and cause autosomal disease, which may be recessive or dominant, and affect males and females equally. The accumulation of abnormal collagen results in a progressive degeneration of the GBM (Fig. 18.14). Patients with autosomal recessive and males with X-linked disease progress from haematuria to ESRD in late adolescence or their twenties. Basement membranes in other organs that contain the same collagen isoforms may be involved, so that Alport syndrome is associated with sensorineural deafness and ocular abnormalities.

ACE inhibitors may slow but not prevent loss of kidney function and these patients are good candidates for SGLT2 inhibitors. Post-transplant, patients may develop an immune response to the normal collagen antigens present in the GBM of the donor kidney and, in a small minority, anti-GBM disease develops and injures the allograft.

Thin glomerular basement membrane disease

Females with a single *COL4A5* mutation and patients with autosomal dominant disease often have thin glomerular basement membrane disease, which typically manifests with non-visible haematuria. However, not all cases are familial, and in many patients the cause is unclear. The glomeruli appear normal by light microscopy but the GBM is abnormally thin on electron microscopy. Monitoring of these patients is advisable, as proteinuria may develop in some, and there appears to be an increased rate of progressive CKD in the long-term.

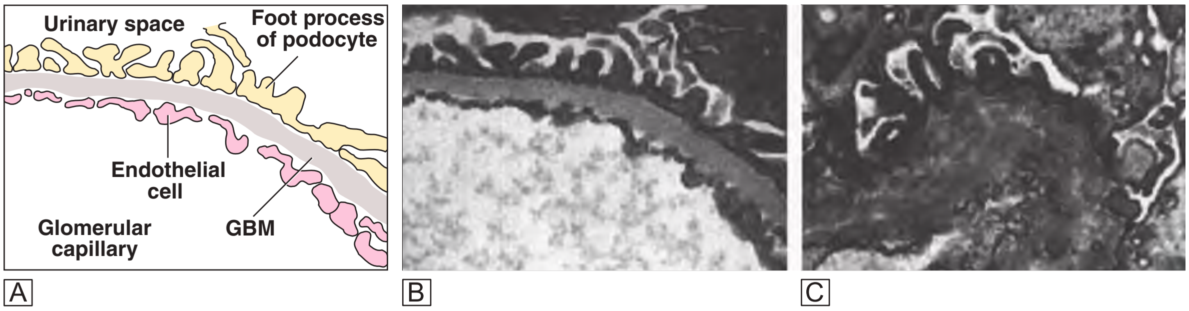

Fig. 18.14 Alport syndrome. **A** Diagrammatic structure of the normal glomerular basement membrane (GBM). **B** The normal GBM (electron micrograph) contains mostly the tissue-specific (α3, α4 and α5) chains of type IV collagen. **C** In Alport syndrome, this network is disrupted and replaced by α1 and α2 chains. Although the GBM appears structurally normal in early life, in time thinning appears, progressing to thickening, splitting and degeneration. *(B, C) Courtesy of Dr J. Collar, St Mary's Hospital, London.*

IgA nephropathy

This is one of the most common types of glomerulonephritis and can present in many ways. Haematuria is the earliest sign, and non-visible haematuria is almost universal, while hypertension is also very common. These are often detected during routine screening; for example, at occupational medical examinations. Proteinuria can also occur but is usually a later feature. In many cases, there is slowly progressive loss of renal function leading to ESRD, though in others, renal function is persistently normal. A particular hallmark of IgA nephropathy in young adults is the occurrence of acute self-limiting exacerbations, often with visible haematuria, in association with minor respiratory infections. This may be so acute as to resemble acute post-infectious glomerulonephritis, with fluid retention, hypertension and oliguria with dark or red urine. Characteristically, the latency from clinical infection to nephritis is short, in contrast to post-infectious glomerulonephritis, when symptoms typically occur after the infection has resolved. Asymptomatic presentations dominate in older adults, with non-visible haematuria, hypertension and reduced GFR. The histological MEST-C score (*m*esangial hypercellularity, *e*ndocapillary hypercellularity, *s*egmental glomerulosclerosis, *t*ubular atrophy/interstitial fibrosis, and presence of *c*rescents) has prognostic value. Management is directed towards the control of blood pressure, especially with RAAS inhibitors. SGLT2 inhibitors have an additive protective effect on renal outcomes. High-dose glucocorticoid treatment may have some benefit when there is a risk of rapid disease progression, although this is usually poorly tolerated. Targeted-release budesonide, which is mainly released in the terminal ileum where it reduces IgA production, may be better tolerated. Newer therapies are emerging, such as complement and endothelin inhibitors.

IgA vasculitis

Previously termed Henoch–Schönlein purpura, this condition most commonly occurs in children but can also be observed in adults. It is a systemic vasculitis that often arises in response to an infectious trigger. It presents with a tetrad of features:

- a characteristic petechial rash typically affecting buttocks and lower legs
- abdominal pain due to vasculitis involving the gastrointestinal tract
- arthralgia
- renal disease characterised by visible or non-visible haematuria, with or without proteinuria.

Renal biopsy shows mesangial IgA deposition and appearances that are indistinguishable from IgA nephropathy (see Fig. 18.13G). Treatment is supportive in nature; in most patients, the prognosis is good, with spontaneous resolution, though relapses are common. Some patients, particularly adults and those with severe or persistent proteinuria, progress to develop ESRD.

Mesangiocapillary glomerulonephritis

Mesangiocapillary glomerulonephritis (MCGN), also known as membranoproliferative glomerulonephritis, is a pattern of injury seen on renal biopsy that is characterised by an increase in mesangial cellularity with thickening of glomerular capillary walls. The typical presentation is with proteinuria and haematuria. Several underlying causes have been identified, as summarised in Box 18.15. It can be classified into two main subtypes. The first is characterised by deposition of immunoglobulins within the glomeruli. This subtype is associated with chronic infections, autoimmune diseases and monoclonal gammopathy. The second is characterised by deposition of complement in the glomeruli and is associated with inherited or acquired abnormalities in the complement pathway. This category comprises 'dense deposit disease', which is typified by electron-dense deposits within the GBM, and C3 glomerulonephritis, where there are deposits of C3 in the glomerulus.

Treatment of MCGN associated with immunoglobulin deposits consists of the identification and treatment of the underlying disease, if possible, and the use of immunosuppressive drugs such as mycophenolate mofetil or cyclophosphamide. There are few specific treatments for MCGN associated with complement dysregulation, although eculizumab, the anti-C5 inhibitor that prevents formation of the membrane attack complex, has shown promise.

Diseases typically presenting with rapidly progressive glomerulonephritis

Rapidly progressive glomerulonephritis (RPGN) is characterised by rapid loss of renal function over days to weeks, usually in association with hypertension and oedema. Non-visible haematuria is almost always present, with variable amounts of proteinuria, while characteristic red cell casts and dysmorphic red cells may be observed on urine microscopy due to glomerular inflammation leading to breakdown of the glomerular basement membrane (see Fig. 18.4). Renal biopsy typically shows crescentic lesions (see Fig. 18.13E), often associated with necrotising lesions within the glomerulus (see Fig. 18.13C), particularly in small-vessel vasculitides.

This pattern of presentation is typical of post-infectious glomerulonephritis, anti-GBM disease and small-vessel vasculitides (Ch. 25). It can also be observed in SLE and occasionally in IgA and other nephropathies (see Fig. 18.10).

Anti-glomerular basement membrane disease

Anti-GBM disease is a rare autoimmune disease in which antibodies develop against the α3 chain of type IV collagen in the GBM. Expression of the α3 chain is largely restricted to the basement membranes of glomeruli and lungs, and hence the disease may present with rapidly progressive glomerulonephritis, lung haemorrhage, or disease of both organs, when it is known as Goodpasture disease. Goodpasture disease is more common in younger patients, while older adult patients often present with renal-limited disease. Patients with anti-GBM disease should be treated with plasma exchange combined with glucocorticoids and immunosuppressants, but early diagnosis is essential, as renal function is rarely recoverable in those requiring dialysis at presentation.

The combination of glomerulonephritis and pulmonary haemorrhage may also be observed with small-vessel vasculitis (particularly granulomatosis with polyangiitis, previously known as Wegener granulomatosis) and SLE.

Infection-related glomerulonephritis

RPGN may occur either during or following an infection. In both cases, circulating immune complexes are present and activation of the complement system promotes consumption of complement factors, resulting in low serum C3 and C4 concentrations (Box 18.17).

Post-infectious glomerulonephritis is mostly observed in children and young adults, and typically presents 10 days *after* a streptococcal throat infection or longer after a skin infection. The clinical presentation ranges from mild abnormalities on urinalysis to RPGN with severe AKI. The anti-streptolysin (ASO) test is positive in up to 95% of patients with streptococcal throat infections. Treatment is supportive, with control of blood pressure and fluid overload with salt restriction, diuretics and dialysis if required. Antibiotic therapy is rarely needed, as the renal disease occurs after the infection has subsided. The medium-term prognosis for children and most adults is good, with recovery of renal function even in those who require initial dialysis. Some patients may develop CKD many years after the original presentation.

i **18.17 Causes of glomerulonephritis associated with low serum complement**

- Post-infectious glomerulonephritis
- Subacute bacterial infection, especially endocarditis
- Systemic lupus erythematosus
- Cryoglobulinaemia
- Mesangiocapillary glomerulonephritis, usually complement type

An immune complex–mediated disease may also be observed *during* an infection, typically a staphylococcal infection such as endocarditis, skin infection or pneumonia, but also with subacute endocarditis due to *Streptococcus viridans*. This occurs more commonly in older adults and the presentation tends not to be as fulminant as with post-streptococcal disease. In addition to supportive measures, antibiotic therapy is required, as infection is usually concurrent with renal disease.

Tubulo-interstitial diseases

These diseases primarily affect the renal tubules and interstitial components of the renal parenchyma. They are characterised by tubular dysfunction with electrolyte abnormalities, moderate levels of proteinuria and varying degrees of renal impairment. Often the urinary output may be relatively preserved for any given GFR, and indeed there may be polyuria and nocturia due to loss of concentrating ability in damaged tubules.

Acute interstitial nephritis

Acute interstitial nephritis (AIN) is an immune-mediated disorder, characterised by acute inflammation affecting the tubulo-interstitium of the kidney. It is commonly drug-induced, typically due to antibiotics and proton pump inhibitors (PPIs), but can be caused by other toxins, and can complicate a variety of systemic diseases. Infectious causes are particularly common in the developing world (Box 18.18).

Clinical features

The clinical presentation is typically with AKI, and it may cause a rapid deterioration in renal function. AIN should always be considered in patients with non-oliguric AKI. In some patients with drug-induced AIN, there may be signs of a generalised drug hypersensitivity reaction with fever and rash. Eosinophilia occurs in 20%–30% of cases, so its absence does not rule out AIN, but its presence should prompt a drug history. Proteinuria is generally modest (PCR < 100 mg/mmol; see Box 18.11 for conversion of mg/mmol to mg/dL). The urine may contain white blood cells and white cell casts but is sterile on culture.

Investigations

Renal biopsy is usually required to confirm the diagnosis (Fig. 18.15D). This typically shows evidence of intense inflammation, with infiltration of the tubules and interstitium by lymphocytes. The presence of eosinophils may suggest drug-induced AIN and a predominant neutrophil infiltration suggests infection. Often granulomas may be evident, especially in drug-induced AIN. The degree of chronic inflammation in a biopsy is a useful predictor of long-term renal function. Eosinophiluria may be present but is not a good discriminator for AIN.

Management

Some patients with drug-induced AIN recover following withdrawal of the drug alone, but high-dose glucocorticoids (prednisolone 1 mg/kg/day) may accelerate recovery and prevent long-term scarring. Other specific causes (see Box 18.18) should be treated, if possible.

18.18 Causes of acute interstitial nephritis

Allergic

Many drugs but particularly:

- Penicillins
- Non-steroidal anti-inflammatory drugs (NSAIDs)
- Proton pump inhibitors
- Mesalazine (delayed)

Immune

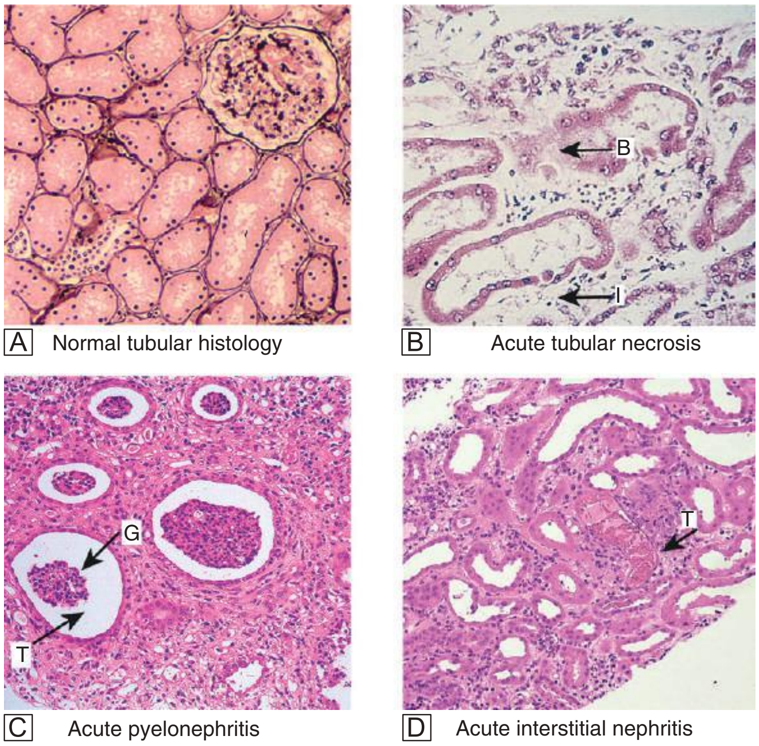
- Autoimmune nephritis ± uveitis
- Transplant rejection

Infections

- Acute bacterial pyelonephritis
- Leptospirosis
- BK virus (transplant)
- Tuberculosis
- Hantavirus

Toxic

- Myeloma light chains
- Calcium phosphate crystallisation after excessive phosphate administration (e.g. phosphate enemas in patients with chronic kidney disease)
- Mushrooms *(Cortinarius)*



A Normal tubular histology
B Acute tubular necrosis
C Acute pyelonephritis
D Acute interstitial nephritis

Fig. 18.15 Tubular histopathology. **A** Normal tubular histology. The tubules are densely packed with minimal space between. Brush borders can be seen on the luminal borders of cells in the proximal tubule. **B** Acute tubular necrosis. There are scattered breaks (B) in tubular basement membranes, swelling and vacuolation of tubular cells, and, in places, apoptosis and necrosis of tubular cells with shedding of cells into the lumen. During the regenerative phase, there is increased tubular mitotic activity. The interstitium (I) is oedematous and infiltrated by inflammatory cells. **C** Acute bacterial pyelonephritis. There is a widespread inflammatory infiltrate that includes many neutrophils. Granulocyte casts (G) are forming within some dilated tubules (T). Other tubules are scarcely visible because of the extent of the inflammation and damage. **D** Acute (allergic) interstitial nephritis. In this patient who received a non-steroidal anti-inflammatory drug (NSAID), an extensive mononuclear cell infiltrate (no neutrophils) in the tubule-interstitium (T) is seen. Sometimes eosinophils are prominent.

Chronic interstitial nephritis

Chronic interstitial nephritis (CIN) is characterised by renal dysfunction with little to no proteinuria. It may follow on from AIN that does not resolve or may be associated with ingestion of various toxins and drugs, particularly those taken chronically, such as lithium or non-steroidal anti-inflammatory drugs (NSAIDs) (Box 18.19).

18.19 Causes of chronic interstitial nephritis

Acute interstitial nephritis

- Any of the causes of acute interstitial nephritis, if persistent (see Box 18.18)

Glomerulonephritis

- Varying degrees of interstitial inflammation occur in association with most types of inflammatory glomerulonephritis

Immune/inflammatory

- Sarcoidosis
- Sjögren syndrome
- Chronic transplant rejection
- Systemic lupus erythematosus, primary autoimmune

Toxic

- *Aristolochia* in herbal medicines and flour (Balkan nephropathy)
- Lead
- Chronic interstitial nephritis in agriculture communities (CKDu)

Drugs

- All drugs causing acute interstitial nephritis
- Tenofovir
- Lithium
- NSAIDs
- Ciclosporin, tacrolimus

Infection

- Consequence of severe pyelonephritis

Congenital/developmental

- Vesico-ureteric reflux: associated but causation not clear
- Renal dysplasias: often associated with reflux
- Genetic: may be autosomal dominant or recessive (see Box 18.20)
- Other: Wilson disease, sickle-cell nephropathy, medullary sponge kidney (nephrocalcinosis)

Metabolic and systemic diseases

- Hypokalaemia
- Hyperoxaluria

(CKDu = chronic kidney disease of unknown cause; NSAIDs = non-steroidal anti-inflammatory drugs)

Pathophysiology

Toxins that have been associated with CIN include those contained within the plant *Aristolochia clematitis* (birthwort). These are responsible for the severe nephrotoxicity that can be associated with treatment with herbal medicines in Asia and for Balkan nephropathy, which affects isolated rural communities in Bosnia, Bulgaria, Croatia, Romania and Serbia, possibly through contaminated flour. Balkan nephropathy is commonly linked with tumours of the collecting system and is due to the mutagenic effects of the plant toxin on the urothelial epithelium. Chronic interstitial nephritis in agricultural communities (also known as CKD of unknown cause, CKDu) is observed in Central American countries and Sri Lanka. The cause is unknown but is likely to reflect a toxin used in agriculture exacerbated by episodes of dehydration due to heat exposure.

It has become evident in recent years that a significant number of cases of CIN have genetic causes, which may be inherited in an autosomal dominant or recessive pattern and include genes predominantly expressed in tubular cells (Box 18.20). This is a heterogeneous group of inherited disorders. Small cysts are sometimes evident, explaining the previous name of ‘medullary cystic kidney disease’, but tubulo-interstitial nephritis is the predominant pattern of injury. Many of these conditions, especially those autosomal recessive disorders formerly known as nephronophthisis, are associated with retinal dystrophies and brain or other abnormalities. Autosomal dominant causes are most commonly due to mutations in *MUC1*, which cause an otherwise featureless CIN, and *UMOD*, which are strongly associated with hyperuricaemia and precocious gout. Many patients will progress to ESRD in later life. Modern genetics have brought clarity to a disease spectrum comprising many different conditions.

Clinical features

Most patients with CIN present in adult life with CKD. A minority have salt-losing nephropathy due to impairment of urine-concentrating ability and sodium reabsorption. This presents with polyuria, nocturia and hypotension and puts them at risk of AKI during an acute illness. Renal tubular acidosis (p. 673) may complicate CIN but is seen most often in myeloma, sarcoidosis, cystinosis, amyloidosis, Sjögren syndrome and with chronic non-steroidal anti-inflammatory consumption. Typically, urinalysis is unremarkable, and small kidneys are observed on ultrasound scan. Renal biopsy demonstrates infiltration of the renal parenchyma by lymphocytes, plasma cells and macrophages, in association with tubular atrophy and interstitial fibrosis.

Management

Management is to identify and withdraw or treat the primary cause, where possible. Otherwise, treatment is supportive in nature, with correction of acidosis and hyperkalaemia; replacement of fluid and electrolytes, as required; and renal replacement therapy if irreversible renal damage has occurred.

18.20 Hereditary tubulo-interstitial kidney diseases

Inheritance	Gene(s)	Other name(s)	Clinical features
Autosomal dominant	*UMOD*	MCKD type 2 Juvenile hyperuricaemic nephropathy	Gout
	MUC1	MCKD type 1	Progressive CKD without other manifestations
	HNF1-beta	Juvenile hyperuricaemic nephropathy	Cystic kidneys, solitary kidney; gout; MODY; abnormal LFTs; pancreatic atrophy; hypomagnesaemia
	REN (codes for renin)	Juvenile hyperuricaemic nephropathy	Gout; hyperkalaemia; anaemia, salt-losing nephropathy
Autosomal recessive	*NPHP* genes (> 20 genes discovered so far)	Nephronophthisis Part of many syndromes (e.g. Bardet–Biedl)	Common cause of paediatric ESRD Occurs earlier than AD interstitial nephritis Extrarenal manifestation common (learning difficulty, eye/limb problems)

(AD = autosomal dominant; CKD = chronic kidney disease; ESRD = end-stage renal disease; LFTs = liver function tests; MCKD = medullary cystic kidney disease; MODY = maturity-onset diabetes of the young)

Papillary necrosis

The renal papillae lie within a hypoxic and hypertonic environment in the renal medulla, at the end of the vasa recta. Hence, they are susceptible to ischaemic damage and can undergo necrosis when their vascular supply is impaired as the result of diabetes mellitus, sickle-cell disorder or long-term ingestion of NSAIDs. There is an association with pyelonephritis, but it is difficult to determine whether this is a cause of papillary necrosis or a complication. The clinical presentation is variable. Some patients are asymptomatic and clinically silent, whereas others present with renal colic and renal impairment as necrosed papillae slough off and cause ureteric obstruction. Urinalysis may be normal, but more frequently haematuria and sterile pyuria are present. Significant proteinuria is unusual. The imaging method of choice to make the diagnosis is CT urogram or intravenous pyelography. Management is based on relieving obstruction, where present, and withdrawal of the offending drugs.

Isolated defects of tubular function

An increasing number of disorders have been identified that are caused by specific defects in transporter molecules expressed in renal tubular cells. Only the most common are mentioned here. Renal glycosuria is a benign autosomal recessive defect of tubular glucose reabsorption, caused by mutations of the sodium-glucose co-transporter *SGLT2*. Glucose appears in the urine in the presence of a normal blood glucose concentration. Notably, SGLT2 inhibitors may also cause glycosuria, even when used in patients without diabetes mellitus.

Cystinuria is a rare condition, in which reabsorption of filtered cystine, ornithine, arginine and lysine is defective. It is caused by mutations in the *SLC3A1* amino acid transporter gene. The high concentration of cystine in urine leads to cystine stone formation (p. 644).

Other uncommon tubular disorders include hereditary hypophosphataemic rickets, in which reabsorption of filtered phosphate is reduced, and hereditary AVP resistance (Ch. 20), in which the tubules are resistant to the effects of AVP. In Bartter and Gitelman syndromes, there are inactivating mutations in the genes that encode the Na-K-2Cl and NaCl transporters, the targets of loop and thiazide diuretics, respectively. Hence, both disorders present with sodium-wasting and hypokalaemia (Ch. 19).

The term 'Fanconi syndrome' is used to describe generalised proximal tubular dysfunction. The condition typically presents with low blood phosphate and uric acid concentrations, glycosuria, aminoaciduria and proximal renal tubular acidosis. In addition to the causes of interstitial nephritis described above, some congenital metabolic disorders are associated with Fanconi syndrome, notably Wilson disease, cystinosis and hereditary fructose intolerance.

Renal tubular acidosis describes the common endpoint of a variety of diseases affecting distal (classical or type 1) or proximal (type 2) renal tubular function. These syndromes may also be inherited and are described in Chapter 19.

Cystic diseases of the kidney

It is common to encounter patients with a single renal cyst or even a few cysts as an incidental finding. However, several genetic diseases are characterised by the formation of multiple renal cysts and are discussed below.

Autosomal dominant polycystic kidney disease

18.21 Autosomal dominant polycystic kidney disease: common clinical features

- Vague discomfort in loin or abdomen due to increasing mass of renal tissue
- Acute loin pain or renal colic due to cyst rupture, haemorrhage into a cyst or ureteric stones
- Hypertension
- Haematuria – often visible, but with little or no proteinuria
- Urinary tract or cyst infections
- Renal failure

Autosomal dominant polycystic kidney disease (ADPKD) is a common condition, with a prevalence of approximately 1:1000. Small cysts lined by tubular epithelium develop from infancy or childhood and enlarge slowly and irregularly. The surrounding normal kidney tissue is compressed and progressively damaged. Mutations in the *PKD1* gene account for 80% of cases and those in *PKD2* for about 15% (coding for polycystin 1 and 2 genes, respectively). Mutations in many other cystic genes have recently been discovered, which explain the remainder. These often have a more benign outcome and the most common is probably the ciliopathy gene, *IFT140*, which tends to cause few, large cysts with preserved kidney function. The median age of ESRD is approximately 50–55 years with a *PKD1* mutation and 70 years with a *PKD2* mutation. Approximately 10% of patients with ESRD have ADPKD.

Clinical features

Common clinical features are shown in Box 18.21. Affected people are usually asymptomatic until later life, and often diagnosed incidentally if they have imaging for other reasons. However, hypertension often occurs from adolescence or early adulthood. One or both kidneys may be palpable, and the surface may feel nodular. Many patients with ADPKD also have hepatic cysts (see Fig. 23.39), but disturbance of liver function is rare. Sometimes, typically in women, the cysts cause massive and symptomatic hepatomegaly. Cysts may also occur in the pancreas and spleen but are rarely of clinical significance. Berry aneurysms of cerebral vessels are an associated feature in about 10% of patients and seem to be largely restricted to certain families (and presumably specific mutations). Mitral and aortic regurgitation is frequent but rarely severe. Colonic diverticula and abdominal wall hernias may also occur.

Investigations

The diagnosis is usually based on family history, clinical findings and ultrasound examination. Ultrasound demonstrates cysts in approximately 95% of affected patients over the age of 20 and is the screening method of choice but may not detect small, developing cysts in younger subjects. Cysts may also be identified by other imaging modalities, such as MRI (Fig. 18.16). Simple renal cysts may occur in normal individuals but are uncommon below the age of 30. The following criteria exist for an ultrasound diagnosis of ADPKD in patients with a family history but unknown genotype:

- 15–39 years of age: at least three unilateral or bilateral kidney cysts
- 40–59 years of age: at least two cysts in each kidney
- 60 years or older: at least four cysts in each kidney.

It is possible to make a molecular diagnosis by DNA sequencing of *PKD1* or *PKD2* and the more recently discovered genes. This is used in cases with an uncertain diagnosis (young patients, few cysts, asymmetric disease, lack of family history), for workup of living kidney donors, or for screening for mutations associated with a worse prognosis (see below). Screening for intracranial aneurysms is not routinely recommended but can be done by MR angiography in families with a history of subarachnoid haemorrhage or those with a high-risk occupation (e.g. airplane pilot). The yield of screening is low, however, and the risk:benefit ratio of intervention in asymptomatic aneurysms in this disease is not clear.

Management

Blood pressure control is important because cardiovascular morbidity and mortality are so common in renal disease. There are data suggesting that targeting a very low blood pressure (< 110/75 mmHg) with ACE inhibitors or angiotensin II receptor blockers (ARBs) leads to slower increases in kidney volume. However, no improvements in eGFR decline were observed in these studies, and these targets are often not tolerated. This tight blood pressure target does lead to improvements in left

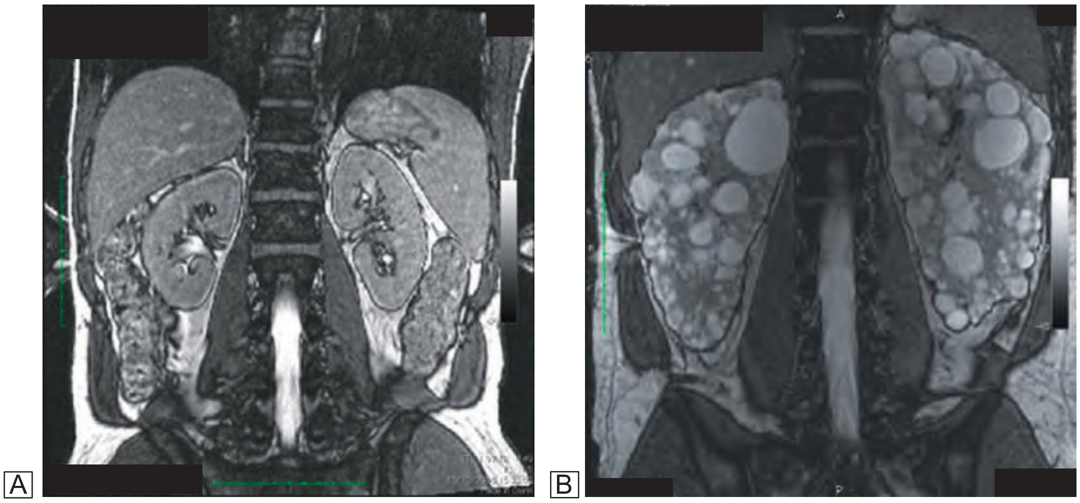


Fig. 18.16 **MRI images of the kidneys.** A Normal kidneys. B Polycystic kidneys; although the kidney enlargement is extreme, this patient had only slightly reduced GFR.

ventricular mass, which may have implications for improved cardiovascular risk later in life.

The AVP V2 receptor antagonist tolvaptan slows the increase in kidney volume and the rate of eGFR decline. All patients will experience polyuria and polydipsia, which may make the drug intolerable for some. It has been licensed in many countries for patients at high risk of progression. Risk factors for progression include large kidneys (more specifically height-adjusted kidney volume), truncating *PKD1* mutations, family history of early progression, male sex, hypertension and development of early symptomatic cysts.

Patients with ADPKD are usually good candidates for dialysis and transplantation. Sometimes kidneys are so large that one or both must be removed to make space for a renal transplant. Otherwise, they are usually left in situ unless they are a source of pain or infection.

Other cystic diseases

Renal cysts and diabetes syndrome is caused by *HNF1-beta* mutations; it has a varying renal phenotype that often causes cysts but may also cause a tubulo-interstitial pattern of injury or congenital anomalies of the kidneys. It also causes maturity-onset diabetes of the young (MODY) and a variety of other manifestations (see Box 18.20).

Autosomal recessive PKD is predominantly caused by mutations in the *PKHD1* gene, encoding fibrocystin. It is less common than autosomal dominant PKD (about 1:20000 live births). Patients often present in infancy or young childhood with renal cysts and congenital hepatic fibrosis.

Some uncommon autosomal dominantly inherited conditions are associated with multiple renal cysts and tumours in adult life. In tuberous sclerosis, replacement of renal tissue by multiple angiomyolipomas may occasionally cause ESRD in adults. Patients may also develop renal cysts and have a higher risk of renal cell carcinoma. Other organs affected include the skin (adenoma sebaceum on the face) and brain (causing seizures and intellectual disability). von Hippel–Lindau syndrome is associated with multiple renal cysts, renal adenomas and renal cell carcinoma. Other involved organs include the central nervous system (haemangioblastomas), pancreas (serous cystadenomas) and adrenals (phaeochromocytoma).

Multicystic dysplastic kidneys are often unilateral and are a developmental abnormality found in children, sometimes with a genetic cause. Most of these seem to involute during growth, leaving a solitary kidney in adults.

Acquired cystic kidney disease can develop in patients with a very long history of renal failure, so it is not an inherited cystic disease. It is associated with increased erythropoietin production and sometimes with the development of renal cell carcinoma. The kidneys are usually normal or small and with a smooth outline, which distinguishes it from classic ADPKD.

Renal vascular diseases

Diseases that affect renal blood vessels may cause renal ischaemia, leading to acute or chronic kidney disease or secondary hypertension. The rising prevalence of atherosclerosis and diabetes mellitus in ageing populations has made renovascular disease an important cause of ESRD.

Renal artery stenosis

A stenosis of more than 50% may be observed on imaging of the renal arteries in up to 20% of older patients with advanced kidney disease; however, a haemodynamically significant effect will be present in only a relatively small proportion. Renal artery stenosis is the most common cause of secondary hypertension, with an estimated prevalence of about 2% in unselected patients, but this may increase to 4% in older patients who have evidence of atherosclerotic disease elsewhere. Most cases of renal artery stenosis are caused by atherosclerosis, but fibromuscular dysplasia involving the vessel wall may be responsible in younger patients.

Pathophysiology

Renal artery stenosis results in a reduction in renal perfusion pressure, which activates the renin–angiotensin system, leading to increased circulating levels of angiotensin II. This results in hypertension by provoking vasoconstriction and increasing aldosterone production by the adrenal, causing sodium retention by the renal tubules (p. 661). Significant reduction of renal blood flow occurs when there is more than 70% narrowing of the artery, and this is commonly associated with distal, post-stenotic dilatation. Atherosclerotic lesions are typically ostial and are associated with more widespread atherosclerosis within the aorta and other vessels, particularly the iliac vessels. There is often concurrent small-vessel disease in affected kidneys, due to subclinical atheroemboli. As the stenosis becomes more severe, global renal ischaemia leads to shrinkage of the affected kidney and may cause renal failure if bilateral or if unilateral in the presence of a single kidney (ischaemic nephropathy).

Untreated, atheromatous renal artery stenosis is thought to progress to complete arterial occlusion in about 15% of cases. This figure increases with more severe degrees of stenosis. If the progression is gradual, collateral vessels may develop and some function may be preserved, preventing infarction and loss of kidney structure. Conversely, most patients with renal artery stenosis will not develop progressive renal impairment, and many patients die from other vascular diseases rather than renal failure. Unfortunately, methods of predicting which patients are at risk of progression or who will respond to treatment are still imperfect.

In younger patients, fibromuscular dysplasia is a more likely cause of renal artery stenosis. This is an uncommon disorder of unknown cause. It is characterised by hypertrophy of the media (medial fibroplasia), which narrows the artery but rarely leads to total occlusion. It may be associated with disease in other arteries; for example, those who have carotid artery dissections are more likely to have renal arteries with this appearance. It most commonly presents with hypertension in patients aged 15–30 years, and women are affected more frequently than men. Irregular narrowing (beading) may occur in the distal renal artery, and this sometimes extends into the intrarenal branches of the vessel.

Rarely, renal artery stenosis may occur as a complication of large- or medium-vessel vasculitis, such as Takayasu arteritis or polyarteritis nodosa (see Ch. 25).

Clinical features

Renal artery stenosis can present in various ways, including hypertension, acute pulmonary oedema, progressive renal failure (with bilateral disease) or a deterioration in renal function when ACE inhibitors or ARBs are administered. Although many patients experience a slight drop in GFR when commencing these drugs, an increase in serum creatinine of 30% or more raises the possibility of renal artery stenosis. Acute pulmonary oedema is particularly characteristic of bilateral renovascular disease, typically occurring at night and associated with severe hypertension, often in the context of normal or only mildly impaired renal and cardiac function. Clinical evidence of generalised vascular disease may be observed, particularly in the legs. Clinical features associated with an increased risk of renal artery stenosis in hypertensive patients are summarised in Box 18.22. However, given the risk of imaging and angiography in patients with renal disease (see Box 18.4), further investigation should be performed only if intervention is being contemplated (see below).

Investigations

When appropriate, imaging of the renal vasculature with either CT angiography or MR angiography should be performed to confirm the diagnosis (Fig. 18.17). Both give good views of the main renal arteries, the vessels most amenable to intervention. Biochemical testing may reveal impaired renal function and an elevated plasma renin activity, sometimes with hypokalaemia due to hyperaldosteronism. Ultrasound may also reveal a discrepancy in size between the two kidneys, although this is insufficiently sensitive or specific to be of value in diagnosis of renovascular disease in hypertensive patients.

Management

The first-line management in patients with renal artery stenosis is medical therapy with antihypertensive drugs, supplemented, where appropriate, by statins, low-dose aspirin and smoking cessation in those with atherosclerotic disease. Interventions to correct the vessel narrowing should be considered in:

- young patients (age below 40 years) suspected of having renal artery stenosis
- those whose blood pressure cannot easily be controlled with antihypertensive agents
- those who have a history of 'flash' pulmonary oedema
- those with accelerated phase (malignant) hypertension
- those whose renal function is deteriorating.

i 18.22 Presentation and clinical features of renal artery stenosis

Renal artery stenosis is more likely if:

- hypertension is severe, of recent onset or difficult to control
- kidneys are asymmetrical in size
- flash pulmonary oedema occurs repeatedly*
- there is peripheral vascular disease of the lower limbs
- there is renal impairment*
- renal function has deteriorated on angiotensin-converting enzyme inhibitors or angiotensin II receptor blockers

*Particularly with bilateral disease.

The most commonly used technique is angioplasty. The best results are obtained in non-atheromatous fibromuscular dysplasia, where correction of the stenosis has a high chance of success in improving blood pressure and protecting renal function. Beyond the indications above, angioplasty and stenting are now rarely performed in atherosclerotic disease, as randomised trials have produced no convincing evidence for overall benefit in terms of renal function, blood pressure control or cardiovascular outcomes. The risks of angioplasty and stenting include renal artery occlusion, renal infarction and atheroemboli (see below) from manipulations in a severely diseased aorta. Small-vessel disease distal to the stenosis may preclude substantial functional recovery.

Acute renal infarction

This is an uncommon condition that occurs as the result of sudden occlusion of the renal artery. The presentation is typically with loin pain of acute onset, usually in association with non-visible haematuria, but pain may be absent in some cases. Severe hypertension is common but not universal. The condition may be caused by thrombosis of a renal artery or by thromboemboli from a distant source, when occlusion may occur in branch arteries distal to the main renal artery. This can cause multiple infarcts within the renal parenchyma of both kidneys, which may be visualised by CT angiography. If occlusion of the main renal arteries is bilateral or if there is occlusion in a single functioning kidney, the presentation is with AKI and the patient is typically anuric. Patients with bilateral occlusion usually have evidence of widespread vascular disease and may show evidence of aortic occlusion, with absent femoral pulses and reduced lower limb perfusion. Management is largely supportive and includes anticoagulation if a source of thromboembolism is identified. It

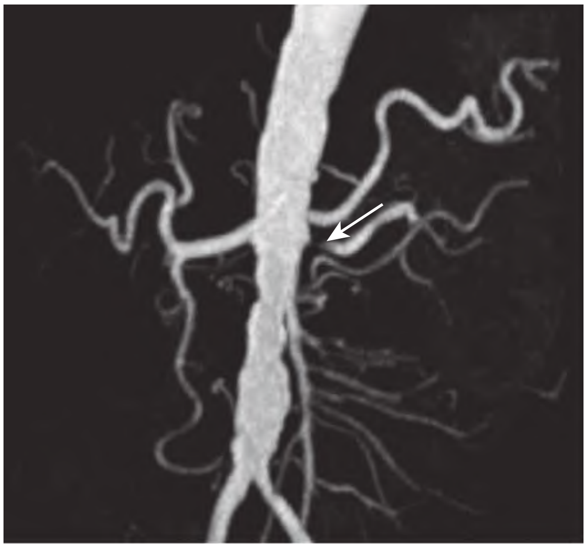

Fig. 18.17 Renal artery stenosis. A magnetic resonance angiogram following injection of contrast. The abdominal aorta is severely irregular and atheromatous. The left renal artery is stenosed (arrow).

is sometimes possible to perform stenting of an acutely occluded main renal artery to try to restore renal blood flow; in most cases, however, presentation is too late to salvage renal function.

Diseases of small intrarenal vessels

Thrombotic microangiopathies

Several conditions are associated with acute damage and occlusion of small blood vessels (arterioles and capillaries) in the kidney (Box 18.23) and other organs. A common feature of these syndromes is microangiopathic haemolytic anaemia (MAHA), in which haemolysis and red cell fragmentation arise because of damage incurred to red blood cells during passage through the abnormal vessels. The red blood cell fragments (schistocytes) may be observed on blood films, together with laboratory features of intravascular haemolysis (p. 976), including an elevated unconjugated bilirubin level, raised serum LDH concentration and decreased circulating levels of haptoglobin. A reticulocytosis is often seen. Endothelial injury is pronounced, leading to increased platelet adherence and a marked reduction in the platelet count. These abnormal blood parameters should alert the physician to the possibility of a thrombotic microangiopathy and may also be useful in monitoring response to treatment. The key is to distinguish between the various aetiologies, as the management differs according to the primary cause (see Box 18.23).

Haemolytic uraemic syndrome

Haemolytic uraemic syndrome (HUS) is characterised by thrombotic microangiopathy that predominantly affects the renal microcirculation, with involvement of other organs (including the brain) observed in more severe cases.

The most common cause of HUS is infection with organisms that produce enterotoxins called Shiga-like toxin or verotoxins. The organisms most commonly implicated are enterohaemorrhagic *Escherichia coli* and *Shigella dysenteriae*. The *E. coli* O157:H7 serotype is the best known but other serotypes that produce verotoxins may also be responsible. Although these bacteria live as commensals in the gut of cattle and other livestock, they can cause haemorrhagic diarrhoea in humans when the infection is contracted from contaminated food products, water or other infected individuals. In a proportion of cases, verotoxin produced by the organisms enters the circulation and binds to specific glycolipid receptors that are expressed on the surface of microvascular endothelial cells. Most cases are sporadic, but large outbreaks related to poor sanitation may occur. In developed countries, Shiga-like toxin-associated HUS is now the most common cause of AKI in children. Recovery is good in most patients, but sometimes renal replacement therapy (RRT) may be required, usually temporarily. Some patients may initially recover but develop CKD in later life. No specific treatments have been shown to accelerate renal recovery.

In the absence of bloody diarrhoea, other (atypical) causes of HUS should be considered, in particular abnormalities of the complement system. Familial forms are due to mutations in various genes that encode components or regulators of the complement cascade, including factor H *(CFH)*, factor I (CFI), factor B *(CFB)*, membrane co-factor protein *(MCP)* and complement component 3 *(C3)*. The penetrance of familial HUS is incomplete, indicating that environmental triggers are also involved: often pregnancy and infection, including diarrhoea, which may cause diagnostic confusion with typical HUS. Sporadic cases may be associated with the development of autoantibodies to complement factor H. In addition to supportive care, including RRT if necessary, management of complement-mediated HUS includes plasma exchange to replace complement components and remove pathogenic autoantibodies. Impressive results have been reported with the anti-C5 monoclonal antibody, eculizumab, which binds to C5, thereby preventing activation of the terminal complement cascade.

Thrombotic thrombocytopenic purpura

Like HUS, thrombotic thrombocytopenic purpura (TTP) is characterised by MAHA and thrombocytopenia; in contrast, however, the brain is more commonly affected in TTP, and involvement of the kidney is usually less prominent. TTP is an autoimmune disorder caused by antibodies against ADAMTS-13, which is involved in regulating platelet aggregation, and a low (< 10%) serum ADAMTS-13 activity level may be useful in distinguishing TTP from HUS. This distinction is important, as early therapy with plasma exchange is crucial in TTP. More details are provided on page 1013.

i 18.23 Thrombotic microangiopathies associated with acute renal damage

Condition	Typical features	Management
Primary thrombotic microangiopathies		
Haemolytic uraemic syndrome:	Renal failure prominent in all causes	
Shiga toxin +ve HUS	Bloody diarrhoea; check stool for *Escherichia coli* 0157:H7	Supportive therapy
Complement-mediated	Positive family history; screen for complement factor mutations	Plasma exchange, eculizumab
Drug-induced: quinine, calcineurin inhibitors, VEGF inhibitors	Drug exposure, fever with quinine	Cessation of offending drug
Thrombotic thrombocytopenic purpura	Neurological manifestations prominent; check ADAMTS-13 activity	Plasma exchange
Thrombotic microangiopathy associated with systemic disorders		
Disseminated intravascular coagulation (DIC)	Clotting system involvement: elevated D-dimers, low fibrinogen, prolonged PT and APTT	Treatment of primary cause
Malignancy	May occur with breast, prostate, lung, pancreas and GI tumours	Treatment of tumour where possible
Systemic sclerosis	Cutaneous features of systemic sclerosis	Blood pressure control with ACE inhibitors
Pre-eclampsia and HELLP syndrome	Typically in third trimester; abnormal LFTs	Resolution with delivery
Malignant hypertension	Blood pressure typically very high; evidence of hypertensive retinopathy including papilloedema	Blood pressure control

(ACE = angiotensin-converting enzyme; ADAMTS-13 = a disintegrin and metalloproteinase with a thrombospondin type 1 motif, member 13; APTT = activated partial thromboplastin time; GI = gastrointestinal; HELLP = haemolysis, elevated liver enzymes and low platelets; HUS = haemolytic uraemic syndrome; LFTs = liver function tests; PT = prothrombin time; VEGF = vascular endothelial growth factor)

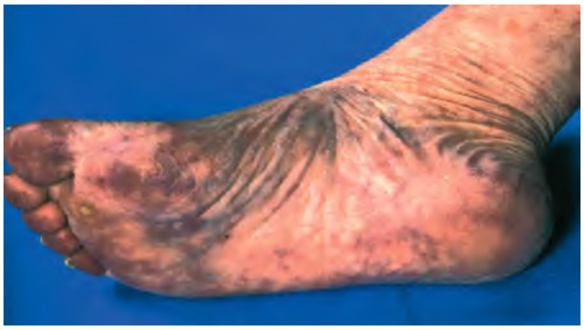

Fig. 18.18 **The foot of a patient who suffered extensive atheroembolism following coronary artery stenting.**

Cholesterol emboli

These present with renal impairment, haematuria, proteinuria and sometimes eosinophilia with inflammatory features that can mimic a small-vessel vasculitis. The symptoms are provoked by showers of cholesterol-containing microemboli, arising in atheromatous plaques in major arteries. The diagnosis should be suspected when these clinical features occur in patients with widespread atheromatous disease, who have undergone interventions such as surgery or arteriography. They may also be precipitated by anticoagulants and thrombolytic agents. On clinical examination, signs of large-vessel disease and microvascular occlusion in the lower limbs (ischaemic toes, livedo reticularis) are common but not invariable (Fig. 18.18). There is no specific treatment.

Small-vessel vasculitis

Renal disease caused by small-vessel vasculitis usually presents with a clinical picture typical of a glomerulonephritis (see Figs. 18.10 and 18.13C). More information is given below.

Renal involvement in systemic conditions

The kidneys may be directly involved in several multisystem diseases or secondarily affected by diseases of other organs. Involvement may be at a pre-renal, renal (glomerular or interstitial) or post-renal level. Many of the diseases are described in other sections of this chapter or in other chapters of the book.

Diabetes mellitus

Diabetic nephropathy is the most common cause of CKD in developed countries. In patients with diabetes mellitus, there is a steady advance from moderately elevated albuminuria (microalbuminuria) to dipstick-positive proteinuria, in association with evolving hypertension and progressive renal failure, as described on page 792. Few patients require renal biopsy to establish the diagnosis, but atypical features such as very rapid progression of proteinuria, rapid decline in renal function or the absence of microvascular disease in other organs, including retinopathy, should lead to suspicion that an alternative condition could be present and prompt consideration of renal biopsy.

Management with ACE inhibitors or ARBs to slow progression is described on page 793. Combination of RAAS blockade with the non-steroidal mineralocorticoid receptor antagonist finerenone may confer additional renoprotection. In patients with type 2 diabetes mellitus, SGLT2 inhibitors reduce cardiovascular mortality and CKD progression; however, they are typically not employed in type 1 diabetes due to the risk of euglycaemic ketoacidosis (p. 793). Glucagon-like peptide-1 (GLP-1) agonists slow CKD progression and reduce cardiovascular mortality in patients with type 2 diabetic nephropathy. Furthermore, GLP-1 agonists promote weight loss; therefore, their use in patients with obesity may in future reduce the incidence of type 2 diabetes and nephropathy. The combination of RAAS and SGLT2 inhibitors may lead to a marked reduction in proteinuria and the rate of eGFR decline, although most patients still have progressive disease, albeit at a slower rate.

18.24 Renal manifestations of multiple myeloma

Condition	Presentation	Pathogenesis
Cast nephropathy ('myeloma kidney')	AKI Little/no proteinuria	Light chains combine with Tamm–Horsfall protein precipitating in tubules
Fanconi syndrome	Aminoaciduria, phosphaturia, glycosuria Proximal (type II) RTA	Proximal tubular injury due to light chain deposition in tubular epithelium
AL (primary) amyloidosis*	Proteinuria/nephrotic syndrome Renal impairment	Misfolded light chains (usually lambda) deposited in the glomeruli form amyloid fibrils
Monoclonal immunoglobulin deposition disease*	Proteinuria (may be in nephrotic range) Renal impairment	Usually light chains (frequently kappa) are deposited in glomeruli, causing a nodular glomerulosclerosis
Hypercalcaemia	Thirst, polyuria, and AKI due to dehydration due to osmotic diuresis	Bone destruction from malignant cells

*These may also occur as primary conditions without myeloma being present.
(AKI = acute kidney injury; RTA = renal tubular acidosis)

Multiple myeloma

In myeloma, a malignant clone of plasma cells produces a paraprotein, often a monoclonal light chain. Renal manifestations are dominated by these toxic light chains, which may cause a variety of insults depending on whether they are trapped in the glomerulus or filtered into the urine (Box 18.24).

Hepatic–renal disease

Severe hepatic dysfunction may cause a haemodynamically mediated type of renal failure, hepatorenal syndrome (HRS), described on page 896. Patients with chronic liver disease are also predisposed to develop acute tubular necrosis (ATN) in response to relatively minor insults, including bleeding, diuretic therapy and infection. Differentiating true HRS (when there is little tubular injury) from ATN can be difficult, but in HRS the urinary sodium is typically low. Patients with true HRS are often difficult to treat by dialysis and have a poor prognosis. Where treatment is justified – for example, if there is a good chance of recovery or of a liver transplant – slow or continuous RRT is less likely to precipitate or exacerbate hepatic encephalopathy. IgA nephropathy (p. 617) is more common in patients with chronic liver disease.

Sarcoidosis

Sarcoidosis may lead to a granulomatous interstitial nephritis, sometimes presenting acutely, where renal function may improve with glucocorticoid therapy. Post-mortem examinations reveal a CIN in 15%–30% of patients with sarcoidosis but clinically relevant disease appears to be much less common.

Systemic vasculitis

Small-vessel vasculitis (Ch. 25) commonly affects the kidneys, with rapid and profound impairment of glomerular function. Histologically, there is inflammatory glomerulonephritis, usually with focal necrosis (see Box 18.15 and Fig. 18.13C) and often with crescentic changes (see Fig.

18.13E). Typically, the patient is systemically unwell with an acute phase response, weight loss and arthralgia. In some patients, it presents as a kidney-limited disorder, with rapidly deteriorating renal function and crescentic nephritis (a rapidly progressive glomerulonephritis). In others, pulmonary haemorrhage may occur, which can be life-threatening.

The most important cause is ANCA-associated vasculitis (Ch. 25). Two subtypes are recognised: granulomatosis with polyangiitis (GPA) and microscopic polyangiitis (MPA). Both may present with constitutional symptoms and glomerulonephritis, though lung and ENT involvement is more common with GPA. Gastrointestinal involvement, arthritis, scleritis/uveitis, purpuric rash and neuropathy may also occur. Serological testing for antibodies to myeloperoxidase (MPO) and proteinase 3 (PR3) is usually positive (see Box 18.10), but these are not specific, and a biopsy of affected tissue should be obtained, if possible, to confirm the diagnosis and assess likelihood of recovery of kidney function.

The standard treatment of glomerulonephritis associated with systemic vasculitis is high-dose glucocorticoids combined with cyclophosphamide and/or rituximab (p. 1038). Plasma exchange can offer additional benefit in patients with severe kidney injury.

Glomerulonephritis secondary to vasculitis may rarely be seen in rheumatoid arthritis, SLE and cryoglobulinaemia, although SLE can affect the kidney in several different ways (see below).

Medium- to large-vessel vasculitis, such as polyarteritis nodosa (Ch. 25), does not cause glomerulonephritis but can cause hypertension, renal aneurysms and infarction if the renal vessels are involved.

Systemic lupus erythematosus

Subclinical renal involvement, with non-visible haematuria and proteinuria but minimally impaired or normal renal function, is common in SLE. Usually, this is due to glomerular disease, although interstitial nephritis may also occur, particularly in patients with overlap syndromes such as mixed connective tissue disease and Sjögren syndrome.

Almost any histological pattern of glomerular disease can be observed in SLE, and the clinical presentation ranges from florid, rapidly progressive glomerulonephritis to nephrotic syndrome due to membranous nephropathy (see Fig. 18.10). The most common presentation is with subacute disease and inflammatory features (haematuria, hypertension, variable renal impairment), accompanied by heavy proteinuria that often reaches nephrotic levels. In severely affected patients, the most common histological pattern is a proliferative glomerulonephritis with substantial deposits of immunoglobulins and complement on immunofluorescence. Complement deposition in the kidney may result in low serum levels of C3 and C4. Randomised controlled trials have shown that high-dose glucocorticoids administered in combination with either cyclophosphamide or mycophenolate mofetil is effective in both induction and maintenance treatment of lupus nephritis and lowers the risk of progression to ESRD.

Many patients with SLE who develop ESRD go into remission, possibly because of immunosuppression related to the ESRD. These patients are usually good candidates for dialysis and transplantation. Although it may recur in renal allografts, the immunosuppression required to prevent allograft rejection usually controls SLE.

Systemic sclerosis

Renal involvement is a serious complication of systemic sclerosis, which is more likely to occur in diffuse cutaneous systemic sclerosis (dcSSc) than in limited cutaneous systemic sclerosis (lcSSc). The renal lesion is caused by intimal cell proliferation and luminal narrowing of intrarenal arteries and arterioles, leading to renal ischaemia and marked activation of the RAAS. Renal involvement usually presents clinically with severe hypertension, microangiopathic features and progressive oliguric renal failure ('scleroderma renal crisis'). Use of ACE inhibitors to control the hypertension has improved the 1-year survival from 20% to 75%, but about 50% of patients continue to require RRT. Onset or acceleration of the syndrome after glucocorticoid use or cessation of ACE inhibitors is well described.

Sickle-cell nephropathy

Improved survival of patients with sickle-cell disorder means that a high proportion now live to develop chronic complications of microvascular occlusion. In the kidney, these changes are most pronounced in the medulla, where the vasa recta are the site of sickling because of hypoxia and hypertonicity. Loss of urinary concentrating ability and polyuria are the earliest changes; distal renal tubular acidosis and impaired potassium excretion are typical. Papillary necrosis may also occur (p. 620). A minority of patients develop ESRD. This is managed according to the usual principles, but response to recombinant erythropoietin is poor because of the haemoglobinopathy. Patients with sickle trait have an increased incidence of non-visible haematuria.

Acute kidney injury

Acute kidney injury (AKI) is not a diagnosis, rather it describes the situation where there is a sudden and often reversible loss of renal function, which develops over days or weeks. AKI affects approximately 7% of all hospitalised patients, and 20% of acutely ill patients develop AKI; therefore, all emergency admissions to hospital should undergo risk assessment for the likelihood of developing AKI. Those with coexisting diseases such as diabetes mellitus, cardiovascular, liver disease and existing CKD are at greater risk and need more regular assessment of renal function. Older patients are at higher risk of developing AKI and have worse mortality and increased risk of subsequent progression to CKD (Box 18.25).

AKI is diagnosed by an acute rise in serum creatinine of >26 mmol/L or >50% of baseline within 48 hours (stage 1 AKI). The greater the rise in creatinine (stage 2 AKI: more than ×2 baseline; stage 3 AKI: more than ×3 baseline), the more likely it is that dialysis will be required, with increased mortality and risk of subsequent CKD, particularly in patients with sepsis or multi-organ failure. Oliguria often occurs; therefore, a urine output of <0.5 mL/kg/hour should prompt clinical assessment and serum creatinine testing.

Pathophysiology

There are many causes of AKI, and it is frequently multifactorial. It is helpful to classify it into three subtypes as these have different presentations and treatment (Fig. 18.19):

- 'pre-renal', when perfusion to the kidney is reduced
- 'renal', when the primary insult affects the kidney itself
- 'post-renal', when there is obstruction to urine flow at any point from the renal pelvis to the urethra.

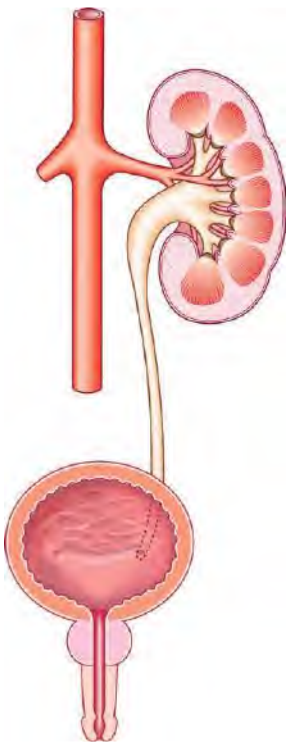
18.25 Acute kidney injury in old age

- **Physiological change**: nephrons decline in number with age and average GFR falls progressively, so many older patients will have established CKD and less functional reserve. Small acute declines in renal function may therefore have a significant impact.
- **Renal tubular function**: declines with age, leading to loss of urinary concentrating ability.
- **Drugs**: increased drug prescription in older people (diuretics, ACE inhibitors and NSAIDs) may contribute to the risk of AKI.
- **Causes**: infection, renal vascular disease, prostatic obstruction, myeloma and comorbidities such as diabetes, hypertension and severe cardiac dysfunction are common.
- **Mortality**: rises with age, primarily because of comorbid conditions.
- **Outcome:** AKI is more likely to progress to CKD due to reduced regenerative capacity

(ACE = angiotensin-converting enzyme; AKI = acute kidney injury; CKD = chronic kidney disease; GFR = glomerular filtration rate; NSAIDs = non-steroidal anti-inflammatory drugs)

Pre-renal AKI results from a reduction in renal perfusion, typically due to a reduction in systemic blood pressure. The drop in renal perfusion activates the RAAS, which promotes sodium retention in the kidney and systemic vasoconstriction (see Fig. 20.19) in order to restore circulatory volume and blood pressure. Angiotensin also preferentially constricts the glomerular efferent arteriole, while prostaglandins are released locally to vasodilate the afferent arteriole (see Figs. 18.1D and 18.20). The combined effect increases glomerular pressure to maintain GFR; however, if the blood pressure is very low, autoregulation fails and the GFR falls. Importantly, in pre-renal AKI, the kidney is not damaged; therefore, GFR can improve rapidly if the renal perfusion is restored.

If the drop in renal perfusion is severe or sustained, pre-renal AKI may progress to renal AKI as ischaemic injury causes ATN. The tubules are more sensitive to ischaemic injury as they have a high oxygen requirement to generate ATP for active transport, whereas their oxygen supply is more easily compromised as they are located in a relatively hypoxic region of the kidney due to the anatomy of the vase recta (see Fig. 18.1B). Histologically, the kidney shows necrotic tubuli, inflammatory changes, focal breaks in the tubular basement membrane and interstitial oedema (see Fig. 18.15B). Dead tubular cells may also be shed into the tubular lumen, leading to tubular obstruction. While ischaemia is the most common cause of ATN in hospital, it may also be caused by toxins and nephrotoxic drugs (see Boxes 18.26 and 18.42). Drugs can also cause allergic interstitial nephritis. The other common 'renal' cause of AKI is glomerulonephritis, in which there is direct inflammatory damage to the glomeruli.



PRE-RENAL

Impaired perfusion:
- Cardiac failure
- Sepsis
- Blood loss
- Dehydration
- Vascular occlusion
- Drugs

RENAL

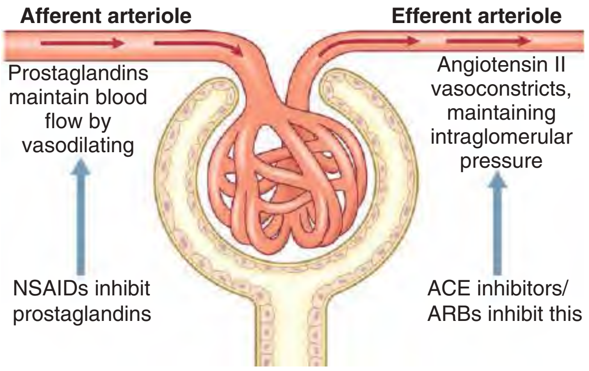
Glomerulonephritis
Small-vessel vasculitis
Acute tubular necrosis
- Drugs
- Toxins
- Prolonged hypotension

Interstitial nephritis
- Drugs
- Toxins
- Inflammatory disease
- Infection, including COVID-19

POST-RENAL

Urinary calculi (bilateral)
Retroperitoneal fibrosis
Benign prostatic hypertrophy
Bladder cancer
Prostate cancer
Cervical cancer
Urethral stricture/valves
Meatal stenosis/phimosis

Fig. 18.19 **Causes of acute kidney injury.**



Afferent arteriole
Efferent arteriole
Prostaglandins maintain blood flow by vasodilating
Angiotensin II vasoconstricts, maintaining intraglomerular pressure
NSAIDs inhibit prostaglandins
ACE inhibitors/ ARBs inhibit this

Fig. 18.20 **Renal haemodynamics and autoregulation of glomerular filtration rate (GFR).** It is evident from this figure how angiotensin-converting enzyme (ACE) inhibitors/angiotensin receptor blockers (ARBs) may be associated with profound drops in GFR in the context of bilateral renal artery stenosis or intravascular volume depletion (which decrease perfusion to afferent arterioles). (NSAIDs = non-steroidal anti-inflammatory drugs)

Post-renal AKI occurs as the result of obstruction to the renal tract (see Box 18.6). This leads to elevation of intraluminal ureteral pressure transmitted to the nephrons, with a subsequent fall in GFR. The obstruction needs to be bilateral to cause renal failure; therefore, it is unusual for renal stones to cause AKI, while obstruction of the bladder outlet is a much more common cause. If obstruction is reversed, the extent of recovery of renal function is dependent on the pre-morbid GFR and the duration of obstruction, with reversal within hours to days usually leading to return to baseline renal function over the next few days.

Clinical assessment

If a patient is found to have a high serum creatinine, it is important to establish whether this is an acute or acute-on-chronic phenomenon, or whether it represents stable CKD. Previous serum creatinine results are the best guide; however, eGFR is not accurate in AKI (see Box 18.2), and it may overestimate renal function in early AKI when creatinine is increasing rapidly. Clinical features of AKI include short duration of symptoms, and an absence of markers of CKD such as anaemia, elevated PTH and small kidneys observed on imaging (see Fig. 18.23). Early recognition of AKI and prompt action to treat the underlying cause is required to prevent rapid progression of renal injury and to increase the likelihood of recovery of renal function.

Early assessment of volume status is necessary. Evidence of hypovolaemia suggests a pre-renal cause for AKI, and this may respond to fluid resuscitation. Conversely, there may be volume overload in intrinsic or post-renal AKI and in this context administration of fluid may provoke fluid overload and pulmonary oedema. Measurement of fluid intake and urine output is essential to determine response to treatment and guide fluid requirement. Insertion of a urinary catheter may be helpful to exclude bladder outlet obstruction and monitor hourly urine output.

Clinical features and pertinent investigations for the different causes of AKI are shown in Box 18.26 and are discussed below.

Pre-renal AKI

Pre-renal AKI is typically associated with evidence of dehydration and volume depletion on clinical examination. With dehydration, there is usually an obvious cause such as vomiting or diarrhoea, and there may be clinical signs such as dry mucous membranes or reduced skin turgor. The cause of intravascular volume depletion may be obvious, such as with dehydration or overt bleeding, but there may also be occult blood loss into the gastrointestinal tract, retroperitoneum (particularly with femoral and pelvic fractures) and into the pregnant uterus. Large volumes of intravascular fluid may also be lost into tissues after crush injuries or burns, following abdominal surgery, in severe inflammatory skin diseases or sepsis. In the early stages of hypovolaemia, blood pressure may remain normal, but there may be tachycardia and postural hypotension (a fall in blood pressure of >20/10 mmHg from lying to standing). More significant hypovolaemia is associated with hypotension and signs of poor peripheral perfusion, such as cold peripheries and delayed capillary return. Warm peripheries in the presence of hypotension may indicate sepsis, as peripheral vasodilatation may be triggered by bacterial toxins and immune mediators. Pre-renal AKI may also occur without systemic hypotension, particularly in patients who are dehydrated or who are taking diuretics, NSAIDs or ACE inhibitors (Fig. 18.20), and in hypertensive

18.26 Categorising acute kidney injury based on history, examination and investigations

Type of AKI	History	Examination	Investigations
Pre-renal	Volume depletion (vomiting, diarrhoea, burns, haemorrhage) Sepsis Cardiac disease Liver disease Drugs (diuretics, ACE inhibitors, ARBs, NSAIDs, calcineurin inhibitors, iodinated contrast)	Low BP relative to normal for patient (including postural drop) Tachycardia Weight decrease Dry mucous membranes Decreased skin turgor JVP not visible even when lying down	Urine Na < 20 mmol/L Fractional excretion Na < 1% High serum urea:creatinine ratio Urinalysis: no blood/protein (unless pre-existing CKD or UTI/post catheter insertion), high specific gravity
Renal ATN	Ischaemic injury due to severe or prolonged pre-renal state Toxic ATN: drugs (aminoglycosides, cisplatin, tenofovir, methotrexate, iodinated contrast) Other (rhabdomyolysis, snake bite, *Amanita* mushrooms)	Fluid assessment – may still be volume depleted or now becoming volume expanded if aggressive resuscitation has occurred Limbs for compartment syndrome	Urine Na > 40 mmol/L Fractional excretion Na ≥ 1% Dense granular ('muddy brown') casts Creatine kinase
Glomerular	Rash, weight loss, arthralgia, ENT, paraesthesia and chest symptoms (pulmonary renal syndromes) Recent infection	Hypertension Oedema Purpuric rash, uveitis, arthritis	Proteinuria, haematuria Red cell casts, dysmorphic red cells ANCA, anti-GBM, ANA, C3 and C4 Renal biopsy
Tubulo-interstitial	Interstitial nephritis: drugs (PPIs, penicillins, NSAIDs) Sarcoidosis	Fever Rash	Eosionophilia Leucocyturia White cell casts Mild proteinuria
	Tubular obstruction: Myeloma (cast nephropathy)		Paraprotein, Bence Jones protein Calcium (myeloma, sarcoidosis)
	Tubular crystal nephropathy: Drugs (aciclovir, indinavir, triamterene, methotrexate) Oxalate (fat malabsorption, ethylene glycol) Urate (tumour lysis)		Urine microscopy for crystals Serum urate Urine collection for oxalate
Vascular (including renal infarction, renal vein thrombosis, cholesterol emboli, malignant hypertension)	Flank pain, trauma Recent angiography (cholesterol emboli) Nephrotic syndrome (renal vein thrombosis) Systemic sclerosis (renal crisis) Diarrhoea (HUS)	Hypertension Hypertensive changes on fundoscopy Livedo reticularis (cholesterol emboli) Scleroderma features	Normal urinalysis or haematuria CT angiography Doppler renal ultrasound C3 and C4 (cholesterol emboli) Platelets, haemolytic screen, LDH (HUS) Consider ADAMTS-13 and complement genetics (if TMA)
Post-renal	Bladder outlet symptoms History of BPH or prostate, bladder or cervical cancer Retroperitoneal fibrosis Neurogenic bladder	Rectal examination (prostate and anal tone) Distended bladder Pelvic mass	Urinalysis frequently normal (may reveal haematuria depending on cause) Renal ultrasound (hydronephrosis) Isotope renogram (delayed excretion) if ultrasound inconclusive

(ACE = angiotensin-converting enzyme; ANA = antinuclear antibody; ANCA = antineutrophil cytoplasmic antibody; ARBs = angiotensin receptor blockers; ATN = acute tubular necrosis; BP = blood pressure; BPH = benign prostatic hypertrophy; GBM = glomerular basement membrane; HIV = human immunodeficiency virus; HUS = haemolytic uraemic syndrome; IV = intravenous; JVP = jugular venous pressure; LDH = lactate dehydrogenase; NSAIDs = non-steroidal anti-inflammatory drugs; PPIs = proton pump inhibitors; TMA = thrombotic microangiopathy)

patients, where normal blood pressure may represent relative hypotension compared to their baseline level.

While diagnosis of pre-renal AKI is usually based on history and assessment of volume status, the most helpful investigations reflect activation of hormonal systems due to intravascular volume depletion. Activation of the RAAS promotes sodium and urea reabsorption in the proximal tubule, leading to a low urinary sodium and a high serum urea:creatinine ratio; vasopressin release promotes water reabsorption leading to a concentrated urine, which may be identified by high specific gravity on urinalysis.

Renal AKI

Factors that can help differentiate the various causes of intrinsic renal AKI are summarised in Box 18.26. ATN is the most common cause of AKI in hospital; therefore, the observation chart should be assessed looking for current or prior episodes of hypotension and the medication chart for nephrotoxic medications. Patients with glomerulonephritis demonstrate haematuria and proteinuria, and may have clinical manifestations of an underlying disease, such as SLE or systemic vasculitis. Although blood tests, including an immunological screen, may suggest the diagnosis in glomerulonephritis, a renal biopsy is usually required. Drug-induced acute interstitial nephritis should be suspected in a previously well patient if there is an acute deterioration of renal function coinciding with introduction of a new drug treatment. Drugs that are commonly implicated include PPIs, NSAIDs and many antibiotics. Vascular disease is included here as diseases of the large and small renal vessels typically present with hypertension and volume expansion, in contrast to the volume depletion observed in pre-renal failure.

Post-renal AKI

Patients should be examined clinically to look for evidence of a distended bladder and should also undergo imaging with either a bladder scan to exclude bladder outlet obstruction or ultrasound of renal tracts to detect hydronephrosis (see Fig. 18.5) and evidence of obstruction above the level of the bladder.

Management

Management options common to all forms of AKI are discussed in more detail below and summarised in Box 18.27.

18.27 Management of acute kidney injury

- Assess fluid status as this will determine fluid prescription:
  - If hypovolaemic: optimise systemic haemodynamic status with fluid challenge and inotropes if necessary
  - Once euvolaemic, match fluid intake to urine output plus an additional 500 mL/24 hrs to cover insensible losses
  - If fluid-overloaded, prescribe diuretics (loop diuretics at high dose will often be required); if the response is unsatisfactory, dialysis may be required
- Treat underlying cause
- If $K^+ > 6.5$ mmol/L and ECG changes of hyperkalaemia are present, administer calcium gluconate to stabilise myocardium, lower potassium by oral potassium exchange resin to prevent potassium absorption, or administer intravenous glucose/insulin or sodium bicarbonate to move potassium intracellularly (see Box 19.17). These are holding measures until a definitive method of removing potassium is achieved (restoration of renal function or dialysis)
- Discontinue potentially nephrotoxic drugs and reduce doses of therapeutic drugs according to level of renal function
- Ensure adequate nutritional support
- Consider proton pump inhibitors to reduce the risk of upper gastrointestinal bleeding
- Screen for intercurrent infections and treat promptly if present

(ECG = electrocardiogram)

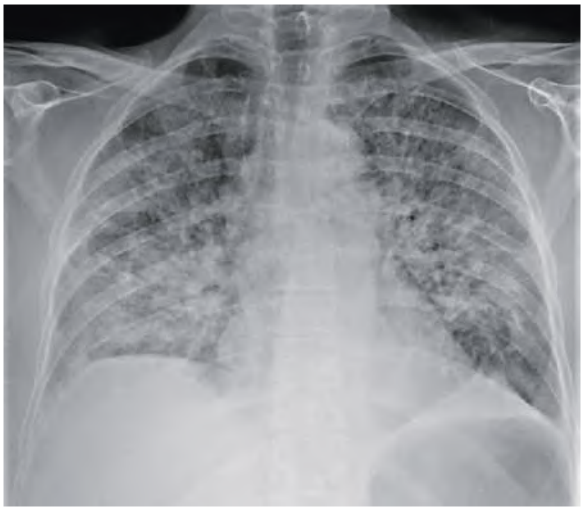


Fig. 18.21 Pulmonary oedema in acute kidney injury. The appearances are indistinguishable from left ventricular failure but the heart size is usually normal. Blood pressure is often high.

Optimisation of volume status

Regular assessment of volume status is essential to guide ongoing fluid requirements. Where clinical assessment is challenging, such as in obesity, invasive monitoring of central venous pressure may be of value. If hypovolaemia is present, it should be corrected by prompt replacement of intravenous fluid or blood. When large volumes of fluid are required, balanced crystalloid solutions, such as Plasma-Lyte or Hartmann's, may be preferable to isotonic saline (0.9% NaCl) to avoid hyperchloraemic acidosis. If after 2 L of fluid resuscitation there has been no improvement in blood pressure and pulse rate, then reassess and consider investigating for occult blood loss or using inotropes, particularly if there is vasodilatation due to sepsis. Once the patient is volume replete, fluid intake should be matched to urine output plus 500 mL per day to cover insensible losses, unless additional losses are anticipated, such as with diarrhoea or high nasogastric aspirates. Excessive administration of fluid should be avoided, since this can provoke pulmonary oedema..

In patients with volume expansion, diuretics may be used, but in those with AKI, high doses may be required and they are not always effective. If pulmonary oedema (Fig. 18.21) is present and urine output cannot be rapidly restored, treatment with dialysis may be required to remove excess fluid.

Treatment of underlying cause

In pre-renal failure, rapid fluid resuscitation may be sufficient for resolution of AKI, which is manifest by an early increase in urine output and subsequent fall in serum creatinine. However, it is important to identify and manage underlying causes such as blood loss, sepsis and cardiac events.

In those with suspected ATN, volume status should be optimised, offending drugs should be discontinued, conditions such as sepsis, compartment syndrome or myeloma identified and treated. However, once ATN is established, even if the underlying cause has been corrected, regeneration of necrotic tubules and recovery of renal function may take days or even weeks and the patient may need support with RRT in the interim. In those with AKI due to rapidly progressive glomerulonephritis, the underlying cause should be treated and in interstitial nephritis potential drug causes should be identified and discontinued.

In post-renal AKI, the obstruction should be relieved as soon as possible. This may involve urinary catheterisation for bladder outflow obstruction, or relief of ureteric obstruction with ureteric stents or percutaneous nephrostomies.

Electrolyte and acid–base disturbances

Hyperkalaemia is common, particularly in patients with rhabdomyolysis, burns, haemolysis or metabolic acidosis, or in those taking medications that inhibit the RAAS. If serum K^+ concentration is > 6.5 mmol/L, an electrocardiogram (ECG) should be performed, and if there are changes consistent with hyperkalaemia, this should be treated immediately, as described in Box 19.17, to prevent life-threatening cardiac arrhythmias.

Severe acidosis can be ameliorated by treatment with sodium bicarbonate if the patient is not volume overloaded. This may also be helpful in lowering serum potassium.

Dilutional hyponatraemia may occur if the patient has continued to drink freely despite oliguria or has received inappropriate amounts of intravenous dextrose. This can be corrected by fluid restriction. Hyperphosphataemia and modest hypocalcaemia is common but rarely requires treatment in the acute setting.

Dietary measures

Adequate nutritional support including enteral or parenteral nutrition may be required to ensure sufficient calorie and protein intake, particularly in patients in catabolic states such as with sepsis and burns. Restriction of dietary potassium or administration of potassium binders that reduce potassium absorption from the gut may be required in hyperkalaemia.

Infection

Sepsis may either be the cause of AKI or a consequence of the depression of humoral and cellular immune mechanisms found in patients with AKI. Regular clinical examination, supplemented by microbiological investigation where appropriate, is required to diagnose infection. If infection is discovered, it should be treated promptly according to standard principles (see Ch. 7).

Medications

Patients with drug-induced AKI (see Box 18.42) should have the offending drug withdrawn. In patients with volume depletion and severe AKI, consider short-term cessation of NSAIDs and drugs that block the RAAS, as they may exacerbate the fall in GFR (see Fig. 18.20) and hyperkalaemia. However, in most circumstances diuretics and RAAS inhibitors should be restarted once the AKI resolves as they confer cardiovascular benefit. Other drug treatments should be reviewed and the doses adjusted, if necessary, to take account of reduced renal function (see p. 33). Non-essential drug treatments should be stopped.

Renal replacement therapy (RRT)

Conservative management can be successful in AKI with meticulous attention to fluid balance, electrolytes and nutrition, but RRT may be required in patients who are not showing signs of recovery with these measures (see Box 18.27). No specific cut-off values for serum urea or creatinine have been identified at which RRT should be commenced, and clinical trials of earlier *versus* later initiation of RRT have not shown differences in outcome in patients with AKI. Furthermore, RRT can be a risky intervention, since it requires the placement of central venous catheters that may become infected, and it may represent a major haemodynamic challenge in unstable patients. Accordingly, the decision to institute RRT should be made on an individual basis, taking account of the potential risks and benefits, comorbidity and an assessment of whether early or delayed recovery is likely. Severe uraemia with pericarditis and neurological signs (uraemic encephalopathy) are uncommon in AKI but, when present, are strong indications for RRT; other indications are given in Box 18.34. The two main options for RRT in AKI are intermittent haemodialysis and continuous renal replacement therapy (CRRT). Peritoneal dialysis is also an option if haemodialysis is not available (p. 637).

Recovery from AKI

Most cases of AKI will recover after the insult resolves, but this may be incomplete in those with pre-existing CKD or following a prolonged, severe or irreversible insult (Fig. 18.22). Recovery is heralded by a gradual return of urine output and a steady reduction in serum creatinine. During recovery from ATN or obstruction, there is often a diuretic phase which may reach several litres/day. This may, in part, be appropriate to excrete excess salt and water retained during AKI, but it may also be due to AVP resistance due to tubular injury. The urine output should be monitored and replaced with oral +/− intravenous fluids, or in patients with evidence of volume expansion, the aim should be to maintain them in negative balance of approximately 1 L/day to slowly achieve euvolaemia. In addition, it may be necessary to provide temporary supplementation of potassium and sometimes calcium, phosphate and magnesium.

Chronic kidney disease

Chronic kidney disease (CKD) refers to an irreversible deterioration in renal function that lasts at least 3 months and usually develops over a period of years (see Box 18.3). Initially, it manifests only as a biochemical abnormality, but eventually, loss of the excretory, metabolic and endocrine functions of the kidney lead to the clinical symptoms and signs of renal failure, collectively referred to as uraemia. When death is likely without RRT (CKD stage 5), it is called end-stage renal disease (ESRD).

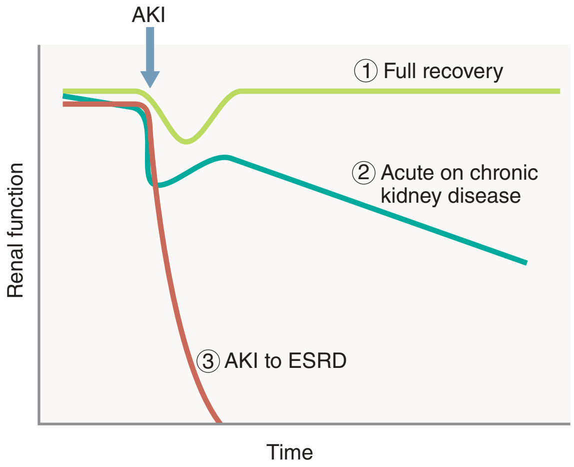

Fig. 18.22 Recovery from acute kidney injury (AKI). Many patients make a full recovery of renal function (1). If the insult is prolonged or prior renal function not normal, however, patients may develop progressive chronic kidney disease (2) or, rarely, irreversible, complete loss of renal function (3). (ESRD = end-stage renal disease)

Epidemiology

The social and economic consequences of CKD are considerable. In many countries, estimates of the prevalence of CKD stages 3–5 (eGFR <60 mL/min/1.73 m^2) are around 5%–7%, mostly affecting people aged 65 years and above (see Box 18.3). The prevalence of CKD in patients with hypertension, diabetes mellitus and vascular disease is substantially higher, and targeted screening for CKD with regular checks of eGFR and albuminuria should be considered in these and other high-risk groups. More than 25% of the population aged over 75 years have an eGFR of <60 mL/min/1.73 m^2, mostly stage 3A CKD (see Box 18.3). In these patients, CKD is often due to kidney injury from cardiovascular comorbidities; therefore, investigation and management should be focused on cardiovascular risk prevention, as very few will ever develop ESRD. However, many primary renal diseases are more common in older people, so investigation is warranted for those with declining renal function or with haematuria/proteinuria on dipstick.

Pathophysiology

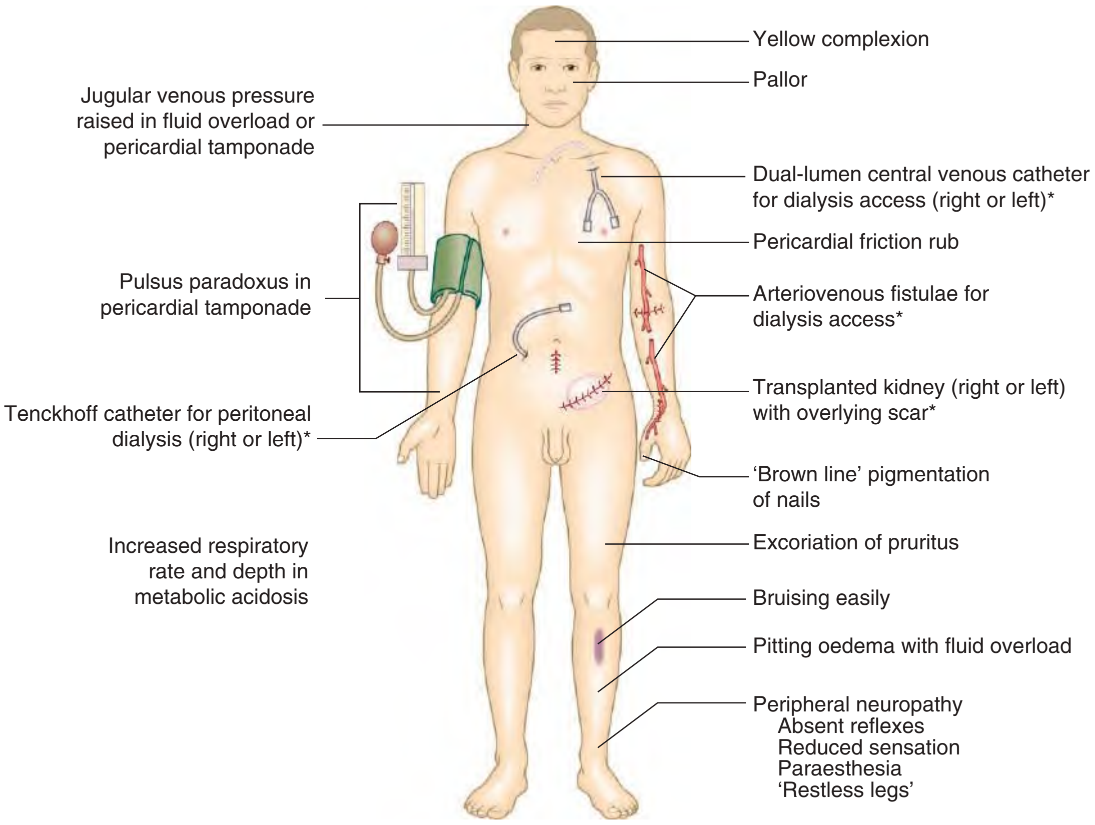
Common causes of CKD are shown in Box 18.28. In many cases the underlying diagnosis is unclear, especially among the large number of older patients with stage 3 CKD in whom the aetiology may be multifactorial. Many patients diagnosed at a late stage have bilateral small kidneys. Renal biopsy is rarely undertaken in this group since it is more risky, less likely to provide a histological diagnosis because of the severity of damage, and unlikely to alter management.

Clinical features

The typical presentation is for a reduced eGFR to be found incidentally during routine blood tests, often during screening of high-risk patients, such as those with diabetes mellitus or hypertension. Most patients with slowly progressive disease are asymptomatic until GFR falls below 30 mL/min/1.73 m^2. When GFR falls below 15–20 mL/min/1.73 m^2, symptoms and signs are common, but are often non-specific and may not immediately raise suspicion of kidney disease (Fig. 18.23). They typically include tiredness or breathlessness, which may be due to renal anaemia or fluid overload. With further deterioration in renal function, patients may suffer pruritus, anorexia, weight loss, nausea, vomiting and hiccups, at which point RRT should be considered, typically when eGFR approaches 10 mL/min/1.73 m^2. In very advanced renal failure, respiration may be particularly deep (Kussmaul breathing) due

i 18.28 Common causes of chronic kidney disease

Disease	Proportion	Comments
Diabetes mellitus	20%–45%	Large racial and geographical differences
Interstitial diseases	20%–30%	Drug-induced, reflux nephropathy, sarcoid/Sjögren syndrome
Glomerular diseases	10%–20%	IgA nephropathy is most common
Hypertension	5%–20%	Causality controversial, much may be secondary to another primary renal disease
Systemic inflammatory diseases	5%–10%	Systemic lupus erythematosus, vasculitis
Renovascular disease	5%	Mostly atheromatous
Congenital and inherited	10%	Polycystic kidney disease, Alport syndrome
Unknown	5%–10%	



Yellow complexion
Pallor
Jugular venous pressure raised in fluid overload or pericardial tamponade
Dual-lumen central venous catheter for dialysis access (right or left)*
Pericardial friction rub
Pulsus paradoxus in pericardial tamponade
Arteriovenous fistulae for dialysis access*
Transplanted kidney (right or left) with overlying scar*
Tenckhoff catheter for peritoneal dialysis (right or left)*
'Brown line' pigmentation of nails
Excoriation of pruritus
Increased respiratory rate and depth in metabolic acidosis
Bruising easily
Pitting oedema with fluid overload
Peripheral neuropathy
Absent reflexes
Reduced sensation
Paraesthesia
'Restless legs'

Fig. 18.23 **Physical signs in advanced chronic kidney disease.** (*Features of renal replacement therapy.)

18.29 Suggested investigations in chronic kidney disease

Initial tests	Interpretation
Creatinine, eGFR	To assess stability/progression: compare to previous results
Urinalysis and quantification of proteinuria	Haematuria and proteinuria may indicate glomerular disease and need for biopsy (p. 606). Proteinuria indicates risk of progressive CKD requiring preventive ACE inhibitor or ARB therapy
Electrolytes	To identify hyperkalaemia and acidosis
Calcium, phosphate, parathyroid hormone and 25(OH)D	Assessment of renal osteodystrophy
Albumin	Low albumin: consider malnutrition, inflammation, nephrotic syndrome
Full blood count (± Fe, ferritin, folate, B_{12})	If anaemic, exclude common non-renal explanations, then manage as renal anaemia
Lipids, glucose ± HbA_{1c}	Cardiovascular risk high in CKD: treat risk factors aggressively
Renal ultrasound	Consider with obstructive urinary symptoms, persistent haematuria, family history of polycystic kidney disease or progressive CKD. Small kidneys suggest chronicity. Asymmetric renal size suggests renovascular or congenital disease
Hepatitis and HIV serology	If dialysis or transplant is planned. Hepatitis B vaccination recommended if seronegative
Other tests	Consider relevant tests from Box 18.26, especially if the cause of CKD is unknown

(ACE = angiotensin-converting enzyme; ARB = angiotensin II receptor blocker; CKD = chronic kidney disease; HIV = human immunodeficiency virus; 25(OH)D = 25-hydroxyvitamin D)

to profound metabolic acidosis, and patients may develop muscular twitching, fits, drowsiness and coma.

Investigations

The recommended investigations in patients with CKD are shown in Box 18.29. Their main aims are:

- to exclude AKI requiring rapid investigation; in patients with unexpectedly high urea and creatinine (when there is an increase from previous results or no prior results are available), renal function should be retested within 2 weeks to avoid missing AKI
- to identify the underlying cause where possible, since this may influence the treatment
- to identify reversible factors that may worsen renal function, such as hypertension or urinary tract obstruction
- to screen for complications of CKD, such as anaemia and renal osteodystrophy
- to screen for cardiovascular risk factors.

Referral to a nephrologist is appropriate for patients with potentially treatable underlying disease and those who are likely to progress to ESRD. Suggested referral criteria are listed in Box 18.30.

Management

The aims of management in CKD are to:

- monitor renal function
- prevent or slow further renal damage
- limit complications of renal failure
- treat risk factors for cardiovascular disease
- prepare for RRT, if appropriate (p. 634).

In addition, patients should be given advice on lifestyle changes, including exercise, healthy diet with low salt intake, smoking cessation and weight loss as appropriate.

Monitoring of renal function

The rate of change in renal function varies between patients and may vary over time in each individual. Renal function should therefore be monitored every 6 months in patients with stage 3 CKD, but more frequently in patients who are deteriorating rapidly or have stage 4 or 5 CKD. A plot of GFR against time (Fig. 18.24) can demonstrate whether therapy has been successful in slowing progression, detect any unexpected increase in the rate of decline that may warrant further investigation and help predict when ESRD will be reached to facilitate timely planning for RRT.

18.30 Criteria for referral of chronic kidney disease patients to a nephrologist

- 5-year risk of needing renal replacement therapy > 5% (kidneyfailurerisk.co.uk)
- Rapid deterioration in renal function (> 25% from previous or > 15 mL/min/1.73 m^2/year)
- Significant proteinuria (PCR > 100 mg/mmol or ACR > 70 mg/mmol*), unless known to be due to diabetes and patient is already on appropriate medications
- ACR > 30 mg/mmol* with non-visible haematuria
- Hypertension that remains poorly controlled despite at least four antihypertensive medications
- Suspicion of renal involvement in multisystem disease

*See Box 18.11 for conversion of mg/mmol to mg/dL.
(ACR = albumin:creatinine ratio; eGFR = estimated glomerular filtration rate; PCR = protein:creatinine ratio)

Reduction of rate of progression

Slowing the rate of progression of CKD may reduce complications and delay symptom onset and the need for RRT (see Fig. 18.24). Therapies directed towards the primary cause of CKD should be employed where possible; tight blood pressure control is applicable to CKD regardless of cause, however, and reducing proteinuria is a key target in those with glomerular disease.

Antihypertensive therapy Lowering of blood pressure slows the rate at which renal function declines in CKD, independently of the agent used (apart from those with proteinuria; see below) and has additional benefits in lowering the risk of hypertensive heart failure and cardiovascular disease. No lower threshold for beneficial effects has been identified and any reduction of blood pressure appears to be beneficial. A target blood pressure of less than 140/90 mmHg is recommended for patients with CKD and low grade albuminuria (ACR < 70 mg/mmol; see Box 18.11 for conversion of mg/mmol to mg/dL). A lower target of 130/80 mmHg is recommended for those with diabetes or an ACR of more than 70 mg/mmol. Achieving these blood pressure targets often requires multiple drugs, and therapeutic success may be limited by adverse effects and poor adherence.

Reduction of proteinuria Patients with proteinuria are at higher risk of CKD progression, and there is strong evidence that reducing proteinuria reduces this risk. ACE inhibitors and ARBs reduce proteinuria and slow the progression of CKD. These effects are partly due to the reduction in blood pressure, but there is evidence for a specific beneficial effect in patients with proteinuria (PCR > 50 mg/mmol or ACR > 30 mg/mmol; see Box 18.11) through a reduction in glomerular perfusion pressure (see Fig. 18.20). In addition, ACE inhibitors have been shown to reduce the risk of cardiovascular events and all-cause mortality in patients with CKD. Accordingly, ACE inhibitors or ARBs should be prescribed to all patients with diabetic nephropathy and patients with CKD and proteinuria, irrespective of whether hypertension is present.

While ACE inhibitors and ARBs are excellent drugs for patients with diabetes mellitus or CKD and proteinuria, they need to be prescribed with care in certain circumstances. Initiation of treatment with ACE inhibitors and ARBs may be accompanied by an immediate reduction in GFR; therefore, patients should have their renal function checked within 7–10 days of

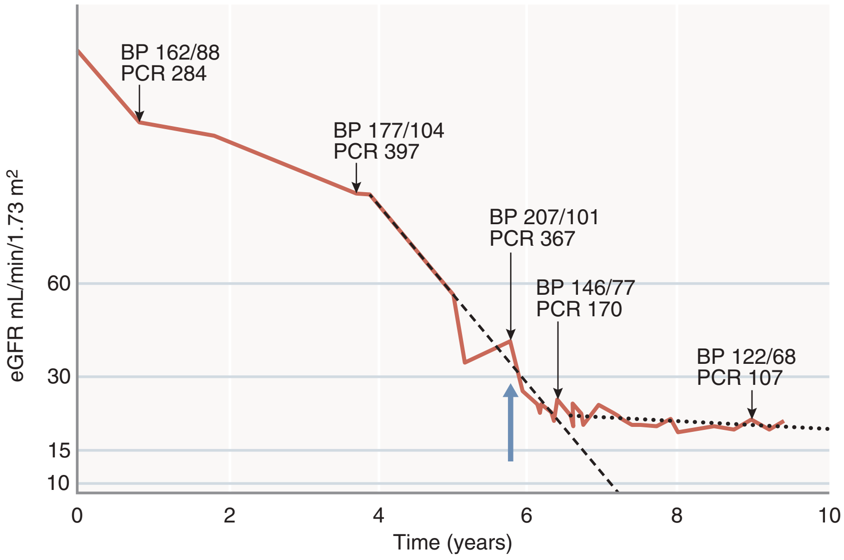


Fig. 18.24 Plot of estimated glomerular filtration rate (eGFR) against time in a patient with type 1 diabetes mellitus. After approximately 6 years of monitoring (blue arrow), this patient entered an aggressive treatment programme aimed at optimising blood pressure (BP) and glycaemic control. The reduction in BP was accompanied by a fall in proteinuria (protein:creatinine ratio, PCR; shown in mg/mmol). At the previous rate of decline in renal function (dashed line), he was likely to reach the level of renal function at which dialysis therapy is typically required (eGFR = 10 mL/min/1.73 m^2) within 18 months; however, the relative stabilisation in his renal function (dotted line) means that this has been deferred, potentially for several years.

18.31 Exemplar medicine sick-day card

When you are unwell with vomiting, diarrhoea or fever, stop taking the following medications:

- ACE inhibitors: medicines ending in '-pril', e.g. lisinopril, ramipril
- Angiotensin receptor blockers: medicines ending in '-sartan', e.g. irbesartan, losartan, candesartan
- Non-steroidal anti-inflammatory painkillers: e.g. ibuprofen (Brufen), diclofenac (Voltarol)
- Diuretics: e.g. furosemide, bendroflumethiazide, indapamide, spironolactone, sodium-glucose transporter inhibitors
- Metformin: a medicine for diabetes

Restart when you are well again (after 24–48 hours of eating and drinking normally).

initiating or increasing the dose of an ACE inhibitor or ARB. Treatment can be continued so long as the reduction in GFR is not greater than 25% and is not progressive. Angiotensin II is critical for autoregulation of GFR in the context of low renal perfusion (see Fig. 18.1D), and so ACE inhibitors or ARBs may exacerbate pre-renal failure (see Fig. 18.20). Patients on ACE inhibitors/ARBs should therefore be warned to stop taking the medication if they become unwell, such as with fever, vomiting or diarrhoea, restarting once they are better. This also applies to other common medications used in patients with CKD, such as diuretics, SGLT2 inhibitors, metformin and NSAIDs, and this advice may be reinforced by providing written information such as 'sick-day rule' cards (Box 18.31). ACE inhibitors and ARBs increase serum potassium and should not be commenced in patients with baseline potassium > 5.5 mmol/L. In patients with serum potassium > 6.0 mmol/L, the dose of ACE inhibitors or ARBs should be reduced or discontinued entirely, but only after all other measures to reduce potassium have been considered (see below). Combination therapy with ACE inhibitors and ARBs or direct renin inhibitors has not been shown to reduce progression of CKD but is associated with higher rates of hyperkalaemia and AKI, and is therefore to be avoided.

Sodium-glucose transporter-2 (SGLT2) inhibitors SGLT2 is a sodium-glucose co-transporter present in the proximal tubule of the kidney. SGLT2 inhibitors were initially developed to promote glycosuria and improve blood glucose control in patients with diabetes mellitus and are effective in slowing progression of diabetic nephropathy. They have now been shown to be equally effective at reducing GFR decline and cardiovascular mortality in non-diabetic CKD in. Hence, it appears that the beneficial effect is largely independent of their effect on blood glucose and may be partly due to natriuresis and modest blood pressure lowering and by reducing intra-glomerular pressure and proteinuria. Indeed, like ACE inhibitors and angiotensin receptor blockers, there is an initial fall in eGFR in the first 4 weeks after starting an SGLT2 inhibitor, but this is not concerning as there is a much slower rate of decline in renal function thereafter. They may have additional beneficial effects such as promoting weight loss and modest increases in urinary potassium and urate excretion. Hence, patients with CKD should be treated with SGLT2 inhibitors to slow disease progression and reduce the risk of heart failure and cardiovascular mortality.

Treatment of complications

The kidneys have many functions in addition to excretion of waste (p. 600). Treatments that substitute for all of the normal roles of the kidneys must therefore be instigated to maintain normal body homeostasis and prevent complications.

Maintenance of fluid and electrolyte balance The kidneys excrete waste and regulate many electrolytes, and so patients with CKD may accumulate waste products and develop electrolyte abnormalities.

Urea is a key product of protein degradation and accumulates with progressive CKD. All patients with stages 4 and 5 CKD should be given dietetic advice aimed at preventing excessive consumption of protein. Severe protein restriction is not recommended, as there is no evidence that this reduces the rate of decline in renal function but may lead to malnutrition.

18.32 Foods high in potassium

- Fruit: bananas, avocados, figs, rhubarb
- Vegetables: tomatoes, spinach, parsnips, courgettes, sprouts, potatoes (including baked, fries, wedges; boiling vegetables reduces potassium content)
- Sweets/snacks: crisps, chocolate, toffee, nuts (including peanut butter)
- Drinks: beer, cider, wine (spirits contain less potassium), hot chocolate, fruit juice, milk, yoghurt
- Some salt substitutes, such as Lo-Salt: sodium chloride is substituted with potassium chloride

Potassium often accumulates in patients with advanced CKD, who should be provided with dietary advice to reduce daily potassium intake to below 70 mmol (Box 18.32). While ACE inhibitors/ARBs increase serum potassium concentration, they are highly effective in slowing CKD progression and reducing cardiovascular disease in patients with proteinuric CKD; therefore, they should only be reduced or stopped if serum potassium exceeds 6 mmol/L despite instigation of all other potassium-lowering measures. Potassium-binding medications such as sodium zirconium or patiromer limit absorption of potassium from the gut and may be a useful adjunctive therapy to enable ACE inhibitors or ARBs to be continued. Other measures that may help regulate potassium include loop or thiazide diuretics and control of acidosis with sodium bicarbonate.

The inability of the failing kidneys to excrete sodium and water commonly leads to their accumulation, which may drive hypertension, particularly in younger patients, and manifest as oedema. Patients with evidence of volume expansion should be instructed to consume a low-sodium diet (< 100 mmol/24 h), and in severe cases fluid intake should also be restricted. Diuretics are commonly required, and as renal function deteriorates, increasing doses of potent loop diuretics or synergistic combinations of loop, thiazide and potassium-sparing diuretics and SGLT2 inhibitors may be necessary.

Occasionally, some patients with tubulo-interstitial disease can develop 'salt-wasting' disease and may require a high sodium and water intake, including supplements of sodium salts, to prevent fluid depletion and worsening of renal function.

Acid–base balance Reduced ability to excrete organic acids in patients with CKD may lead to an anion-gap metabolic acidosis. In addition, in patients with tubulo-interstitial disease or diabetic nephropathy, there may be specific defects in acid–base regulation within the kidney, causing a non-anion-gap renal tubular acidosis (p. 673). Although acidosis is usually asymptomatic, it may be associated with increased tissue catabolism and decreased protein synthesis and may exacerbate bone disease and the rate of decline in renal function. Hence, plasma bicarbonate concentrations should be maintained above 22 mmol/L by prescribing sodium bicarbonate supplements. This may also reduce serum potassium levels, and there is some evidence that correcting acidosis may reduce the rate of decline in renal function.

Renal bone disease Disturbances of calcium and phosphate metabolism are almost universal in advanced CKD (Fig. 18.25). The sequence of events that leads to renal bone disease is complex, but two primary factors are: impaired excretion of phosphate and failure of the renal tubular cells to convert 25-hydroxyvitamin D to its active metabolite 1,25-dihydroxyvitamin D. A rise in serum phosphate concentration promotes production of the hormone fibroblast growth factor 23 (FGF23) from osteocytes (see Fig. 25.2) and stimulates parathyroid hormone (PTH) release and hyperplasia of the parathyroid glands. The FGF23 and PTH promote tubular phosphate excretion, thereby partly compensating for the reduced glomerular filtration of phosphate. The reduced 1,25-dihydroxyvitamin D level also stimulates PTH release and reduces intestinal absorption of calcium.

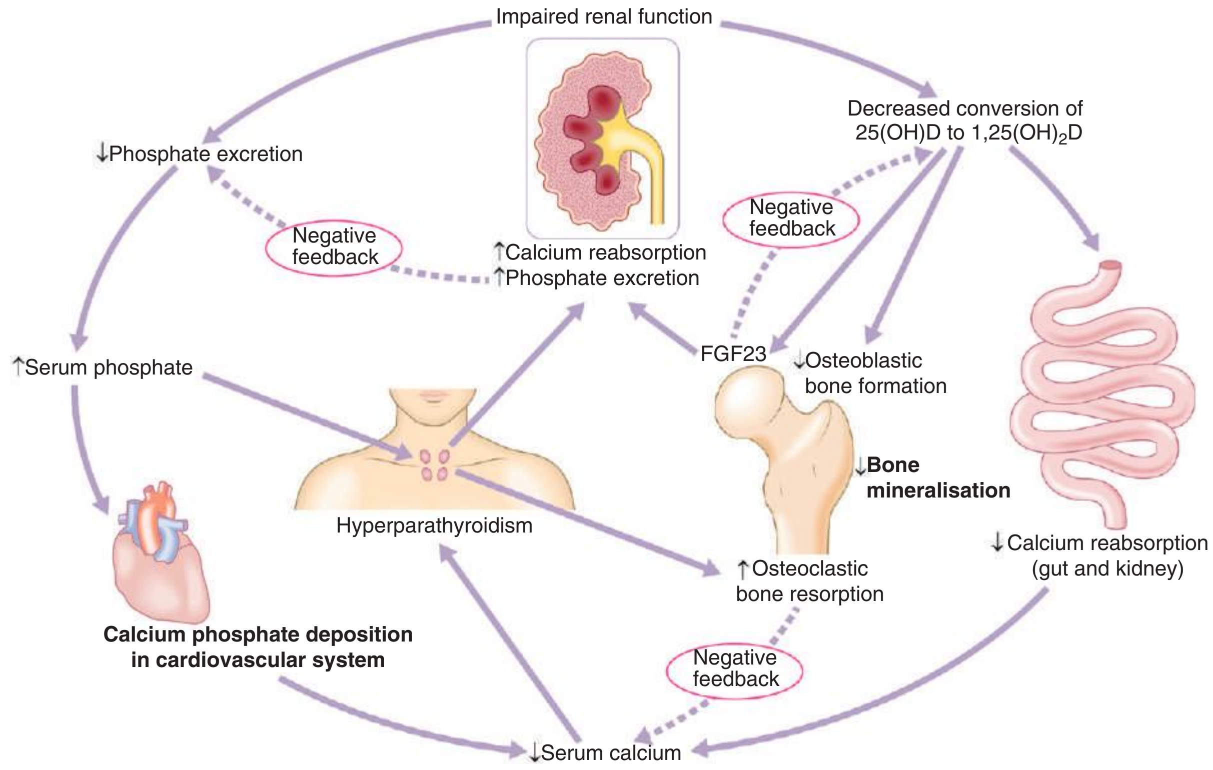

Fig. 18.25 Pathogenesis of renal osteodystrophy. Impaired renal clearance of phosphate promotes elevated serum phosphate, which binds to calcium, lowering the serum calcium and leading to calcium phosphate deposition in tissues including the cardiovascular system. Low 1,25-dihydroxyvitamin D (1,25(OH)$_2$D) levels reduce calcium absorption from gut and kidney, exacerbating hypocalcaemia. Low serum calcium and 1,25(OH)$_2$D levels (arrow not shown in figure for ease of reading) and high phosphate stimulate release of parathyroid hormone (PTH), which increases osteoclastic bone resorption, contributing to renal osteodystrophy. The elevated PTH and production of fibroblast growth factor 23 (FGF23) from osteocytes promotes phosphate excretion; however, this is insufficient to prevent hyperphosphataemia in advanced chronic kidney disease.

In addition, raised levels of serum phosphate complex with calcium in the extracellular space, leading to calcium phosphate deposition in tissues including the cardiovascular system. The combination of reduced absorption and increased deposition of calcium promotes hypocalcaemia, which also stimulates PTH production by the parathyroid glands. Hence, in many patients with CKD, compensatory responses initially maintain phosphate and calcium levels at the upper and lower ends of their respective normal ranges, at the expense of an elevated PTH level (secondary hyperparathyroidism). This is associated with bone resorption (osteitis fibrosa cystica), and in severe cases this may result in bony pain and increased risk of fractures. Conversely, there is increased deposition of calcium phosphate in many tissues, most notably blood vessels and heart valves, which may contribute to the increased risk of cardiovascular disease in patients with CKD (see below). In some cases, tertiary hyperparathyroidism supervenes, due to autonomous production of PTH by the enlarged parathyroid glands; this presents with hypercalcaemia. Additional bone metabolism disorders in CKD include low bone turnover (adynamic bone disease) in patients who have been over-treated with vitamin D metabolites and osteoporosis in patients with poor nutritional intake.

The key focus in the management of renal bone disease should be directed towards the two main driving factors, hyperphosphataemia and inadequate activation of vitamin D. Hyperphosphataemia should be treated by dietary restriction of foods with high phosphate content (milk, cheese, eggs and protein-rich foods) and by the use of phosphate-binding drugs that inhibit phosphate reabsorption in the gut. Various drugs are available, including calcium carbonate or acetate, polymer-based phosphate binders such as sevelamer, or lanthanum carbonate, all of which should be taken with meals. The aim is to avoid very high levels of phosphate (> 1.7 mmol/L), but adherence can be a problem. Active vitamin D metabolites (either 1-α-hydroxyvitamin D or 1,25-dihydroxyvitamin D) should be administered in patients who are hypocalcaemic or have severe and progressive hyperparathyroidism, which typically occurs in stage 5 CKD. However, care must be exercised in order to avoid hypercalcaemia and aggravating calcium-phosphate deposition in cardiovascular tissues. In patients with persistent hypercalcaemia (tertiary hyperparathyroidism), parathyroidectomy may be required. If parathyroidectomy is unsuccessful or not possible, calcimimetic agents, such as cinacalcet, may be used. These bind to the calcium-sensing receptor in the parathyroid glands and reduce PTH secretion.

Anaemia Anaemia, due to deficiency in production of erythropoietin, is common in patients with CKD and contributes to many of the non-specific symptoms, including fatigue and shortness of breath. The anaemia is typically normochromic, normocytic and the presence of micro-/macrocytosis, leucopenia or thrombocytopenia should prompt investigation for other causes, such as haematinic deficiencies or marrow failure. Haemoglobin concentration below 100 g/L is uncommon until eGFR falls below 30 mL/min/1.73 m^2, and anaemia disproportionate to the severity of CKD should also prompt investigation for other causes. Iron deficiency is common in patients with CKD, and even more prevalent in those on haemodialysis as a result of haemolysis in the dialysis circuit. Hence, many patients require iron supplements, which may be given intravenously for those with iron intolerance or in those on haemodialysis. Once iron deficiency and other causes of anaemia have been excluded or corrected, recombinant human erythropoietin is very effective in correcting the anaemia of CKD and improving symptoms. However, correcting haemoglobin to normal levels confers higher risk of hypertension and thrombosis; therefore, the target haemoglobin is usually between 100 and 120 g/L. Erythropoietin is less effective in the presence of iron deficiency, active inflammation or malignancy, in particular myeloma.

Treatment of risk factors for cardiovascular disease

The risk of cardiovascular disease is substantially increased in patients with a GFR below 60 mL/min/1.73 m^2 and in those with albuminuria, the combination of reduced eGFR and albuminuria being particularly unfavourable (see Fig. 18.3). Patients with CKD have a higher prevalence of traditional risk factors for atherosclerosis, such as hypertension, hyperlipidaemia and diabetes mellitus; however, additional mechanisms of cardiovascular disease may also be implicated. Left ventricular hypertrophy is commonly found in patients with CKD, secondary to hypertension or anaemia. Calcification of the media of blood vessels, heart valves, myocardium and the conduction system of the heart is also common and may be due, in part, to the high serum phosphate levels. Reflecting this fact, serum FGF23 levels, which increase in response to serum phosphate, are an independent predictor of mortality in CKD. Both left ventricular hypertrophy and cardiac calcification may increase the risk of arrhythmias and sudden cardiac death, which is a much more common mode of death in patients with CKD than in the general population, particularly in those with more advanced disease and those on dialysis.

To reduce vascular risk, patients with CKD should be encouraged to adopt a healthy lifestyle, including regular exercise, weight loss and smoking cessation where appropriate. Lipid-lowering drugs reduce cardiovascular events in patients with CKD, although their efficacy may be lower once patients require dialysis.

Preparing for renal replacement therapy

It is crucial that patients who are known to have progressive CKD are prepared well in advance for the institution of RRT. They should be referred to a nephrologist in a timely manner, as those who are referred late, when they are very close to requiring dialysis, tend to have poorer outcomes. Since there is no evidence that early initiation of RRT improves outcome, the overall aim is to commence RRT when symptoms of CKD begin to impact on quality of life but before serious complications have occurred. While there is wide variation between patients, this typically occurs when the eGFR approaches 10 mL/min/1.73 m^2. This may be a useful marker to predict the timing of initiation of RRT by extrapolating from a plot of serial eGFR measurements over time (see Fig. 18.24). Preparations for starting RRT should begin at least 12 months before the predicted start date. Several decisions need to be taken in discussion with the patient and family. The first is to decide whether RRT is an appropriate choice or whether conservative treatment might be preferable (see the next section). This is especially relevant in patients with significant comorbidity. For those who decide to go ahead with RRT, there are further choices between haemodialysis and peritoneal dialysis (Box 18.33), between hospital and home treatment, and on referral for renal transplantation.

The patient should be able to access psychological and social support, including an assessment of home circumstances (Fig. 18.26). Depression is common in patients who are on or approaching RRT, and support from the renal multidisciplinary team should be provided both for them and for their relatives, to explain and help them adapt to the changes to lifestyle that may be necessary once RRT starts; this may help to reduce their anxieties about these changes. Physical preparations include establishment of timely vascular access for haemodialysis or peritoneal catheter insertion and vaccination against hepatitis B.

Renal replacement therapy

Renal replacement therapy (RRT) may be required on a temporary basis in patients with AKI or on a permanent basis for those with advanced CKD. Since the advent of long-term RRT in the 1960s, the number of patients with ESRD who are kept alive by dialysis and transplantation has increased considerably. By the end of 2022, more than 70000 patients were on RRT in the UK, with a median age of 60 years. After a long period of expansion, the number of patients on dialysis in the UK and the United States has begun to stabilise; however, the total number of patients on RRT continues to expand, due to an increasing proportion (56%) of patients with a functional transplant. The remaining patients were on haemodialysis (39%) and peritoneal dialysis (5%).

i 18.33 Comparison of haemodialysis and peritoneal dialysis

Haemodialysis	Peritoneal dialysis
Efficient; 4 hrs three times per week is usually adequate	Less efficient; four exchanges per day are usually required, each taking 30–60 mins (continuous ambulatory peritoneal dialysis) or 8–10 hrs each night (automated peritoneal dialysis)
2–3 days between treatments	A few hours between treatments
Requires visits to hospital (although home treatment is possible with adaptations for some patients)	Performed at home
Requires adequate vascular access	Requires an intact peritoneal cavity without major scarring from previous surgery
Careful adherence to diet and fluid restrictions required between treatments	Diet and fluid less restricted
Fluid removal compressed into treatment periods; may cause symptoms and haemodynamic instability	Slow continuous fluid removal, usually asymptomatic
Infections related to vascular access may occur	Peritonitis and catheter-related infections may occur
Patients are usually dependent on others	Patients can take full responsibility for their treatment

There are variations in the number of patients receiving RRT in different countries because of differences in the incidence of predisposing disease, as well as differences in medical practice. For example, the incidence rate for RRT in the United States in 2021 was three times higher than in the UK (410 versus 123 patients per million population), with countries such as Mexico and Taiwan having even higher rates than the US. Diabetic kidney disease is the most common cause of ESRD in many countries, accounting for 30% of all new cases of ESRD in the UK and 45% in the United States. The large increase in the prevalence of type 2 diabetes mellitus in developing countries is resulting in a predictable rise in cases of ESRD, which is challenging already stretched health-care resources.

Survival on dialysis is strongly influenced by age and presence of complications such as diabetes (Fig. 18.27). For this reason, conservative care rather than RRT may be a more appropriate option for older patients or those with extensive comorbidities. Although many young patients without extrarenal disease lead normal and active lives on RRT, those aged 30–34 have a mortality rate 25 times higher than that of age-matched controls.

The aim of RRT is to replace the excretory functions of the kidney and to maintain normal electrolyte concentrations and fluid balance. Various options are available, including haemodialysis, haemofiltration, haemodiafiltration, peritoneal dialysis and renal transplantation, and each of these is discussed in more detail below. Indications for starting RRT in both AKI and CKD may be found in Box 18.34.

Conservative treatment

In patients with multiple comorbidities, conservative treatment of stage 5 CKD, aimed at limiting the adverse symptoms of ESRD without commencing RRT, is increasingly viewed as a positive choice (Box 18.35). Current evidence suggests that survival of these patients without dialysis can be similar or only slightly shorter than that of patients who undergo RRT, but they avoid the hospitalisation and interventions associated with dialysis. Patients are offered full medical, psychological and social support to optimise and sustain their existing renal function and to treat complications, such as anaemia, for as long as possible, with appropriate palliative care in the terminal phase of their disease. Many of these patients enjoy a good quality of life for several months to years even with eGFR <10 mL/min/1.73 m^2. When quality of life on dialysis is poor, it is

Fig. 18.26 Options for renal replacement therapy. **A** In haemodialysis, there is diffusion of solutes from blood to dialysate across a semipermeable membrane down a concentration gradient. **B** In haemofiltration, both water and solutes are filtered across a porous semipermeable membrane by a pressure gradient. Replacement fluid is added to the filtered blood before it is returned to the patient. **C** In peritoneal dialysis (PD), fluid is introduced into the abdominal cavity using a catheter. Solutes diffuse from blood across the peritoneal membrane to PD fluid down a concentration gradient, and water diffuses through osmosis (see text for details). **D** In transplantation, the blood supply of the transplanted kidney is generally anastomosed to the external iliac vessels and the ureter to the bladder. The transplanted kidney replaces all functions of the failed kidney.

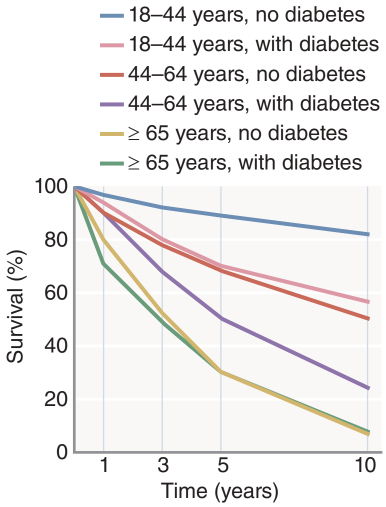

Fig. 18.27 Percentage survival after commencing renal replacement therapy according to age group and presence of diabetes.

appropriate to discuss discontinuation of dialysis with the patient and family and to offer palliative care.

Haemodialysis

Haemodialysis is the most common form of dialysis employed in ESRD and is also used in AKI. Haemodialysis involves gaining access to the circulation, either through a dual lumen central venous catheter or an arteriovenous fistula or graft. The patient's blood is pumped through a haemodialyser, which allows bidirectional diffusion of solutes between blood and the dialysate across a semipermeable membrane down a concentration gradient (see Fig. 18.26A). The composition of the dialysate can be varied to achieve the desired solute gradient, and fluid can be removed by applying negative pressure to the dialysate side.

Haemodialysis in AKI

Haemodialysis offers the best rate of small-solute clearance in AKI, compared with other techniques such as haemofiltration, but should be started gradually because of the risk of delirium and convulsions due to cerebral oedema (dialysis disequilibrium). Typically, 1–2 hours of dialysis are prescribed initially, but subsequently patients with AKI who are

18.34 Indications for dialysis with examples for AKI and CKD

Indication*	Acute examples	Chronic examples
Uraemia	Pericarditis Encephalopathy	Uraemic syndrome including anorexia, nausea, lethargy (generally not seen until eGFR < 10 mL/min/1.73 m^2)
Fluid overload	Acute pulmonary oedema	Intractable dependent oedema resistant to diuretics Pulmonary oedema Severe hypertension
Hyperkalaemia	High potassium (generally > 6.5 mmol/L) with ECG changes (especially broad QRS)	Potassium resistant to dietary control and medical intervention
Metabolic acidosis	Severe acidosis (H^+ > 79 nmol/L; pH < 7.1)	Chronic acidosis resistant to bicarbonate therapy
Other (often relative indications)	Bleeding diathesis considered due to uraemia-induced platelet dysfunction	Intractable anaemia despite erythropoietin and iron Hyperphosphataemia despite binders

*The presence of anuria in AKI will modify the above indications, as these complications will not resolve if the patient is persistently anuric. Most indications to commence chronic dialysis are relative indications; a holistic approach is taken to making this decision.
(AKI = acute kidney injury; CKD = chronic kidney disease; ECG = electrocardiogram; eGFR = estimated glomerular filtration rate)

18.35 Renal replacement therapy in old age

- **Quality of life**: age itself is not a barrier to good quality of life on RRT.
- **Coexisting cardiovascular disease**: older people are more sensitive to fluid balance changes, predisposing to hypotension during dialysis and pulmonary oedema prior to the next dialysis session.
- **Confusion**: sudden changes in serum electrolyte composition during dialysis may exacerbate confusion in patients with early dementia.
- **Provision of treatment**: peritoneal dialysis may avoid the problems due to sudden changes in fluid and electrolyte status; however, older patients often require assistance with performing peritoneal dialysis, typically assistance setting up fluids and connecting/disconnecting to automated peritoneal dialysis.
- **Survival on dialysis**: difficult to predict for an individual patient, but old age plus substantial comorbidity are associated with poor survival. In such patients, similar survival may be achieved through conservative care, without the complications associated with dialysis.
- **Withdrawal from dialysis**: may be appropriate whenever quality of life deteriorates irreversibly, usually in the context of severe comorbidity.
- **Transplantation**: relative risks of surgery and immunosuppression exclude many older people from transplantation.
- **Conservative therapy**: without dialysis but with adequate support. This is an appropriate option for patients at high risk of complications from dialysis who have a limited prognosis.

haemodynamically stable can be treated by 4–5 hours of haemodialysis on alternate days, or 2–3 hours every day. During dialysis, it is standard practice to anticoagulate patients, typically using heparin, but the dose may be reduced if there is a bleeding risk. In patients undergoing short treatments and in those with abnormal clotting, it may be possible to avoid anticoagulation altogether. In AKI, dialysis is performed through a large-bore, dual-lumen catheter inserted into the femoral or internal jugular vein (Fig. 18.28A).

Haemodialysis in ESRD

In ESRD, vascular access for haemodialysis is gained by formation of an arteriovenous fistula (AVF), usually in the forearm, up to a year before dialysis is contemplated (Fig. 18.28B). After 4–6 weeks, increased pressure transmitted from the artery causes distension and thickening of the wall of the vein leading from the fistula (arterialisation). Two large-bore needles can then be inserted into the vein to provide access for each haemodialysis treatment.

In patients with progressive renal disease who may require haemodialysis in the future, it is important to avoid venepuncture in order to preserve the integrity of arm veins. If creation of an AVF is not possible, synthetic polytetrafluoroethylene (PTFE) grafts may be fashioned between an artery and a vein, or central venous catheters may be used for short-term access (Fig. 18.28C). These are tunnelled under the skin to reduce infection risk.

All patients starting dialysis must be screened in advance for hepatitis B, hepatitis C and HIV, and vaccinated against hepatitis B if they are not immune. All dialysis units should have segregation facilities for hepatitis B-positive patients, given its easy transmissibility. Patients with hepatitis C and HIV are less infectious and can be treated satisfactorily using machine segregation and standard infection control measures.

Haemodialysis is usually carried out for 3–5 hours three times weekly, either at home or in an outpatient dialysis unit. The intensity and frequency of dialysis should be adjusted to achieve a reduction in urea during dialysis (urea reduction ratio) of over 65%; below this level there is an increase in mortality. Most patients notice an improvement in symptoms during the first 6 weeks of treatment. The intensity of dialysis can be increased by:

- escalating the number of standard sessions to four or more per week
- performing short, frequent dialysis sessions of 2–3 hours 5–7 times per week
- performing nocturnal haemodialysis, when low blood-pump speeds are used for approximately 8 hours overnight 5–6 times per week
- including a filtration component (haemodiafiltration) to achieve greater clearance of larger molecules.

More frequent dialysis and nocturnal dialysis can achieve better fluid balance and phosphate control, improve left ventricular mass and possibly improve mortality, although the latter has not yet been robustly demonstrated. Box 18.36 summarises some of the problems related to haemodialysis.

Haemofiltration

Haemofiltration is employed continuously for long periods daily using a dual-lumen intravenous catheter and is hence termed continuous venovenous haemofiltration (CVVH). This technique is principally used in the treatment of AKI in patients who are haemodynamically unstable and who therefore may not tolerate the rapid fluid and electrolyte changes associated with intermittent haemodialysis. Large volumes of water are filtered from blood across a porous semipermeable membrane under a pressure gradient. Solutes are removed via ‘solvent drag’ rather than by diffusion; therefore, this method is less efficient at clearing urea and potassium than haemodialysis. Replacement fluid of a suitable electrolyte composition is added to the blood after it exits the haemofilter. If removal of fluid is required, then less fluid is added back than is removed (see Fig. 18.26B). Typically, 1–2 L of filtrate is replaced per hour (equivalent to a GFR of 15–30 mL/min/1.73 m^2); higher rates

of filtration may be of benefit in patients with sepsis and multi-organ failure. Issues concerning anticoagulation are similar to those for haemodialysis but may be more problematic because longer or continuous anticoagulation is necessary.

Haemodiafiltration combines haemodialysis with approximately 20–30 L of ultrafiltration (with replacement of filtrate) over a 3- to 5-hour treatment. It uses a large-pore membrane and combines the improved clearance of medium-sized molecules observed in haemofiltration with the higher small-solute clearance of haemodialysis. It is sometimes used in the treatment of AKI, often as continuous therapy. Haemodiafiltration is increasingly employed in patients on chronic dialysis, and there is evidence that it may reduce mortality compared with haemodialysis.

Peritoneal dialysis

Peritoneal dialysis is principally used in the treatment of CKD, though it may occasionally be employed in AKI. It requires the insertion of a permanent Silastic catheter into the peritoneal cavity (see Fig. 18.26C). Two types are in common use. In continuous ambulatory peritoneal dialysis (CAPD), about 2 L of sterile dialysis fluid are introduced and left in place for approximately 4–6 hours. Metabolic waste products diffuse from peritoneal capillaries into the dialysis fluid down a concentration gradient. The fluid is then drained and fresh dialysis fluid introduced, in a continuous four-times-daily cycle. The inflow fluid is rendered hyperosmolar by the addition of glucose or glucose polymer; this results in net removal of fluid from the patient during each cycle, due to diffusion of water from the blood through the peritoneal membrane down an osmotic gradient (ultrafiltration). The patient is mobile and able to undertake normal daily activities. Automated peritoneal dialysis (APD) is similar to CAPD but uses a machine to perform the fluid exchanges during the night, typically leaving some fluid in the peritoneum during the day for ongoing dialysis.

CAPD is particularly useful in children, as a first treatment in adults with some residual renal function, and as a treatment for older patients with cardiovascular instability. The long-term use of peritoneal dialysis may be limited by episodes of bacterial peritonitis and damage to the peritoneal membrane, including encapsulating peritoneal sclerosis, but some patients have been treated successfully for more than 10 years. Box 18.37 summarises some of the problems related to CAPD treatment.

Renal transplantation

Renal transplantation offers the best chance of long-term survival in ESRD and is the most cost-effective treatment. All patients with ESRD should be considered for transplantation, but many are not suitable due to a combination of comorbidity and advanced age (although no absolute age limit applies). Active vasculitis, malignancy and cardiovascular comorbidity are common contraindications to transplantation, with risk of recurrence of the original renal disease (generally glomerulonephritides) being a less common problem.

Optimal transplant outcomes are generally from living donors. Deceased donors are traditionally retrieved after brain death but increasingly may come from donors after circulatory death, when there is a higher risk of delayed allograft function but long-term outcomes are equivalent.

As described in the section on transplantation and graft rejection in Chapter 4, matching of a donor to a specific recipient is strongly influenced by immunological factors, since allograft rejection is the major cause of transplant failure. Compatibility of ABO blood group between donor and recipient is usually required and the degree of matching for major histocompatibility (MHC) antigens, particularly human leucocyte antigens (HLA) A, B and DR, influences the incidence of rejection. Immediately prior to transplantation, cross-matching should be performed for anti-HLA antibodies (traditionally by mixing of recipient serum with donor lymphocytes but increasingly 'virtual', where recipient serum is mixed with commercial beads coated with HLA antigens) (Ch. 4). Positive tests predict early rejection and worse graft survival. Although some ABO- and HLA-incompatible transplants are possible, this involves appropriate preparation with pre-transplant plasma exchange and/or immunosuppression, so that recipient antibodies to the donor's tissue are reduced to acceptably low levels. This option is generally only available for live donor transplants because of the preparation required. A new IgG cleaving drug, imlifidase, can destroy pre-formed HLA antibodies over a few hours and hence may enable transplantation in very select high-risk patients. Paired exchanges, in which a donor–recipient pair who are incompatible, either due to blood group or anti-HLA antibodies, are computer-matched with another pair to overcome the mismatch, are also used to increase the number of successful transplants that can be performed.

During the transplant operation, the kidney is placed in the pelvis; the donor vessels are usually anastomosed to the recipient's external iliac artery and vein, and the donor ureter to the bladder (see Fig. 18.26D).

18.36 Problems with haemodialysis

Problem	Clinical features	Cause	Treatment
During treatments			
Hypotension	Sudden ↓BP; often leg cramps; sometimes chest pain	Fluid removal and hypovolaemia, particularly with cardiac disease	Pause fluid removal; saline infusion; exclude cardiac ischaemia
Cardiac arrhythmias	Hypotension; sometimes chest pain	Potassium and acid–base shifts	Check K^+; review dialysis prescription; stop dialysis
Haemorrhage	Blood loss (overt or occult); hypotension	Anticoagulation Venous needle disconnection	Stop dialysis; seek source; consider heparin-free treatment
Air embolism	Circulatory collapse; cardiac arrest	Disconnected or faulty lines and equipment malfunction	Stop dialysis
Dialyser hypersensitivity	Acute circulatory collapse	Allergic reaction to dialysis membrane or sterilisant	Stop dialysis; change to different artificial kidney
Sepsis	Rigors; fever; ↓BP	Usually involves infected vascular catheter	Blood cultures; antibiotics
Between treatments			
Pulmonary oedema	Breathlessness	Fluid overload	Ultrafiltration, fluid restriction, lower dry weight

(BP = blood pressure)

18.37 Problems with continuous ambulatory peritoneal dialysis

Problem	Clinical features	Cause	Treatment
Peritonitis	Cloudy drainage fluid; abdominal pain and systemic sepsis are variable	Usually entry of skin contaminants via catheter; bowel organisms less common	Culture of peritoneal dialysis fluid Intraperitoneal antibiotics Catheter removal sometimes required
Catheter exit site infection	Erythema and pus around exit site	Usually skin organisms	Antibiotics; sometimes surgical drainage
Peritoneal membrane leaks	Fluid leak from tunnel or pleural effusion (typically unilateral and right-sided)	Leak adjacent to catheter or via congenital pleuroperitoneal communication	Temporary reduction in volume of dialysis fluid. However, pleuroperitoneal leaks are likely to require switch to haemodialysis
Ultrafiltration failure	Fluid overload	Damage to peritoneal membrane, leading to rapid transport of glucose and loss of osmotic gradient	Replacement of glucose with synthetic, poorly absorbed polymers for some exchanges (icodextrin)
Peritoneal membrane failure	Inadequate clearance of urea etc.	Scarring/damage to peritoneal membrane	Increase in exchange volumes; consideration of automated peritoneal dialysis or switch to haemodialysis
Sclerosing peritonitis	Intermittent bowel obstruction Malnutrition	Unknown; typically occurs after many years on peritoneal dialysis	Switch to haemodialysis (may still progress) Surgery and tamoxifen may be used

The native kidneys are typically left in place but may be removed pre-transplant if they are a source of repeated sepsis or to make room for a transplant kidney in patients with very large kidneys due to ADPKD.

All transplant patients require regular life-long follow-up to monitor renal function, complications of immunosuppression and cardiovascular risk. Allograft dysfunction is often asymptomatic and picked up during routine surveillance blood tests. The common causes at different time points post transplant are summarised in Box 18.38. Immunosuppressive therapy (Box 18.39) is required to prevent rejection and is more intensive in the early post-transplantation period, when rejection risk is highest. A common regimen is triple therapy with prednisolone; ciclosporin or tacrolimus; and azathioprine or mycophenolate mofetil. Sirolimus is an alternative that can be introduced later but is generally not used initially due to impaired wound healing. Basiliximab, an interleukin (IL)-2 receptor antagonist, is frequently used at induction to lower rates of rejection. Anti-lymphocyte preparations (e.g. anti-thymocyte globulin, ATG) may also be used as induction, especially in transplants at higher immunological risk.

Acute rejection may be cellular (T cell–mediated) or humoral (antibody-mediated, 'vascular') (see Box 4.21). Acute cellular rejection is common (10%–20%) in the first 1–3 months and treated, in the first instance, by high-dose intravenous glucocorticoids. ATG is used for glucocorticoid-resistant, or more severe, cellular rejection. Antibody-mediated rejection, usually due to donor-specific anti-HLA antibodies, is more difficult to treat and usually requires plasma exchange and intravenous immunoglobulin (Ch. 4). Complications of immunosuppression include infections and malignancy, particularly non-melanomatous skin cancer, so ongoing use of sun protection cream is warranted (Ch. 4).

The outcomes after kidney transplantation are generally very good. Contemporary UK statistics for transplants from deceased donors indicate 97% patient survival and 95% graft survival at 1 year, and 87% patient and 87% graft survival at 5 years. Even better figures are obtained with living donor transplantation (93% graft survival and 94% patient survival at 5 years).

Renal disease in pregnancy

Pregnancy has important physiological effects on the renal system. Some diseases are more common in pregnancy (Box 18.40), the

18.38 Common causes of renal allograft dysfunction

Time post transplant	Cause	Risk factors
Hours to days	Renal artery/vein thrombosis	Technically difficult surgery Thrombophilia/SLE
	Ureteric anastomotic leak	Small bladder/anuria pre-transplant
	Delayed graft function (i.e. transplant does not start working immediately)	Prolonged cold ischaemia time* Donation after circulatory death Older, hypertensive donor with stroke as cause of death, high tacrolimus level
	Hyperacute rejection	Pre-formed anti-HLA antibodies HLA mismatch Previous transplant
Weeks	Acute rejection (especially <3 months; can occur later with non-adherence/insufficient immunosuppression)	Pre-formed anti-HLA antibodies HLA mismatch Previous transplant
Months	BK virus nephropathy	Intensive immunosuppression Ureteric stent use
	Renal artery stenosis	Donor disease Injury at organ retrieval
Years	Chronic allograft injury (often antibody-mediated)	Previous acute rejections Non-adherence/insufficient immunosuppression
Any time	Tacrolimus/ciclosporin toxicity	High doses/serum levels Concurrent use of drugs that inhibit cytochrome P450 system
	Recurrence of disease: Early (FSGS/MCGN/aHUS) Later (IgA nephropathy/membranous glomerulonephritis) Sepsis (opportunistic and conventional)	Primary FSGS and MCGN Previous transplant recurrence Immunosuppression

*Time from organ retrieval in the donor until implantation into the recipient.
(aHUS = atypical haemolytic uraemic syndrome; FSGS = focal segmental glomerulosclerosis; HLA = human leucocyte antigen; IgA = immunoglobulin A; MCGN = mesangiocapillary glomerulonephritis; SLE = systemic lupus erythematosus)

18.39 Immunosuppressive drugs used to prevent transplant rejection

Drug	Maintenance dose	Mechanism of action	Main adverse effects
Azathioprine	3–5 mg/kg/day used at time of transplantation reduced gradually to 1–3 mg/kg/day orally	Inhibit lymphocyte proliferation by blocking DNA synthesis	Increased susceptibility to infection Leucopenia
Mycophenolate mofetil	2–3 g daily orally		Increased susceptibility to infection Leucopenia Hepatotoxicity
Ciclosporin	5–10 mg/kg/day, divided into two doses, used at time of transplantation reduced gradually to 3–6 mg/kg/day orally	Calcineurin inhibitors. Both inhibit lymphocyte activation and block cytokine transcription	Increased susceptibility to infection Hypertension Nephrotoxicity Diabetes (especially tacrolimus) Gingival hypertrophy, hirsutism (ciclosporin)
Tacrolimus	0.1–0.2 mg/kg/day, divided into two doses orally. Dose is adjusted based on target trough blood levels		
Glucocorticoids	Prednisolone 20 mg daily initially then reduced or stopped	Inhibits lymphocyte activation, antibody production and cytokine release	Increased susceptibility to infection, osteoporosis, diabetes
Anti-thymocyte globulin (ATG)	1–1.5 mg/kg daily IV for 3–9 days	Targets multiple cell surface proteins on lymphocytes to deplete T-cells and block activation	Profound non-specific immunosuppression Increased susceptibility to infection
Basiliximab	20 mg IV given 2 days before and 4 days after transplantation	Inhibits CD25 (IL-2Rα chain), expressed on activated T cells	Increased susceptibility to infection Gastrointestinal side-effects
Belatacept	10 mg/kg IV 1 day before transplantation with repeat infusions after transplantation	Selectively inhibits T-cell activation through blockade of CD80/CD86	Increased susceptibility to infection and malignancy Gastrointestinal side-effects Hypertension Anaemia/leucopenia

(IV = intravenous)

18.40 Renal diseases in pregnancy

- **Eclampsia**: severe hypertension, encephalopathy and fits
- **'HELLP' syndrome**: haemolysis, elevated liver enzymes, low platelets: severe part of pre-eclampsia spectrum with thrombotic microangiopathy and higher risk of AKI
- **Thrombotic microangiopathy**: may be part of pre-eclampsia spectrum and can also occur post-partum (including thrombotic thrombocytopenic purpura/haemolytic uraemic syndrome)
- **Acute fatty liver of pregnancy**: high risk of AKI in this setting
- **Disseminated intravascular coagulation**

18.41 Kidney disease in adolescence

- **Adherence**: young adults moving from parental supervision may become disengaged. There may also be reduced adherence to prophylactic and therapeutic treatment, including immunosuppressive medications, diet and fluid restrictions and dialysis.
- **Adverse events**: there is an increased risk of transplant loss and other adverse events in young adults on renal replacement therapy.
- **Management**: joint transition clinics should be established with the paediatric team to facilitate transfer to adult specialist clinics.

manifestations of others are modified during pregnancy, and a few diseases, such as pre-eclampsia (see Box 30.8), are unique to pregnancy. These are discussed in detail in Chapter 30.

Renal disease in adolescence

Many causes of renal failure present during infancy or childhood, such as congenital urological malformations and inherited disorders like cystinosis and autosomal recessive polycystic kidney disease. The consequences continue throughout the patient's life, and the situation often arises whereby patients transition from paediatric to adult nephrology services. Some of the issues and challenges surrounding this transition are summarised in Box 18.41.

Drugs and the kidney

Drug-induced renal disease

The kidney is susceptible to damage by drugs because it is the route of excretion of many water-soluble compounds, including drugs and their metabolites. Some may reach high concentrations in the renal cortex as a result of proximal tubular transport mechanisms. Others are concentrated in the medulla by the operation of the countercurrent system.

Toxic renal damage may occur by a variety of mechanisms (Box 18.42). Very commonly, drugs contribute to the development of acute tubular necrosis as one of multiple insults. Numerically, reactions to NSAIDs and ACE inhibitors are the most important. Haemodynamic renal impairment, acute tubular necrosis and allergic reactions are usually reversible if recognised early enough. Other types, however, especially those associated with extensive fibrosis, are less likely to be reversible.

Non-steroidal anti-inflammatory drugs

Impairment of renal function may develop in patients on NSAIDs, since prostaglandins play an important role in regulating renal blood flow by vasodilating afferent arterioles (see Fig. 18.20). This is particularly likely in patients with other disorders, such as volume depletion, heart failure, cirrhosis, sepsis and pre-existing renal impairment. In addition, idiosyncratic immune reactions may occur, causing minimal change nephrotic syndrome, membranous nephropathy (p. 616) and acute interstitial nephritis (p. 618). Analgesic nephropathy (see Box 18.19) is now a rare complication of long-term use.

ACE inhibitors

These abolish the compensatory angiotensin II–mediated vasoconstriction of the glomerular efferent arteriole that takes place in order to maintain glomerular perfusion pressure distal to a renal artery stenosis and in renal hypoperfusion (see Figs. 18.1 and 18.20). Monitoring of renal function before and after initiation of therapy is essential, and an expected rise in creatinine of about 20% is frequently observed.

Prescribing in renal disease

Many drugs and drug metabolites are excreted by the kidney and so the presence of renal impairment alters the required dose and frequency (p. 33). Immunosuppressive medications such as tacrolimus or ciclosporin are metabolised by the cytochrome P450 system, hence drug interactions need to be considered before prescribing other medications.

Infections of the urinary tract

In health, bacterial colonisation is confined to the lower end of the urethra and the remainder of the urinary tract is sterile (see Ch. 7). The urinary tract can become infected with various bacteria, but the most common is *E. coli* derived from the gastrointestinal tract. The most common presenting problem is cystitis with urethritis (generally referred to as urinary tract infection (UTI)).

Urinary tract infection

UTI is a common disorder, accounting for 1%–3% of consultations in general medical practice. The prevalence of UTI in women is about 3% at the age of 20, increasing by about 1% in each subsequent decade. In males, UTI is uncommon, except in the first year of life and in men over 60, when it may complicate bladder outflow obstruction.

Pathophysiology

Urine is an excellent culture medium for bacteria; in addition, the urothelium of susceptible persons may have more receptors, to which virulent strains of *E. coli* become adherent. In women, the ascent of organisms into the bladder is easier than in men; the urethra is shorter, and the absence of bactericidal prostatic secretions may be relevant. Sexual intercourse may cause minor urethral trauma and transfer bacteria from the perineum into the bladder. Instrumentation of the bladder may also introduce organisms. Multiplication of organisms then depends on a number of factors, including the size of the inoculum and virulence of the bacteria. Conditions that predispose to UTI are shown in Box 18.43.

Clinical features

Typical features of cystitis and urethritis include:

- abrupt onset of frequency of micturition and urgency
- burning pain in the urethra during micturition (dysuria)
- suprapubic pain during and after voiding
- intense desire to pass more urine after micturition, due to spasm of the inflamed bladder wall (strangury)
- urine that may appear cloudy and have an unpleasant odour
- non-visible or visible haematuria.

Systemic symptoms are usually slight or absent. However, infection in the lower urinary tract can spread to cause acute pyelonephritis. This is suggested by prominent systemic symptoms with fever, rigors, vomiting, hypotension and loin pain, guarding or tenderness, and may be an

18.42 Mechanisms and examples of drug-induced renal disease/dysfunction

Mechanism	Drug or toxin	Comments
Haemodynamic	NSAIDs	Reduce renal blood flow due to inhibition of prostaglandin synthesis causing afferent arteriolar vasoconstriction
	ACE inhibitors	Reduce efferent glomerular arteriolar tone, so especially problematic in the presence of renal artery stenosis and other causes of renal hypoperfusion (e.g. sepsis)
	Radiographic contrast media, calcineurin inhibitors	Multifactorial aetiology may include intense vasoconstriction
Acute tubular necrosis	Aminoglycosides, amphotericin	In most examples there is evidence of direct tubular toxicity, but haemodynamic and other factors probably contribute
	Paracetamol overdose	May occur with or without serious hepatotoxicity
	Radiographic contrast media	Directly toxic to proximal tubular cells
Glomerulonephritis (immune-mediated)	Penicillamine, gold	Membranous nephropathy
	Penicillamine, propylthiouracil, hydralazine	Crescentic or focal necrotising glomerulonephritis in association with ANCA and systemic small-vessel vasculitis
	NSAIDs	Minimal change nephropathy, membranous nephropathy
Proteinuria	Can occur with VEGF inhibitors used in cancer treatment	Injury to podocytes
Haemolytic uraemic syndrome	Calcineurin and VEGF inhibitors	Podocyte-derived VEGF is required for healthy glomerular endothelia
Interstitial nephritis (immune-mediated)	NSAIDs, penicillins, proton pump inhibitors, many others	Acute interstitial nephritis
Interstitial nephritis (toxicity)	Lithium	Chronic exposure at lower dose than causes acute toxicity Also cause loss in urinary concentrating ability
Papillary necrosis	Various NSAIDs	Ischaemic damage secondary to NSAID effects on renal blood flow
Tubular obstruction (crystal formation)	Aciclovir	Crystals of the drug form in tubules Aciclovir is now more common than the original example of sulphonamides
	Chemotherapy	Uric acid crystals form as a consequence of tumour lysis (typically, a first-dose effect in haematological malignancy)
Nephrocalcinosis	Oral sodium phosphate-containing bowel cleansing agents	Precipitation of calcium phosphate occurring in 1%–4% and exacerbated by volume depletion Usually mild but damage can be irreversible
Retroperitoneal fibrosis	Ergolinic dopamine agonists (cabergoline),	Idiopathic retroperitoneal fibrosis is more common

(ACE = angiotensin-converting enzyme; ANCA = antineutrophil cytoplasmic antibody; NSAIDs = non-steroidal anti-inflammatory drugs)

18.43 Risk factors for urinary tract infection

Bladder outflow obstruction	
Benign prostatic enlargement Prostate cancer	Urethral stricture
Anatomical abnormalities	
Vesico-ureteric reflux Uterine prolapse	Bladder fistula
Neurological problems	
Multiple sclerosis Spina bifida	Diabetic neuropathy
Foreign bodies	
Urethral or suprapubic catheter Ureteric stent	Nephrostomy tube Urolithiasis
Loss of host defences	
Atrophic urethritis and vaginitis in post-menopausal women	

indication for hospitalisation. Only about 30% of patients with acute pyelonephritis have associated symptoms of cystitis or urethritis. Prostatitis is suggested by perineal or suprapubic pain, pain on ejaculation and prostatic tenderness on rectal examination.

The differential diagnosis of lower urinary tract symptoms includes urethritis due to sexually transmitted disease, notably chlamydia (Ch. 15) and urethritis associated with reactive arthritis (Ch. 25). Some patients, usually female, have symptoms suggestive of urethritis and cystitis, but no bacteria are cultured from the urine ('urethral syndrome'). Possible explanations include infection with organisms not readily cultured by ordinary methods (such as *Chlamydia* and certain anaerobes), intermittent or low-count bacteriuria, reaction to toiletries or disinfectants, symptoms related to sexual intercourse, or post-menopausal atrophic vaginitis.

The differential diagnosis of acute pyelonephritis includes pyonephrosis, acute appendicitis, diverticulitis, cholecystitis, salpingitis, ruptured ovarian cyst or ectopic pregnancy. In pyonephrosis due to an infected and obstructed upper urinary tract, patients may become extremely ill, with fever, leucocytosis and positive blood cultures. With a perinephric abscess, there is marked pain and tenderness, and often bulging of the loin on the affected side. Urinary symptoms may be absent in this situation and urine testing negative, containing neither pus cells nor organisms.

Investigations

An approach to investigation is shown in Box 18.44. In an otherwise healthy woman with a single lower urinary tract infection, urine culture prior to treatment is not mandatory. Investigation is necessary, however, in patients with recurrent infection or after failure of initial treatment, during pregnancy, or in patients susceptible to serious infection, such as the immunocompromised, those with diabetes or an indwelling catheter, and older people (Box 18.45). The diagnosis can be made from the combination of typical clinical features and abnormalities on

18.44 Investigation of patients with urinary tract infection

All patients

- Dipstick* estimation of nitrite, leucocyte esterase and glucose
- Microscopy/cytometry of urine for white blood cells, organisms
- Urine culture

Infants, children, anyone with fever or complicated infection

- Full blood count; creatinine, eGFR
- Blood cultures

Pyelonephritis: men, children, women with recurrent infections

- Renal tract ultrasound or CT
- Pelvic examination in women, rectal examination in men

Continuing haematuria or other suspicion of bladder lesion

- Cystoscopy

*May substitute for microscopy and culture in simple uncomplicated infection.

(CT = computed tomography; eGFR = estimated glomerular filtration rate)

18.45 Urinary infection in old age

- **Prevalence of asymptomatic bacteriuria**: rises with age. Among the most frail in institutional care it rises to 40% in women and 30% in men.
- **Decision to treat**: treating asymptomatic bacteriuria does not improve chronic incontinence or decrease mortality or morbidity from symptomatic urinary infection. It risks adverse effects from the antibiotic and the emergence of resistant organisms. Bacteriuria should not be treated in the absence of urinary symptoms.
- **Source of infection:** the urinary tract is the most frequent source of bacteraemia in older patients admitted to hospital. It may present with an acute confusional state.
- **Incontinence**: new or increased incontinence is a common presentation of UTI in older women.
- **Treatment**: post-menopausal women with acute lower urinary tract symptoms may require longer than 3 days' therapy.

(UTI = urinary tract infection)

urinalysis. In symptomatic infections, urine dipstick tests may be positive for leucocyte esterase released from neutrophils and nitrites, due to conversion of nitrates to nitrites by urinary pathogens. The absence of both nitrites and leucocyte esterase in the urine makes UTI unlikely. Interpretation of bacterial counts in the urine, and of what is a 'significant' culture result, is based on probabilities. Urine taken by suprapubic aspiration should be sterile, so the presence of any organisms is significant. If the patient has symptoms and there are neutrophils in the urine, a small number of organisms is significant. In asymptomatic patients, more than 10^5 organisms/mL is usually regarded as significant (asymptomatic bacteriuria; see below).

Typical organisms causing UTI in the community include *E. coli* derived from the gastrointestinal tract (about 75% of infections), *Proteus* spp., *Pseudomonas* spp., streptococci and *Staphylococcus epidermidis*. In hospital, *E. coli* still predominates but *Klebsiella* and streptococci are becoming more common. Certain strains of *E. coli* have a particular propensity to invade the urinary tract.

Investigations to detect underlying predisposing factors for UTI are used selectively, most commonly in children, men or patients with recurrent infections (see Box 18.44).

Management

Antibiotics are recommended in all cases of proven UTI (Box 18.46), but not asymptomatic bacteriuria (see below). If urine culture has been performed, treatment may be started while awaiting the result. For infection of the lower urinary tract, treatment for 3 days is the norm and is less likely to induce significant alterations in bowel flora, including *Clostridioides* (formerly *Clostridium*) *difficile*, than more prolonged therapy. Trimethoprim or nitrofurantoin is the usual first choice of drug for initial treatment; however, between 10% and 40% of organisms causing UTI are resistant to trimethoprim, the lower rates being seen in community-based practice. Trimethoprim and nitrofurantoin are not recommended if eGFR is < 30 mL/min/1.73 m^2 due to reduced efficacy/increased risk of toxicity. In addition, trimethoprim may increase serum potassium and creatinine levels and lead to artefactual reductions in eGFR, which resolve once the drug is discontinued. Quinolone antibiotics such as ciprofloxacin and cephalosporins such as cefalexin are also generally effective. Co-amoxiclav and amoxicillin are no longer recommended as blind therapy, as up to 30% of organisms are resistant. They may be used once cultures confirm that the organism is sensitive. Penicillins and cephalosporins are safe to use in pregnancy, but trimethoprim, sulphonamides, quinolones and tetracyclines should be avoided.

In more severe infection, antibiotics should be continued for 7–14 days. Seriously ill patients may require intravenous therapy with gentamicin for a few days (see Box 18.46), later switching to an oral agent.

A fluid intake of at least 2 L/day is usually recommended, although this is not based on evidence and may exacerbate symptoms of dysuria.

Persistent or recurrent UTI

If the causative organism persists on repeat culture despite treatment, or if there is reinfection with any organism after an interval, then an underlying cause is more likely to be present (see Box 18.43) and more detailed investigation is justified (see Box 18.44). In women, recurrent infections are common, and investigation is justified only if infections are frequent (three or more per year) or unusually severe. Recurrent UTI, particularly in the presence of an underlying cause, may result in permanent renal damage, whereas uncomplicated infections rarely (if ever) do so (see chronic reflux nephropathy below).

If an underlying cause cannot be treated, suppressive antibiotic therapy (see Box 18.46) can be used to prevent recurrence and reduce the risk of sepsis and renal damage. Urine should be cultured at regular intervals; a regimen of two or three antibiotics in sequence, rotating every 6 months, is often used in an attempt to reduce the emergence of resistant organisms. Other simple measures may help to prevent recurrence (Box 18.47). Trimethoprim or nitrofurantoin is recommended for prophylaxis. Alternative antibiotics include cefalexin, co-amoxiclav and ciprofloxacin, but these should be avoided if possible, because of adverse effects and the generation of resistance.

Asymptomatic bacteriuria

This is defined as more than 10^5 organisms/mL in the urine of apparently healthy asymptomatic patients. Approximately 1% of children under the age of 1 year, 1% of schoolgirls, 0.03% of schoolboys and men, 3% of non-pregnant adult women and 5% of pregnant women have asymptomatic bacteriuria. It is increasingly common in those aged over 65. There is no evidence that this condition causes renal scarring in adults who are not pregnant and have a normal urinary tract, and, in general, treatment is not indicated. Up to 30% will develop symptomatic infection within 1 year, however. Treatment is required in infants, pregnant women and those with urinary tract abnormalities.

Catheter-related bacteriuria

In patients with a urinary catheter, bacteriuria increases the risk of gram-negative bacteraemia fivefold. Bacteriuria is common, however, and almost universal during long-term catheterisation. Treatment is usually avoided in asymptomatic patients, as this may promote antibiotic resistance. Careful sterile insertion technique is important and the catheter should be removed as soon as it is not required.

18.46 Antibiotic regimens for urinary tract infection in adults[1]

Scenario	Drug	Regimen	Duration	Comment
Cystitis				
First choices	Trimethoprim	200 mg twice daily	3 days	7–10 days in men
	Nitrofurantoin	50 mg 4 times daily		
Second choices[1]	Cefalexin	250 mg 4 times daily		
	Ciprofloxacin	250 mg twice daily		
	Pivmecillinam	400 mg 3 times daily		
In pregnancy	Nitrofurantoin	50 mg 4 times daily	7 days	Avoid trimethoprim and quinolones during pregnancy; avoid nitrofurantoin at term
	Cefalexin	250 mg 4 times daily		
Prophylactic therapy				
First choice	Trimethoprim	100 mg at night	Continuous	
Second choice[1]	Nitrofurantoin	50 mg at night		
Pyelonephritis				
First choices	Cefalexin	1 g 4 times daily	14 days	Admit to hospital if no response within 24 hrs
	Ciprofloxacin	500 mg twice daily	7 days	
Second choices	Gentamicin[2]	Adjust dose according to renal function and serum levels	14 days	Switch to appropriate oral agent as soon as possible
	Cefuroxime	750–1500 mg 3 times daily		
Epididymo-orchitis				
Young men	Ciprofloxacin	100 mg twice daily	14 days	Refer young men to genito-urinary department to check for *Chlamydia trichomatis* and *Neisseria gonorrhoeae*, which requires addition of a single dose of ceftriaxone 500 mg IM
Older men	Ciprofloxacin	500 mg twice daily		
Acute prostatitis				
First choice	Ciprofloxacin	500 mg twice daily	14 days	
Second choice	Trimethoprim	200 mg twice daily		

[1] In all cases, the choice of drug should take locally determined antibiotic resistance patterns into account.
[2] See Hartford nomogram (Fig. 7.19).
(IM = intramuscular)

18.47 Prophylactic measures to be adopted by women with recurrent urinary infections

- Fluid intake of at least 2 L/day
- Regular complete emptying of bladder
- Good personal hygiene
- Emptying of bladder before and after sexual intercourse
- Cranberry juice/tablets and/or D-mannose may be effective

Acute pyelonephritis

The kidneys are infected in a minority of patients with UTI. Acute renal infection (pyelonephritis) presents as a classic triad of loin pain, fever and tenderness over the kidneys. The renal pelvis is inflamed and small abscesses are often evident in the renal parenchyma (see Fig. 18.15C).

Renal infection is almost always caused by organisms ascending from the bladder, and the bacterial profile is the same as for lower urinary tract infection (see above). Rarely, bacteraemia may give rise to renal or perinephric abscesses, most commonly due to staphylococci. Predisposing factors may facilitate infection, such as cysts or renal scarring.

Rarely, acute pyelonephritis is associated with papillary necrosis. Fragments of renal papillary tissue are passed per urethra and can be identified histologically. They may cause ureteric obstruction and, if this occurs bilaterally or in a single kidney, it may lead to AKI. Predisposing factors include diabetes mellitus, chronic urinary obstruction, analgesic nephropathy and sickle-cell disorder. A necrotising form of pyelonephritis with gas formation, emphysematous pyelonephritis, is occasionally seen in patients with diabetes mellitus. Xanthogranulomatous pyelonephritis is a chronic infection that can resemble renal cell cancer. It is usually associated with obstruction, is characterised by accumulation of foamy macrophages and generally requires nephrectomy. Infection of cysts in ADPKD (p. 620) requires prolonged antibiotic treatment.

Appropriate investigations are shown in Box 18.44 and management is described above and in Box 18.46. Intravenous rehydration may be needed in severe cases. If complicated infection is suspected or response to treatment is not prompt, urine should be re-cultured and renal tract ultrasound performed to exclude urinary tract obstruction or a perinephric collection. If obstruction is present, drainage by a percutaneous nephrostomy or ureteric stent should be considered and the underlying cause treated.

Tuberculosis

Tuberculosis of the kidney and renal tract is secondary to tuberculosis elsewhere and is the result of blood-borne infection. Initially, lesions develop in the renal cortex; these may ulcerate into the renal pelvis and involve the ureters, bladder, epididymis, seminal vesicles and prostate. Calcification in the kidney and stricture formation in the ureter are typical.

Clinical features may include symptoms of bladder involvement (frequency, dysuria); haematuria (sometimes macroscopic); malaise, fever, night sweats, lassitude and weight loss; loin pain; associated genital disease; and chronic renal failure as a result of urinary tract obstruction or destruction of kidney tissue.

Neutrophils are present in the urine, but routine urine culture may be negative (sterile pyuria). Special techniques of microscopy and culture may be required to identify tubercle bacilli and are most usefully performed on early morning urine specimens. Bladder involvement should be assessed by cystoscopy. Radiology of the urinary tract and a chest X-ray to look for pulmonary tuberculosis are mandatory. Antituberculous chemotherapy follows standard regimens (see Box 17.52). Surgery to relieve urinary tract obstruction or to remove a very severely infected kidney may be required.

Urolithiasis

Renal stone disease is common, affecting people of all countries and ethnic groups. In the UK, the prevalence is about 1.2%, with a lifetime risk of developing a renal stone by age 60–70 of approximately 7% in men. In some regions, the risk is higher, most notably in Saudi Arabia, where the lifetime risk of developing a renal stone in men aged 60–70 is just over 20%.

Pathophysiology

Urinary calculi consist of aggregates of crystals, usually containing calcium or phosphate in combination with small amounts of proteins and glycoproteins. The most common types are summarised in Box 18.48. A number of risk factors have been identified for renal stone formation (Box 18.49); however, in developed countries most calculi occur in healthy young men, in whom investigations reveal no clear predisposing cause. Renal stones vary greatly in size, from sand-like particles anywhere in the urinary tract to large, round stones in the bladder. In developing countries, bladder stones are common, particularly in children, whereas in developed countries, renal stones are more common. Staghorn calculi fill the whole renal pelvis and branch into the calyces (Fig. 18.29); they are usually associated with infection and composed largely of struvite. Deposits of calcium may be present throughout the renal parenchyma, giving rise to fine calcification within it (nephrocalcinosis), especially in patients with renal tubular acidosis, hyperparathyroidism, vitamin D intoxication and healed renal tuberculosis. Cortical nephrocalcinosis may occur in areas of cortical necrosis, typically after AKI in pregnancy or other severe AKI.

Clinical features

The clinical presentation is highly variable. Many patients with renal stone disease are asymptomatic, whereas others present with pain, haematuria, UTI or urinary tract obstruction. A common presentation is with acute loin pain together with haematuria: a symptom complex termed renal or ureteric colic. This is most commonly caused by ureteric obstruction by a calculus, but the same symptoms can occur in association with a sloughed renal papilla, tumour or blood clot. The patient is suddenly aware of pain in the loin, which radiates round the flank to the groin and often into the testis or labium, in the sensory distribution of the first lumbar nerve. The pain steadily increases in intensity to reach a peak in a few minutes. The patient is restless and generally tries unsuccessfully to obtain relief by changing position or pacing the room. There is pallor, sweating and often vomiting. Frequency, dysuria and haematuria may occur. The intense pain usually subsides within 2 hours but may continue unabated for hours or days. It is usually constant during attacks, although slight fluctuations in severity may be seen. Subsequent to an attack of renal colic, intermittent dull pain in the loin or back may persist for several hours.

Investigations

Patients with symptoms of renal colic should be investigated to determine whether or not a stone is present, to identify its location and to assess whether it is causing obstruction. About 90% of stones contain calcium, and these can be visualised on plain abdominal X-ray (radio-opaque stones), but non-contrast CT KUB (see Fig. 18.29) is the gold standard for diagnosing a stone within the kidney or ureter, as 99% of stones are visible using this method. Ultrasound can show stones within the kidney and dilatation of the renal pelvis and ureter if the stone is obstructing urine flow; it is useful in unstable patients or young women, in whom exposure to ionising radiation is particularly undesirable.

18.48 Composition of renal stones

Composition	Percentage
Calcium oxalate[1]	60%
Calcium phosphate	15%
Uric acid	10%
Magnesium ammonium phosphate (struvite)[2]	15%
Cystine and others	1%

[1]Stones often contain small amounts of calcium phosphate.
[2]Associated with urine infection.

A minimum set of investigations (Box 18.50) should be performed in patients with a first renal stone. The yield of more detailed investigation is low, and hence is usually reserved for those at high risk for further stone formation (see Box 18.50). Chemical analysis of stones is often helpful in defining the underlying cause. Since most stones pass spontaneously through the urinary tract, ideally the urine should be sieved for a few days after an episode of colic in order to collect the calculus for analysis.

Management

The immediate treatment of renal colic is with analgesia and antiemetics. Renal colic is often unbearably painful and demands powerful analgesia; a non-steroidal anti-inflammatory drug (NSAID), e.g. diclofenac, given by any route is first-line treatment and is often very effective. Intravenous paracetamol should be given if NSAIDs are contraindicated or are not giving sufficient pain relief. An opioid should then be considered, e.g. morphine (10–20 mg) or pethidine (100 mg) intramuscularly.

Patients with renal or ureteric stones are at high risk of infection; if surgery is contemplated, the patient should be covered with appropriate

18.49 Predisposing factors for kidney stones

General factors

- Early onset of urolithiasis (especially children and adolescents)
- Previous history of urolithiasis
- Familial stone formation
- Uric acid and urate-containing stones
- Infection stones
- High ambient temperatures

Diseases associated with stone formation

- Hyperparathyroidism
- Metabolic syndrome
- Nephrocalcinosis
- Pancreas insufficiency or ileal disease or resection (increases oxalate absorption and urinary excretion)
- Polycystic kidney disease (PKD)
- Increased levels of vitamin D
- Sarcoidosis
- Spinal cord injury, neurogenic bladder

Environmental and dietary causes

- Low urine volumes: high ambient temperatures, low fluid intake
- Chronic lead and cadmium exposure

Congenital and inherited causes

- Cystinuria (type A, B and AB)
- Renal tubular acidosis type I (distal)
- Primary hyperoxaluria
- Xanthinuria
- Lesch–Nyhan syndrome
- Cystic fibrosis

Anatomical abnormalities associated with stone formation

- Medullary sponge kidney
- Pelvi-ureteric junction obstruction
- Calyceal diverticulum
- Ureteric stricture
- Ureteric reflux
- Horseshoe kidney
- Ureterocele

antibiotics. Urgent drainage of the affected collecting system with a ureteric stent or percutaneous nephrostomy is required if infection occurs in the stagnant urine proximal to the stone (pyonephrosis), and in patients with a solitary kidney who develop anuria in association with a stone in the ureter.

Asymptomatic stones less than 5 mm in diameter can be observed as they are not likely to affect quality of life and up to 90% may pass spontaneously without intervention. Conversely, only 10% of stones > 6 mm in diameter pass spontaneously through the urinary tract and hence these may need an intervention. Stones can be fragmented by extracorporeal shock wave lithotripsy (ESWL), in which shock waves generated outside the body are focused on the stone, breaking it into small pieces that can pass easily down the ureter (Fig. 18.30). Surgical options are ureteroscopy and stone fragmentation, usually with a laser, or percutaneous nephrolithotomy (PCNL) and fragmentation with an ultrasonic disaggregator. The recommended treatment depends on stone size, location and patient characteristics. Figure 18.30 details options by stone location.

Measures to prevent further stone formation are guided by the investigations in Box 18.50. Some general principles apply to almost every patient with calcium-containing stones (Box 18.51), while other measures apply to specific stone types. Urate stones can be prevented by allopurinol, but its role in patients with calcium stones and high urate excretion is uncertain. Stones formed in cystinuria can be reduced by penicillamine therapy. It may also be helpful to attempt to alkalinise the urine with sodium bicarbonate, as a high pH discourages urate and cystine stone formation.

Diseases of the collecting system and ureters

Congenital abnormalities

Various congenital anomalies of the kidney and urinary tract (often abbreviated as CAKUT) can occur (Fig. 18.31); they affect more than 10% of infants. If not immediately lethal, they can lead to complications in later life, including obstructive nephropathy and CKD.

Single kidneys

About 1 in 500 infants is born with only one kidney. In isolation this is usually compatible with normal life, although it may be associated with other developmental abnormalities.

Medullary sponge kidney disease

Medullary sponge kidney is a congenital disorder characterised by malformation of the papillary collecting ducts in the pericalyceal region of the renal pyramids. This leads to the formation of microscopic and large medullary cysts. Patients often present as adults with renal stones, but the renal function usually remains adequate. The diagnosis is made by ultrasound, CT or intravenous urography, where contrast medium is seen to fill dilated or cystic tubules, which are sometimes calcified.

Ureterocele

A ureterocele occurs behind a pin-hole ureteric orifice when the intramural part of the ureter dilates and bulges into the bladder. It can become very large and cause lower urinary tract obstruction. Incision of the pinhole opening relieves the obstruction.

Ectopic ureters and duplex kidneys

Ectopic ureters occur with congenital duplication of one or both kidneys (duplex kidneys). Developmentally, the ureter has two main branches and, if this arrangement persists, the two ureters of the duplex kidneys

i 18.51 Measures to prevent calcium stone formation

Diet

Fluid
- At least 2 L output per day (intake 3–4 L): check with 24-hr urine collections
- Intake distributed throughout the day (especially before bed)
- Add fresh lemon juice to drinking water (high in citrate, which may prevent calcium binding to other stone components and thus prevents stone formation)
- Avoid carbonated drinks

Sodium
- Restrict intake

Protein
- Moderate, not high

Calcium
- Maintain normal calcium intake (calcium forms an insoluble salt with dietary oxalate, lowering oxalate absorption and excretion)
- Avoid calcium supplements separate from meals (increase calcium excretion without reducing oxalate excretion)

Oxalate
- Avoid foods that are rich in oxalate (spinach, rhubarb)

Drugs

Potassium citrate
- Can reduce the recurrence of calcium oxalate and calcium oxalate/calcium phosphate stones in adults

Thiazide diuretics
- Reduce calcium excretion
- Valuable in recurrent stone formers and hypercalciuria

Allopurinol
- If urate excretion high (unproven except for urate stones)

Avoid
- Vitamin D supplements (increase calcium absorption and excretion)
- Vitamin C supplementation (increases oxalate excretion)

may drain separately into the bladder. The lower pole moiety enters the bladder superiorly and laterally, while the upper pole moiety enters the bladder inferomedially to the lower pole moiety ureter or, more rarely, enters the vagina or seminal vesicle. The lower pole moiety has an ineffective valve mechanism, so that urine passes up the ureter on voiding (vesico-ureteric reflux, see below), whereas the upper pole moiety is often associated with a ureterocele.

Megaureter

A megaureter is a ureter dilated to more than 5 mm in diameter. It may be obstructed or non-obstructed and refluxing or non-refluxing. Some 50% of cases are asymptomatic but patients may present with pain, haematuria or infection. Radiographic and pressure/flow studies may be needed to determine whether there is obstruction to urine flow. Patients with symptoms or reduced renal function are treated. Ideally, treatment is expectant with antibiotic prophylaxis. Surgery (narrowing of the ureter and/or reimplantation) may, however, be needed for recurrent symptoms, reduction of more than 10% in renal function or complications (i.e. stones).

Pelvi-ureteric junction obstruction

Pelvi-ureteric junction obstruction (PUJO) causes idiopathic hydronephrosis and results from a functional obstruction at the junction of the ureter and renal pelvis. The abnormality is likely to be congenital and is often bilateral. It can be seen in very young children, but gross hydronephrosis may present at any age. The common presentation is ill-defined renal pain or ache, exacerbated by drinking large volumes of liquid (Dietl crisis). Rarely, it is asymptomatic. The diagnosis is often suspected after ultrasound or CT scan and can be confirmed with a ^{99m}Tc-MAG3 renogram followed by diuretic. In a PUJO, the MAG3 renogram shows a pathognomonic 'rising curve' as the radioisotope accumulates in the renal pelvis and still does not drain following the diuretic injection. Treatment is surgical excision of the pelvi-ureteric junction and reanastomosis (pyeloplasty), which can now be performed laparoscopically or by robot-assisted surgery. Less invasive alternatives are also possible, including balloon dilatation and endoscopic pyelotomy, but are generally less effective.

Reflux nephropathy

This condition, which was previously known as chronic pyelonephritis, is a specific type of chronic interstitial nephritis associated with vesico-ureteric reflux (VUR) in early life and with the appearance of scars in the kidney, as demonstrated by various imaging techniques. About 12% of patients in Europe requiring treatment for ESRD may have this disorder, but diagnostic criteria are imprecise.

Pathophysiology

Reflux nephropathy is thought to be due to chronic reflux of urine from the bladder into the ureters, in association with recurrent UTI in childhood. It was previously assumed that ascending infection was necessary for progressive renal damage in patients with VUR, but there is evidence to suggest that renal scars can occur, even in the absence of infection. Furthermore, studies have found that efforts to surgically correct VUR or use prophylactic antibiotics to prevent the UTIs are ineffective in halting progression of the disease.

Susceptibility to VUR has a genetic component and may be associated with renal dysplasia and other congenital abnormalities of the urinary tract. It can be connected with outflow obstruction, usually caused by urethral valves, but usually occurs with an apparently normal bladder.

Clinical features

Usually, the renal scarring and dilatation are asymptomatic, and the patient may present at any age with hypertension (sometimes severe), proteinuria or features of CKD. There may be no history of overt UTI. However, symptoms arising from the urinary tract may be present and include frequency of micturition, dysuria and aching lumbar pain. VUR may occur in children but diminishes as the child grows, and usually has disappeared by adulthood. Urinalysis often shows the presence of leucocytes and moderate proteinuria (usually < 1 g/24 hrs), but these are not always present. The risk of renal stone formation is increased. A number of women first present with hypertension and/or proteinuria in pregnancy. Children and adults with small or unilateral renal scars have a good prognosis, provided renal growth is normal. With significant unilateral scars there is usually compensatory hypertrophy of the contralateral kidney. In patients with more severe bilateral disease, prognosis is related to the severity of renal dysfunction, hypertension and proteinuria. If the serum creatinine is normal and hypertension and proteinuria are absent, then the long-term prognosis is usually good.

Investigations

Renal scarring can be detected by ultrasound but it has poor sensitivity and is only capable of detecting major defects and excluding significant obstruction. Radionuclide DMSA scans are more sensitive (see Fig. 18.7), and serial imaging by MRI or CT may be useful in assessing progression. Abnormalities may be unilateral or bilateral and of any grade of severity. Gross scarring of the kidneys, commonly at the poles, is seen, with reduced kidney size and narrowing of the cortex and medulla. Renal scars may be juxtaposed to dilated calyces. In patients who develop heavy proteinuria and hypertension, renal biopsies show glomerulomegaly and focal glomerulosclerosis, probably as a secondary response to reduced nephron numbers. Radionuclide techniques can also be used to demonstrate VUR as a non-invasive alternative to micturating cystourethrography (MCUG; the bladder is filled with contrast media through a urinary catheter, and images are taken during and after micturition; Fig. 18.32). As surgical intervention for VUR has declined in popularity (see below), however, this type of imaging is used less often.

Management

Infection, if present, should be treated; if recurrent, it should be prevented with prophylactic therapy, as described above in this chapter for UTI, although as mentioned above this does not prevent CKD. If recurrent pyelonephritis occurs in an abnormal kidney with minimal function, nephrectomy may be indicated. Occasionally, hypertension is cured by the removal of a diseased kidney when the disease is predominantly or entirely unilateral.

As most childhood reflux tends to disappear spontaneously and trials have shown small or no benefits from anti-reflux surgery, such intervention is now less common. Severe reflux may be managed by ureteric reimplantation or subtrigonal injection of Teflon or polysaccharide (STING) beneath the ureteric orifice.

Retroperitoneal fibrosis

Fibrosis of the retroperitoneal connective tissues may encircle and compress the ureter(s), causing obstruction. The fibrosis is most commonly idiopathic but can represent a reaction to infection, radiation or aortic

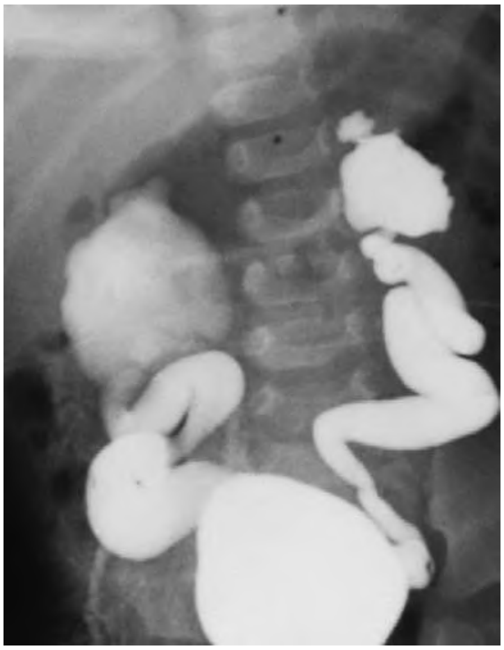

Fig. 18.32 Vesico-ureteric reflux (grade IV) shown by micturating cystogram. The bladder has been filled with contrast medium through a urinary catheter. After micturition, there was gross vesico-ureteric reflux into widely distended ureters and pelvicalyceal systems. *Courtesy of Dr A.P. Bayliss and Dr P. Thorpe, Aberdeen Royal Infirmary.*

aneurysm, or be caused by metastatic cancer. It is recognised as part of the spectrum of disorders associated with elevated IgG4 levels. Rarely, it can be associated with inflammatory bowel disease. Patients usually present with ill-defined symptoms of ureteric obstruction. Typically, there is an acute phase response (high CRP and ESR, and polyclonal hypergammaglobulinaemia). Imaging with CT or IVU shows ureteric obstruction with medial deviation of the ureters. Idiopathic retroperitoneal fibrosis may respond well to glucocorticoids (with a reduction in inflammatory marker levels), but ureteric stenting is often necessary to relieve obstruction and preserve renal function. Failure to improve indicates the need for surgery (ureterolysis), both to relieve obstruction and to exclude malignancy.

Tumours of the kidney and urinary tract

Several malignant tumours can affect the kidney and urinary tract, including renal cell cancer, upper urinary tract urothelial cancers, bladder cancer, prostate cancer and cancers of the testis and penis. The urogenital tract can also be affected by benign tumours and secondary tumour deposits, which can cause obstructive uropathy. Renal cell cancer and bladder cancer are described here, while prostate cancer and testicular tumours are covered later in this chapter.

Renal cell cancer

Renal cell cancer (RCC) is by far the most common malignant tumour of the kidney in adults, making up 2.5% of all adult cancers, with a prevalence of 16 cases per 100 000 population. It is twice as common in males. The peak incidence is between 65 and 75 years of age, and it is uncommon before 40. RCCs of differing histological subtype arise from different parts of the nephron or collecting duct. Haemorrhage and necrosis give the cut surface a characteristic mixed golden-yellow and red appearance (Fig. 18.33A). Microscopically, clear cell RCCs are the most common histological subtype (85%), with papillary, chromophobe and collecting duct tumours comprising the majority of the remainder. In RCC, there is potentially spread along the renal vein and the inferior vena cava. Direct invasion of perinephric tissues is common. Lymphatic spread occurs to para-aortic nodes, while distant metastases (which may be solitary) most commonly develop in the lungs, bone and brain.

Clinical features

In 50% of patients, asymptomatic renal tumours are identified as an incidental finding during imaging investigations carried out for other reasons. Among symptomatic patients, about 60% present with haematuria, 40% with loin pain and a few with a palpable mass. About 10% present with a triad of pain, haematuria and a mass; this usually represents advanced disease. RCC is one of the great mimics of medicine as patients may present with a remarkable range of systemic effects, including fever, raised ESR, polycythaemia, disorders of coagulation, hypercalcaemia and abnormalities of plasma proteins, and liver function tests. The patient may present with pyrexia of unknown origin (PUO) or, rarely, with neuropathy. Some of these systemic effects are caused by secretion of products by the tumour, such as renin, erythropoietin, parathyroid hormone-related protein (PTHrP) and gonadotrophins. The effects disappear when the tumour is removed but may reappear when metastases develop.

Investigations

Ultrasound is often the initial investigation and allows differentiation between solid tumour and simple renal cysts. If the results are suggestive of a tumour, contrast-enhanced CT of the abdomen and chest should be performed for staging (Fig. 18.33B). For tumours with no evidence of metastatic spread and when the nature of the lesion is uncertain, ultrasound or CT-guided biopsy may be used to avoid nephrectomy for benign disease.

Management

Radical nephrectomy that includes the perirenal fascial envelope is the treatment of choice. Nephrectomy is commonly performed laparoscopically, with equivalent outcomes to open surgery. Partial nephrectomy, which may be carried out by open but increasingly by minimally invasive robot-assisted or laparoscopic surgery, is recommended, where possible, for tumours of 7 cm or less, as there is a lower incidence of long-term cardiac- and renal-related morbidity. Patients at high operative risk who have small tumours may also be treated percutaneously by cryotherapy or radiofrequency ablation. Active surveillance with serial imaging in those with renal masses < 4 cm is a management option that should also be discussed with patients. Surgery may also play a role in the treatment

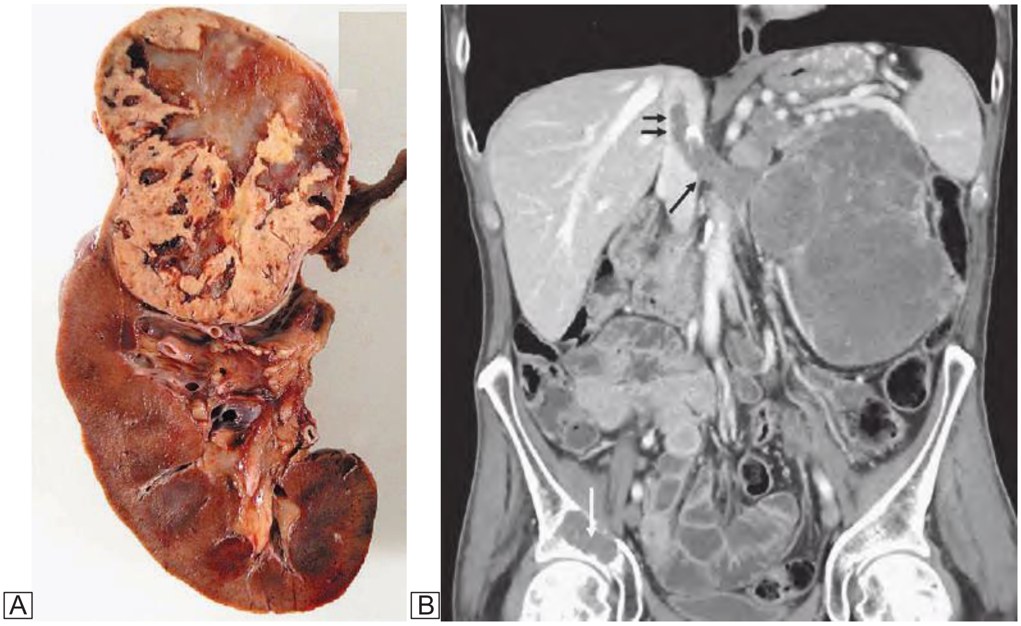

Fig. 18.33 Renal cell cancer. A Pathology specimen showing typical necrosis of a renal cell cancer. B Coronal CT demonstrating large renal cell carcinoma replacing the left kidney with tumour invasion of the left renal vein (long black arrow) extending onto the IVC (short double black arrows). There is also a lytic metastasis of the right acetabulum (white arrow). *(A) Courtesy of Dr A.P. Bayliss and Dr P. Thorpe, Aberdeen Royal Infirmary.*

of solitary metastases, since these can remain single for long periods and excision may be curative.

RCC is resistant to most chemotherapeutic agents. Tyrosine kinase inhibitors (TKIs) such as sunitinib and pazopanib are the mainstay of treatment. Recently, T-cell checkpoint inhibitors such as PD-L1, PD-1 and CTLA-4 inhibitors have been licensed for use as single agents or in combination (PD-L1/PD-1 with CTLA-4 inhibitor or TKI) as first-line treatment options for metastatic RCC.

In previous years, patients who presented with distant metastases were treated with cytoreductive nephrectomy, in which nephrectomy was coupled with systemic cytokine treatment, since this was shown to improve survival as compared with either treatment in isolation. The benefit of cytoreductive nephrectomy is less clear with TKIs and hence is used sparingly; the benefit is unknown for T-cell checkpoint inhibitors.

Current survival data indicate that, if RCC is confined to the kidney, 5-year survival is 75%, but this falls to 12% when there are distant metastases.

Urothelial tumours

Tumours arising from the transitional epithelium of the renal tract can affect the renal pelvis, ureter, bladder or urethra. They are rare under the age of 40, affect men 3–4 times more often than women, and account for about 3% of all malignant tumours. The bladder is by far the most frequently affected site. Although almost all tumours are urothelial cell cancer (previously known as transitional cell cancers), squamous cell cancer may occur in urothelium that has undergone metaplasia, usually following chronic inflammation due to stones or schistosomiasis. The appearance of a urothelial cell cancer ranges from a delicate papillary structure with a relatively good prognosis to a solid ulcerating mass in more aggressive disease.

Pathophysiology

Risk factors include cigarette smoking and exposure to industrial carcinogens such as aromatic amines, aniline dyes and aldehydes.

Clinical features

More than 80% of patients present with painless, visible haematuria. It should be assumed that such bleeding is from a tumour until proven otherwise (p. 609). Tumours of the ureter or bladder may also cause symptoms of obstruction, depending on the site of involvement, and tumours of the bladder present with dysuria or storage symptoms. Physical examination is usually unremarkable, except in patients with very advanced disease, when bimanual examination may reveal a palpable mass.

Investigations

Cystoscopy (usually flexible cystoscopy under a local anaesthetic) is used to evaluate the bladder in cases of haematuria or suspected bladder cancer. Imaging of the upper urinary tract (CT urogram is the gold standard but IVU combined with renal ultrasound is also acceptable) is also important to rule out abnormalities of the kidney, ureters and renal pelvis in patients with haematuria. If a suspicious defect is seen on CT urography or IVU in the ureter or renal pelvis, a retrograde ureteropyelogram, ureteroscopy and biopsy are required. If evidence of a solid invasive urothelial tumour is found, CT of the abdomen, pelvis and chest should be performed to define tumour stage.

Management

Most bladder tumours are low-grade, non-muscle-invasive lesions that can be successfully treated endoscopically by transurethral resection of the tumour. Intravesical chemotherapy with mitomycin C is usually administered as a one-off treatment post resection to prevent tumour recurrence or may be given as a prolonged course to treat multiple low-grade bladder tumours. Patients with carcinoma in situ have a high risk of progression to invasive cancer. These patients often respond well to intravesical bacille Calmette–Guérin (BCG) treatment, but more radical treatment by cystectomy may be required if this is unsuccessful. Following initial treatment and endoscopic clearance of bladder tumours, regular check cystoscopies are required to look for evidence of recurrence. Patients with recurrences of non-muscle-invasive disease can usually be treated by further resection and diathermy, but if this is unsuccessful, a cystectomy may be needed.

The management of muscle-invasive bladder cancer involves radical cystectomy with urinary diversion into an incontinent ileal conduit or a continent catheterisable bowel pouch; the latter is usually reserved for patients under the age of 70 years.

The prognosis of bladder cancer depends on tumour stage and grade. In patients where the cancer has not invaded the bladder muscle at diagnosis, 5% of low-grade tumours and 50% of high-grade tumours progress to develop invasion of the bladder muscle. Overall, the 5-year survival for patients with muscle-invasive bladder cancer of either grade is 50%–70%.

Urothelial cell cancer of the renal pelvis and ureter is usually treated by minimally invasive/laparoscopic surgery or open nephro-ureterectomy, but if the tumour is solitary and low-grade, it may be treated endoscopically.

Urinary incontinence

Urinary incontinence is defined as any involuntary leakage of urine. It may occur in patients with a normal urinary tract, as the result of dementia or poor mobility, or transiently during an acute illness or hospitalisation, especially in older people (Box 18.52). The prevalence of any form of incontinence in all females is 25%–45%. Childbirth, hysterectomy, obesity, recurrent UTI, smoking, caffeine and constipation are risk factors for incontinence.

Pathophysiology

In the normal micturition cycle, urine accumulates in the bladder during the storage phase, the sphincter tone gradually increases, but there are no significant changes in vesical pressure, detrusor pressure or intra-abdominal pressure. During voiding, intravesical pressure increases as a result of detrusor contraction and the sphincter relaxes, allowing urine to flow from the bladder until it is empty. Clinical disorders associated with incontinence relate to various abnormalities in this cycle, and these are discussed in more detail below.

Stress incontinence

This occurs because passive bladder pressure exceeds the urethral pressure, due either to poor pelvic floor support or a weak urethral sphincter. Usually there is an element of both these factors. Stress incontinence is very common in women and seen most frequently following childbirth. It is rare in men and usually follows surgery to the prostate. The presentation is with incontinence during coughing, sneezing or exertion. In women, perineal inspection may reveal leakage of urine when the patient coughs.

Urge incontinence

This usually occurs because of detrusor over-activity, which produces an increased bladder pressure that overcomes the urethral sphincter.

18.52 Incontinence in old age

- **Prevalence**: urinary incontinence affects 15% of women and 10% of men aged over 65 years.
- **Cause**: incontinence may be transient and due to delirium, urinary infection, medication (such as diuretics), faecal impaction or restricted mobility, and these should be treated before embarking on further specific investigation. Routine urinalysis is rarely helpful and can be misleading.
- **Detrusor over-activity**: established incontinence in old age is most commonly due to detrusor over-activity, which may be caused by damage to central inhibitory centres or local detrusor muscle abnormalities.
- **Catheterisation**: poor manual dexterity or cognitive impairment may necessitate the help of a carer to assist with intermittent catheterisation.

Urgency with or without incontinence may also be driven by a hypersensitive bladder resulting from UTI or a bladder stone. Detrusor over-activity is usually idiopathic, other than in patients with neurological conditions such as spina bifida or multiple sclerosis, in whom it is neurogenic. The incidence of urge incontinence increases with age, occurring in 10%–15% of the population aged over 65 years and in approximately 50% of patients requiring nursing home care. It is more common in women but is also seen in men with lower urinary tract obstruction and most often remits after the obstruction is relieved.

Continual incontinence

This is suggestive of a fistula, usually between the bladder and vagina (vesicovaginal), or the ureter and vagina (ureterovaginal). It is most common following gynaecological surgery but is also seen in patients with gynaecological malignancy or post radiotherapy. In parts of the world where obstetric services are scarce, prolonged obstructed labour can be a common cause of vesicovaginal fistulae. Continual incontinence may also be seen in infants with congenital ectopic ureters. Occasionally, stress incontinence is so severe that the patient leaks continuously.

Overflow incontinence

This occurs when the bladder becomes chronically over-distended and may lead to AKI (high-pressure chronic urinary retention). It is most commonly seen in men with benign prostatic enlargement or bladder neck obstruction (see below) but may arise in either sex as a result of failure of the detrusor muscle (atonic bladder). The latter may be idiopathic but more commonly is the result of damage to the pelvic nerves, either from surgery (commonly, hysterectomy or rectal excision), trauma or infection, or from compression of the cauda equina by disc prolapse, trauma or tumour. Incontinence due to prostatic enlargement can be regarded as a type of overflow incontinence.

Post-micturition dribble

This is very common in men, even in the relatively young. It is due to a small amount of urine becoming trapped in the U-bend of the bulbar urethra, which leaks out when the patient moves. Post-micturition dribble is more pronounced if associated with a urethral diverticulum or urethral stricture. It may occur in women with a urethral diverticulum and may mimic stress incontinence.

Clinical assessment

Patients should be encouraged to keep a voiding diary, including the measured volume voided, frequency of voiding, a note of incontinence pad usage, precipitating factors and associated features, such as urgency, since this can be of diagnostic value. Structured questionnaires may help objectively quantify symptoms. The patient should be assessed for evidence of cognitive impairment and impaired mobility. A neurological assessment should be performed to detect disorders such as multiple sclerosis that may affect the nervous supply of the bladder, and the lumbar spine should be inspected for features of spina bifida occulta. Perineal sensation and anal sphincter tone should be assessed. Rectal examination is needed to assess the prostate in men and to exclude faecal impaction as a cause of incontinence. Genital examination should be done to identify phimosis or paraphimosis in men, and vaginal mucosal atrophy, cystoceles or rectoceles in women.

Investigations

Urinalysis and culture should be performed in all patients. Ultrasound examination can be helpful in identifying patients with overflow incontinence who have incomplete bladder emptying, as it may reveal a significant amount of fluid in the bladder (> 100 mL) post-micturition. Urine flow rates and full urodynamic assessment by cystometrography may be required to diagnose the type of incontinence and are indicated in selected cases when the diagnosis is unclear on clinical grounds. A CT scan and cystoscopy should be performed in patients with continual incontinence who are suspected of having a fistula. Imaging with MRI is indicated when a urethral diverticulum is suspected.

Management

Weight reduction in obese patients will aid resolution of incontinence. Women with stress incontinence respond well to physiotherapy. The mainstay of treatment for urge incontinence is bladder retraining, which involves teaching patients to hold more urine voluntarily in their bladder, assisted by anticholinergic medication.

Surgery may be required in patients who have severe daytime incontinence despite conservative treatment. In neurologically intact patients, stress urinary incontinence in males is treated surgically by artificial urinary sphincter and in females by returning the urethra and bladder neck to their normal position with a pubovaginal sling or colposuspension. For urge incontinence, intravesical injection of botulinum neurotoxin type A has excellent results. Further surgical options are sacral nerve stimulation, detrusor myectomy or bladder augmentation.

The treatment of incontinence secondary to fistula formation is surgical. Patients with overflow incontinence due to bladder obstruction should be treated surgically or with long-term catheterisation (intermittent or continuous). Incontinence secondary to neurological diseases can be managed by intermittent self-catheterisation.

Prostate disease

Prostatitis

This results from inflammation of the prostate gland. Acute or chronic bacterial prostatitis can be caused by infection with the same bacteria that are associated with UTI (p. 640), but chronic prostatitis can also be 'non-bacterial', in which case no organism can be cultured from the urine. This is also known as chronic pelvic pain syndrome. Clinical features of prostatitis include frequency, dysuria, painful ejaculation, perineal or groin pain, difficulty passing urine and, in acute disease, considerable systemic disturbance. The prostate is enlarged and tender. Bacterial prostatitis is confirmed by a positive culture from urine or from urethral discharge obtained after prostatic massage, and the treatment of choice is a quinolone antibiotic. A 6-week course of antibiotics is required (see Box 18.46). Treatment of chronic pelvic pain syndrome is challenging, but some patients respond to a combination of α-adrenoceptor antagonists (α-blockers), NSAIDs and amitriptyline.

Benign prostatic enlargement

Benign prostatic enlargement (BPE) is extremely common. It has been estimated that about half of all men aged 80 years and over will have lower urinary tract symptoms associated with bladder outlet obstruction (BOO) due to BPE. Benign prostatic hyperplasia (BPH) is the histological abnormality that underlies BPE.

Pathophysiology

The prostate gland increases in volume by 2.4 cm^3 per year on average from 40 years of age. The process begins in the periurethral (transitional) zone and involves both glandular and stromal tissue to a variable degree. The cause is unknown, although BPE does not occur in patients with hypogonadism, suggesting that hormonal factors may be important.

Clinical features

The primary symptoms of BPE arise because of difficulty in voiding urine due to obstruction of the urethra by the prostate; these voiding symptoms consist of hesitancy, poor urinary flow and a sensation of incomplete emptying. Other storage symptoms include urinary frequency, urgency of micturition and urge incontinence, although these are not specific to BPE. Some patients present suddenly with acute urinary retention, when they are unable to micturate and develop a painful, distended bladder. This is often precipitated by excessive alcohol intake, constipation or prostatic infection. Severity of symptoms can be ascertained by using the International Prostate Symptom Score (IPSS) questionnaire (Box 18.53), which serves as a valuable starting point for assessment of the patient.

18.53 The International Prostate Symptom Score (IPSS)

Symptom	Question	Example score
Straining	How often have you had to push or strain to begin urination?	1
Urgency	How often have you found it difficult to postpone urination?	2
Intermittency	How often have you found that you stopped and started again several times when you urinated?	1
Emptying	How often have you had a sensation of not emptying your bladder completely after you finished urinating?	3
Frequency	How often have you had to urinate again less than 2 hours after you finished urinating?	1
Weak stream	How often have you had a weak urinary stream?	2
Nocturia	How many times did you most typically get up to urinate from the time you went to bed at night until the time you got up in the morning?	1
Total score		**11**

0 = not at all; 1 = less than one-fifth of the time; 2 = less than half the time; 3 = about half of the time; 4 = more than half of the time; 5 = almost always.
A score of 0–7 indicates mild symptoms, 8–19 moderate symptoms and 20–35 severe symptoms. In the example shown, the patient had moderate symptoms.

Once a baseline value is established, any improvement or deterioration may be monitored on subsequent visits. The IPSS is combined with a quality-of-life score, in which patients are asked the following question: 'If you were to spend the rest of your life with your urinary condition the way it is now, how would you feel about that?' Responses range from 0 (delighted) to 6 (terrible).

Patients may also present with chronic urinary retention. Here, the bladder slowly distends due to inadequate emptying over a long period of time. Patients with chronic retention can also develop acute retention: so-called acute-on-chronic retention. This condition is characterised by pain-free bladder distension, which may result in hydroureter, hydronephrosis and renal failure (high-pressure chronic retention, of which nocturnal incontinence is a pathognomonic symptom). On digital rectal examination (DRE), patients with BPE have evidence of prostatic enlargement with a smooth prostate gland. Abdominal examination may also reveal evidence of bladder enlargement in patients with urinary retention.

Investigations

The diagnosis of BOO secondary to BPE is a clinical one, but flow rates can be accurately measured with a flow meter, post-void residual volume of urine assessed with ultrasound, and prostate volume by transrectal ultrasound scan (TRUS). Objective assessment of obstruction is possible by urodynamics and should be undertaken if symptoms are mixed, with both voiding and storage making underlying pathophysiology uncertain and/or flow test equivocal for obstruction (<150 mL voided or >10 mL/s). If symptoms or signs, such as a palpable bladder, nocturnal enuresis, recurrent UTI or a history of renal stones, are present, renal function should be assessed; if it is abnormal, screening should be conducted for evidence of obstructive uropathy by ultrasound examination.

Management

Patients who present with acute retention require urgent treatment and should undergo immediate catheterisation to relieve the obstruction. Those with mild to moderate symptoms can be treated by medication (Box 18.54). The first-line treatments are α_{1A}-adrenoceptor blockers such as tamsulosin, which reduce the tone of smooth muscle cells in the prostate and bladder neck, thereby reducing the obstruction. The 5α-reductase inhibitors finasteride and dutasteride inhibit conversion of testosterone to the nine times more potent dihydrotestosterone in the prostate and so cause the prostate to reduce in size. This class of drugs is indicated in patients with an estimated prostate size of more than 30 g or a prostate-specific antigen (PSA) level of more than 1.4 ng/mL. Patients who fail to respond to a single drug may be treated with a combination of α-blockers and 5α-reductase inhibitors, since this is more efficacious than either agent alone. Symptoms that are resistant to medical therapy require surgical treatment to remove some of the prostate tissue that is causing urethral obstruction. This is usually achieved by transurethral resection of the prostate (TURP), but enucleation of the prostate by holmium or thulium laser or vaporisation by potassium-titanyl-phosphate (KTP) laser (Greenlight laser) is equally effective and has potentially fewer complications. Open surgery is very rarely needed, as very large glands can be treated with holmium laser treatment.

18.54 Treatment for benign prostatic enlargement

Medical

- Prostate <30 g: α-blockers
- Prostate >30 g: 5α-reductase inhibitors ± α-blockers

Surgical

- Transurethral resection of the prostate (TURP)
- Laser enucleation
- Laser vaporisation
- Open prostatectomy

Prostate cancer

Prostate cancer is the most common malignancy in men in the UK, with an incidence of ~170 per 100 000 population. It is also common in northern Europe and the United States (particularly in the African American population) but is rare in China and Japan. It is uncommon in India, but the incidence is increasing. Prostate cancer rarely occurs before the age of 50 and has a mean age at presentation of 70 years.

Pathophysiology

Prostate cancers tend to arise within the peripheral zone of the prostate, and almost all are adenocarcinomas. Metastatic spread to pelvic lymph nodes occurs early and metastases to bone, mainly the lumbar spine and pelvis, are common. Genetic factors are known to play an important role in pathogenesis, and multiple genetic loci have been found to predispose to the disease in genome-wide association studies. A family history of prostate cancer greatly increases a man's chances of developing the disease.

Clinical features

Most patients either are asymptomatic or present with lower urinary tract symptoms indistinguishable from BPE. On DRE the prostate may feel nodular and stony-hard, and the median sulcus may be lost, but up to 45% of cancers are impalpable. Symptoms and signs due to metastases are much less common at the initial presentation but may include back pain, weight loss, anaemia and obstruction of the ureters.

Investigations

Measurement of PSA levels in a peripheral blood sample, together with DRE, is the cornerstone of diagnosis. Prior to a PSA test, men should be given careful counselling about the limitations of the test: namely, a normal level does not exclude prostate cancer, while a high value does not confirm the diagnosis but will open a discussion about biopsy and possible future treatments with potential side-effects (Box 18.55). The need for radical treatment of localised prostate cancer is still not established; radical treatments have significant potential morbidity and mortality, yet early identification and treatment of prostate cancer may save lives. Current evidence suggests that population-based

i **18.55 Advantages and disadvantages of prostate-specific antigen (PSA) testing in order to identify men with prostate cancer**

Advantages

- Identification of prostate cancer at a treatable stage, which otherwise may not have been identified*

Disadvantages

- High false-positive rate: 50%–60% of men with an elevated PSA will not have prostate cancer
- High false-negative rate: 25% of men with a normal PSA have prostate cancer
- Leads to further invasive tests (biopsy) with morbidity (e.g. sepsis or bleeding)
- May lead to diagnosis of prostate cancer, which is often over-treated by surgery or radiotherapy with associated side-effects (e.g. impotence or incontinence)
- If PSA is elevated but biopsy is normal, there is a potential need for further testing and associated anxiety

*The advantages of identifying prostate cancer earlier than would be the case if the man developed symptomatic disease must be considered against the limitations of PSA testing.

screening for prostate cancer with PSA is of limited value, due in part to the fact that over 700 patients would need to be screened to cure 1 man of prostate cancer. Individuals suspected of having prostate cancer, based on an elevated PSA and/or abnormal DRE, should undergo transrectal or transperineal ultrasound-guided prostate biopsies. About 40% of patients with a serum PSA of 4.0–10 ng/mL or more will have prostate cancer on biopsy, although 25% of patients with a PSA of less than 4 ng/mL may also have prostate cancer. Occasionally, a small focus of tumour is found incidentally in patients undergoing TURP for benign hyperplasia. If the diagnosis of prostate cancer is confirmed, staging should be performed by pelvic MRI to assess the presence and extent of local involvement (Fig. 18.34). An isotope bone scan should be carried out if distant metastases are suspected (rare if the PSA is below 20 ng/mL); very high levels of serum PSA (> 100 ng/mL) almost always indicate distant bone metastases (Fig. 18.35). Following diagnosis, serial assessment of PSA levels is useful for monitoring response to treatment and disease progression.

Management

Tumour confined to the prostate is potentially curable by radical prostatectomy, radical radiotherapy or brachytherapy (implantation of small radioactive particles into the prostate). These options should be considered only in patients with more than 10 years' life expectancy. Patients who are found to have small-volume, low-grade disease do not appear to require specific treatment but should be followed up periodically with PSA testing, DRE and a schedule of biopsies; this is known as active surveillance. Prostate cancer, like breast cancer, is sensitive to steroid hormones; metastatic prostate cancer is treated by androgen depletion, involving either surgery (orchidectomy) or, more commonly, androgen-suppressing drugs. Androgen receptor blockers, such as bicalutamide or cyproterone acetate, may also prevent tumour cell growth. Gonadotrophin-releasing hormone (GnRH) analogues, such as goserelin, continuously occupy pituitary receptors, preventing them from responding to the GnRH pulses that normally stimulate luteinising hormone (LH) and follicle-stimulating hormone (FSH) release. Most of these agents initially cause an increase in testosterone before producing a prolonged reduction, and for this reason the initial dose must be covered with an androgen receptor blocker to prevent a tumour flare.

A small proportion of patients fail to respond to endocrine treatment. A larger number respond for a year or two, but then the disease progresses. Chemotherapy with docetaxel can then be effective and provide a modest (around 3 months) survival advantage. Newer hormonal agents such as enzalutamide and abiraterone acetate also provide some survival benefit. There is also a role for initial prostate radiotherapy in those with low volume metastatic prostate cancer. Radiotherapy is useful for localised bone pain but the basis of treatment remains pain control by analgesia (p. 175). Provided that patients do not die of another cause, the 10-year survival rate of patients with tumours localised to the prostate is 95%, but if metastases are present, this falls to 10%. Life expectancy is not reduced in patients with small foci of tumour.

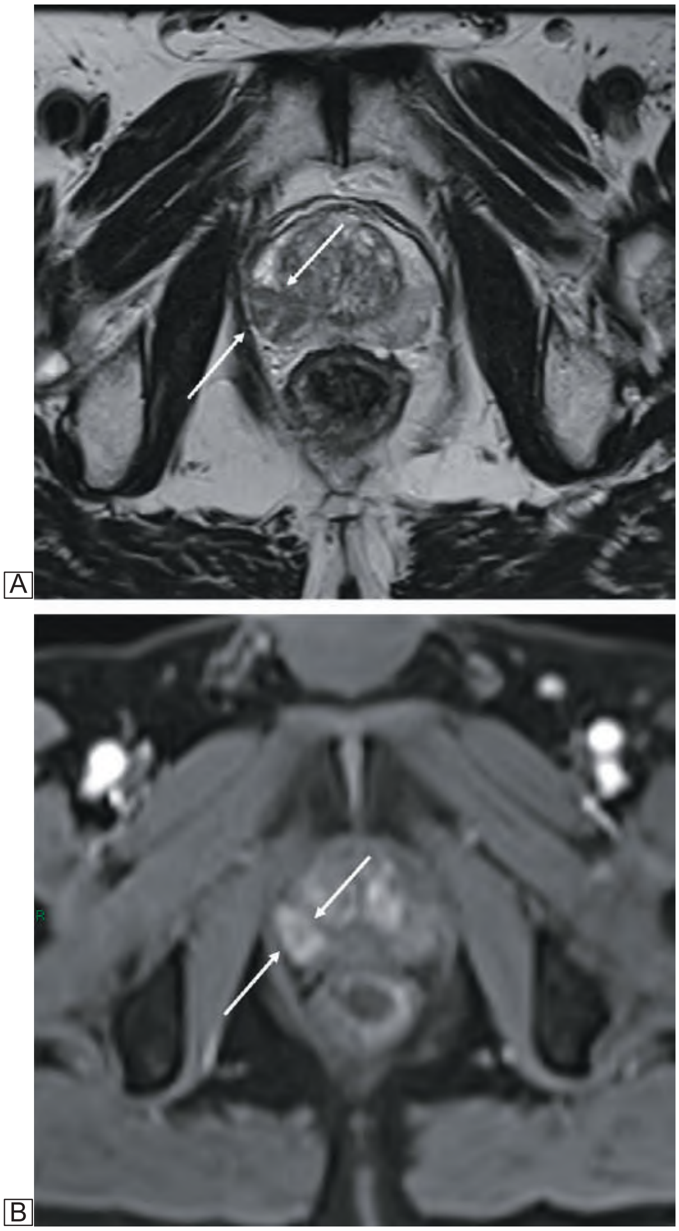

Fig. 18.34 Axial T2 prostate MRI scan (A) demonstrating low signal tumour focus within the peripheral zone of the right lateral lobe of the prostate gland with corresponding focus of contrast enhancement on the post contrast scan (B) (arrows).

Testicular tumours

Testicular tumours are uncommon, with a prevalence of 5 cases per 100 000 population. They occur mainly in young men aged between 20 and 40 years. They often secrete α-fetoprotein (AFP) and β-human chorionic gonadotrophin (β-hCG), which are useful biochemical markers for both diagnosis and prognosis. Seminoma and non-seminomatous germ cell tumours (NSGCT) account for ~85% of all tumours of the testis. Leydig cell tumours are less common.

Seminomas arise from seminiferous tubules and represent a relatively low-grade malignancy. Metastases can occur through lymphatic spread, however, and typically involve the lungs.

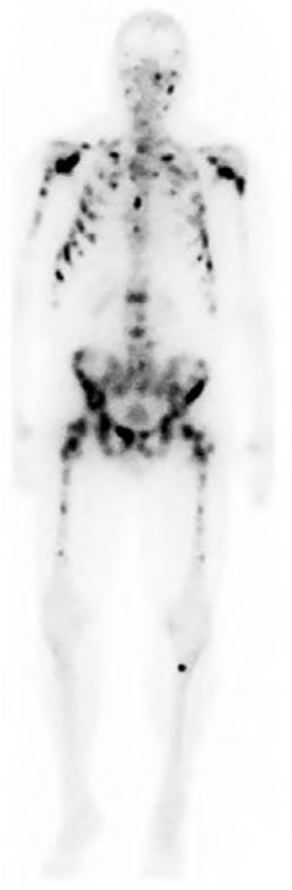

Fig. 18.35 **Whole body planar bone scan demonstrating multiple focal areas of isotope uptake consistent with multiple bone metastases in a patient with prostate cancer and PSA of 140 ng/mL.**

NSGCTs arise from primitive germinal cells and tend to occur at a younger age than seminomas. They may contain cartilage, bone, muscle, fat and a variety of other tissues, and are classified according to the degree of differentiation. Well-differentiated tumours are the least aggressive; at the other extreme, trophoblastic teratoma is highly malignant. Occasionally, teratoma and seminoma occur together.

Leydig cell tumours are usually small and benign but secrete oestrogens, leading to presentation with gynaecomastia.

Clinical features and investigations

The common presentation is incidental discovery of a painless testicular lump, although some patients complain of a testicular ache.

All suspicious scrotal lumps should be imaged by ultrasound. Serum levels of AFP and β-hCG are elevated in extensive disease. Oestradiol may be elevated, suppressing LH, FSH and testosterone. Accurate staging is based on CT of the lungs, liver and retroperitoneal area.

Management and prognosis

The primary treatment is surgical inguinal orchidectomy. Subsequent adjuvant treatment depends on the histological type and stage. Adjuvant chemotherapy with carboplatin is the treatment of choice for early stage but high-risk seminoma. NSGCTs confined to the testes may be managed conservatively, but more advanced cancers are treated with chemotherapy, usually with the combination of bleomycin, etoposide and cisplatin. Follow-up is by CT and assessment of LDH, AFP and β-hCG. Retroperitoneal lymph node dissection is performed for residual or recurrent nodal masses.

The 5-year survival rate for patients with seminoma is 90%–95%. For NSGCT, the 5-year survival varies between 60% and 95%, depending on tumour type, stage and volume.

i 18.56 Causes of erectile dysfunction

With reduced libido

- Hypogonadism
- Depression

With intact libido

- Psychological problems, including anxiety
- Vascular insufficiency (atheroma)
- Neuropathic causes (diabetes mellitus, alcohol excess, multiple sclerosis)
- Drugs (β-blockers, thiazide diuretics)

Erectile dysfunction

Causes of erectile failure are shown in Box 18.56. Vascular, neuropathic and psychological causes are most common. Exclusion of previously unrecognised cardiovascular disease is important in men presenting with erectile dysfunction. With the exception of diabetes mellitus, endocrine causes are relatively uncommon and are characterised by loss of libido, as well as erectile dysfunction. Erectile dysfunction and reduced libido occur in over 50% of men with advanced CKD or those on dialysis, and is a markedly under-diagnosed problem. It is important to discuss matters frankly with the patient, and to establish whether there are associated features of hypogonadism and if erections occur at any other time. If the patient has erections on wakening, vascular and neuropathic causes are much less likely, and a psychological cause should be suspected.

Investigations

Blood should be taken for glucose, lipids, prolactin, testosterone, LH and FSH. Several further tests are available but are rarely employed because they do not usually influence management. These include nocturnal tumescence monitoring (using a plethysmograph placed around the shaft of the penis overnight) to establish whether blood supply and nerve function are sufficient to allow erections to occur during sleep; intracavernosal injection of prostaglandin E_1 to test the adequacy of blood supply; and internal pudendal artery angiography.

Management

First-line therapy is usually with oral phosphodiesterase type 5 inhibitors, such as sildenafil, which elevate cyclic guanosine monophosphate (cGMP) levels in vascular smooth muscle cells of the corpus cavernosum, causing vasodilatation and penile erection. Co-administration of these drugs with nitric oxide donors, such as glycerol trinitrate, is contraindicated because of the risk of severe hypotension. Other treatments for impotence include self-administered intracavernosal injection or urethral administration of prostaglandin E1; vacuum devices that achieve an erection maintained by a tourniquet around the base of the penis; and prosthetic implants, either of a fixed rod or an inflatable reservoir. Psychotherapy involving the patient and sexual partner may be helpful for psychological problems. Erectile dysfunction associated with peripheral neuropathy and vascular disease is difficult to treat. If hypogonadism is detected, it should be managed as described on page 712.

Multiple Choice Questions

18.1. A previously well 5-year-old girl presents with leg and periorbital oedema and is found to have 4+ proteinuria on urine dipstick testing. Her renal function is normal. She has no family history of note. Her initial management should involve:

A. A kidney biopsy
B. No kidney biopsy, but treat initially with corticosteroids
C. Prophylactic antibiotics
D. No kidney biopsy, but treat initially with cyclophosphamide
E. An ACE inhibitor

Answer: B.

This child has nephrotic syndrome so this is very likely to be minimal change disease, such that a biopsy is usually not performed but treatment is commenced with corticosteroids. A biopsy is only considered in a child with nephrotic syndrome if they fail to respond adequately to corticosteroids. Prophylactic antibiotics are sometimes used in children with reflux nephropathy and recurrent UTIs but are not indicated in nephrotic syndrome. The proteinuria should resolve, often very quickly, with corticosteroids, so ACE inhibition is not warranted.

18.2. The following are valid therapeutic interventions for renal bone disease except:

A. Activated vitamin D supplementation
B. Parathyroidectomy
C. Injections of recombinant human parathyroid hormone (PTH)
D. Dietary phosphate restriction
E. Calcimimetic drugs (e.g. cinacalcet) which bind the calcium-sensing receptor on the parathyroid gland

Answer: C.

Renal bone disease is caused by decreased excretion of phosphate and decreased activation of vitamin D (i.e. impaired conversion of 25-hydroxyvitamin D to 1,25-dihydroxyvitamin D in the kidney). These events, as well as low calcium levels caused by low vitamin D activation, directly stimulate the parathyroid glands to produce PTH in an effort to correct the low calcium and high phosphate. Therefore, interventions such as activated vitamin D supplementation and dietary phosphate restriction will help. Reducing PTH levels either medically (calcimimetics) or surgically may be needed in resistant cases. Administering PTH will obviously not help.

18.3. A 64-year-old man presents with fever and shortness of breath. He has a history of type 2 diabetes, hypertension and chronic kidney disease and is prescribed lisinopril, amlodipine, metformin and simvastatin. Observations show: SaO_2 86% on FiO_2 35%, pulse 130 beats/min, BP 142/68 mmHg. He tests positive for SARS-CoV-2 and his condition deteriorates, and his increasing oxygen requirements necessitate his transfer to ICU for ventilation. He develops anuria and requires dialysis. What is the most likely cause of his acute decline in kidney function?

A. Acute tubular necrosis
B. Metformin
C. Obstructive nephropathy
D. Post-infectious glomerulonephritis
E. Pre-renal failure

Answer: A.

The tubular region of the kidneys is most susceptible to injury due to the relative hypoxia at baseline in the medulla and the high oxygen demand of the tubules. Intercurrent illness may cause AKI by promoting systemic hypoxia or reduced renal perfusion. SARS-CoV-2 can cause a number of kidney problems, including proteinuria, microthrombi and ATN through hypoxia or direct viral infection.

Metformin should be discontinued in AKI; however, this is due to the risk of accumulation of metformin leading to a lactic acidosis, and metformin per se does not cause kidney injury.

Obstructive nephropathy is a possibility given this man's age and the fact that he has developed anuria, but is much less likely in this context.

Post-infectious glomerulonephritis typically occurs after the infection and is less common with viral infections.

While there may have been an element of pre-renal failure earlier in his illness, his blood pressure is now adequate and the anuria implies that he has developed ATN. Hence, further fluid resuscitation is unlikely to result in recovery of renal function, and he will need dialysis support until his condition improves and his necrotic tubules regenerate. Unfortunately, the severity of his disease is consistent with a poor prognosis.

18.4. A 62-year-old man presents with shortness of breath, which came on suddenly during the night. He has noticed a wheeze, but no cough or sputum. He has end-stage renal disease due to diabetic nephropathy. He is anuric and has been on haemodialysis for 2 years and is due his regular dialysis session the next day. His observations are: temperature 37.6°C, SaO_2 88% on FiO_2 35%, pulse 120 bpm, BP 178/100 mmHg. What is the most likely cause of his shortness of breath?

A. Acidosis due to renal failure
B. Exacerbation of obstructive airways disease
C. Pulmonary embolus
D. Pulmonary oedema
E. Renal anaemia

Answer: D.

This is a classical presentation, where a patient with anuric end-stage renal disease on haemodialysis accumulates fluid between dialysis sessions and develops pulmonary oedema, with paroxysmal nocturnal dyspnoea prior to their next haemodialysis session.

While renal anaemia and acidosis can cause shortness of breath, they do not typically cause hypoxia. An exacerbation of obstructive airways disease is possible, given the wheeze, but there is no history of obstructive airways disease and a wheeze can also be present in pulmonary oedema.

Pulmonary embolus is also a cause of acute shortness of breath, but would be less likely than pulmonary oedema in this context.

18.5. A 66-year-old woman who smokes 15 cigarettes per day presents with painful visible haematuria, which persists despite treatment with two courses of oral antibiotics. What is the optimal next management step?

A. A course of intravenous antibiotics
B. Rigid cystoscopy under general anaesthetic
C. Flexible cystoscopy and upper tract imaging
D. Urine culture and CT urogram
E. Ureteroscopy

Answer: C.

Visible haematuria is a red flag symptom and should be investigated. Although the symptom may be due to a urinary tract infection, repeated courses of antibiotics should not be given; rather, urgent referral to a urologist should occur. The urology department will likely have a haematuria clinic where the patient can be investigated urgently with flexible cystoscopy (under local anaesthetic) to evaluate for intravesical lesions and upper tract imaging (ultrasound or CT urogram) to evaluate the upper urinary tract.

18.6. An otherwise fit and well 69-year-old man with a 6 cm biopsy-proven clear cell renal cell cancer and associated bilateral lung (largest lesion 4 cm diameter), bone and pancreatic metastases is best treated with which of the following treatments?

A. Tyrosine kinase inhibitor
B. Immediate cytoreductive nephrectomy
C. Nephrectomy and metastasectomies
D. Platinum-based chemotherapy
E. Anti-androgen therapy

Answer: A.

This is a case of widespread metastatic clear cell renal cell cancer. Recommended treatment is with systemic therapy, of which there are many options: tyrosine kinase inhibitors (TKIs), T-cell checkpoint inhibitors, mTOR inhibitors or a combination of TKIs with T-cell checkpoint inhibitors. Immediate cytoreductive nephrectomy is not recommended as there is no survival advantage over systemic therapy and may never be recommended unless there is a dramatic response to the metastatic disease burden. Multiple metastasectomies would be very morbid and very unlikely to be curative. Anti-androgen therapy is used in prostate cancer and platinum-based chemotherapy in urothelial cancers.

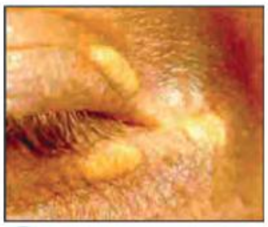
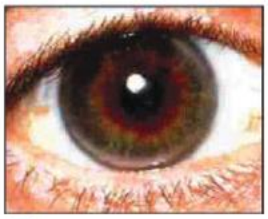
Clinical examination in biochemical and metabolic disorders

Many biochemical and metabolic disorders are clinically silent or present with non-specific manifestations and are first detected by laboratory testing. Several abnormalities can be picked up by history and physical examination, however, as summarised below.

Hyperlipidaemia

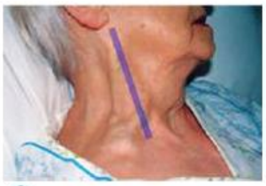


H Xanthelasma



G Corneal arcus

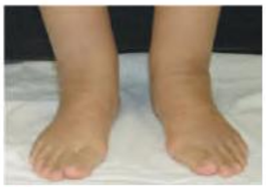
Hypervolaemia



F Raised jugular venous pressure

E Extra heart sounds

D Lung crepitations



C Ankle oedema

Hypovolaemia

B Low blood pressure

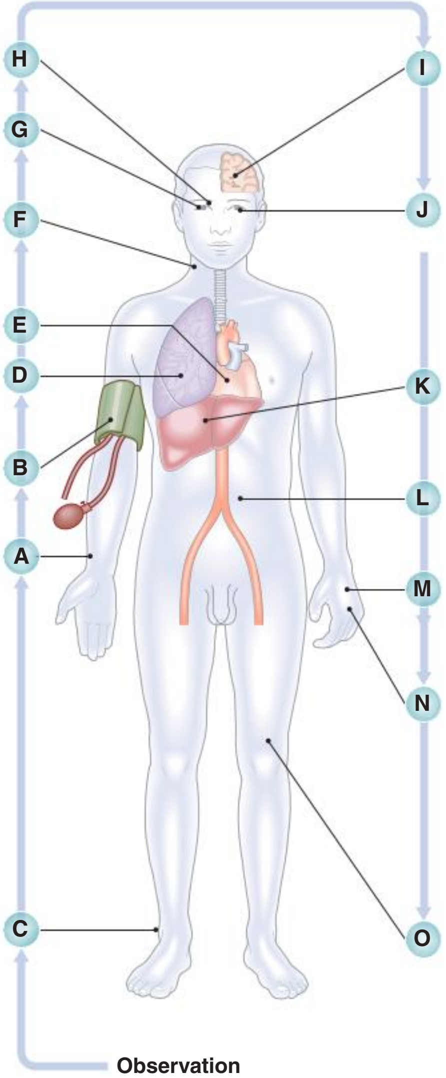
A Rapid pulse

Acute hypernatraemia

I Dizziness
Delirium
Weakness

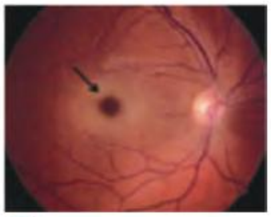
Acute hyponatraemia

I Cerebral oedema
Vomiting
Somnolence
Seizures
Coma



Observation
- General appearance
- Skin turgor
- Oedema
- Rash
- Eyes

Gangliosidosis



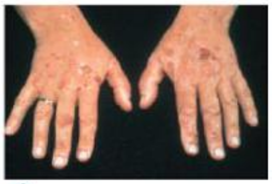
J Cherry-red spot fundus

Glycogen storage disease

K Hepatomegaly

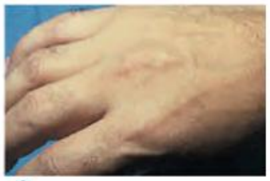
Porphyria

L Abdominal pain

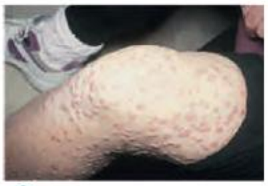


M Photosensitive rash

Hyperlipidaemia



N Tendon xanthoma



O Eruptive xanthoma

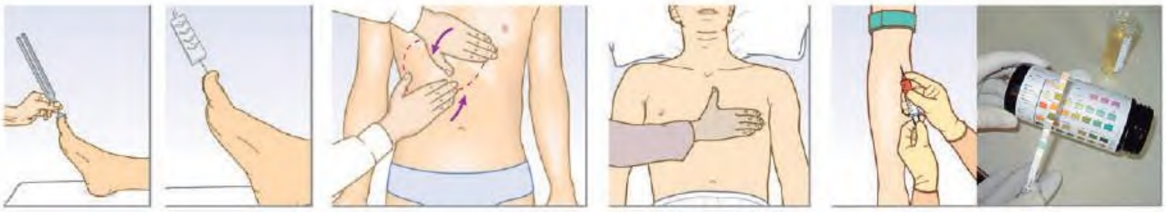
Examine for signs of multisystem disease



Check for peripheral neuropathy and for muscle tenderness or weakness

Check for hepato-splenomegaly

Check for cardiomegaly and arrhythmias

Check bloods and urine for metabolic biochemistry

There is a worldwide trend towards increased use of laboratory-based diagnostic investigations and biochemical investigations. In the healthcare systems of higher-income countries, it has been estimated that 60%–70% of all critical decisions taken about patients, and over 90% of data stored in electronic medical records systems, involve a laboratory service or result.

This chapter covers a diverse group of disorders affecting adults that are not considered elsewhere in this book, whose primary manifestation is in abnormalities of biochemistry laboratory results, or whose underlying pathophysiology involves disturbance in specific biochemical pathways.

Biochemical investigations

There are three broad reasons why a clinician may request a biochemical laboratory investigation:

- to screen an asymptomatic subject for the presence of disease
- to assist in diagnosis of a patient's presenting complaint
- to monitor changes in test results, as a marker of disease progression or response to treatment.

Contemporary medical practice has become increasingly reliant on laboratory investigation and, in particular, on biochemical investigation. This has been associated with extraordinary improvements in the analytical capacity and speed of laboratory instrumentation and the following operational trends:

- Large central biochemistry laboratories feature extensive use of automation and information technology. Specimens are transported from clinical areas to the laboratory using high-speed transport systems (such as pneumatic tubes) and identified with machine-readable labels (such as bar codes). Laboratory instruments have been miniaturised and integrated with robot transport systems to enable multiple rapid analyses of a single sample. Statistical process control techniques are used to assure the quality of analytical results, and increasingly to monitor other aspects of the laboratory, such as the time taken to complete the analysis ('turn-around time').
- Point-of-care testing (POCT) brings selected laboratory analytical systems into clinical areas, to the patient's bedside or even connected to an individual patient. These systems allow the clinician to receive results almost instantaneously for immediate treatment of the patient, although often with lesser precision or at greater cost than using a central laboratory.
- The diversity of analyses has widened considerably with the introduction of many techniques borrowed from the chemical or other industries (Box 19.1).

Good medical practice involves the appropriate ordering of laboratory investigations and correct interpretation of test results (Box 19.2). The key principles, including the concepts of sensitivity and specificity, are described in Chapter 1. Reference intervals for laboratory results are provided in Chapter 33. Many laboratory investigations can be subject to variability arising from whether the sample is being taken in the fed or fasted state; the timing of sample collection, in relation to diurnal variation of analytes; dosage intervals for therapeutic drug monitoring; sample type, such as serum, plasma; use of anticoagulants, such as ethylenediamine-tetra-acetic acid (EDTA), which can interfere with some assays; or artefacts, such as taking a venous sample proximal to the site of an intravenous infusion. It is therefore important for clinical and laboratory staff to communicate effectively and for clinicians to follow local recommendations concerning collection and transport of samples in the appropriate container and with appropriate labelling.

19.1 Range of analytical modalities used in the clinical biochemistry laboratory

Analytical modality	Analyte	Typical applications
Ion-selective electrodes	Blood gases, electrolytes (Na, K, Cl)	Point-of-care testing (POCT) High-throughput analysers
Colorimetric chemical reaction or coupled enzymatic reaction	Simple mass or concentration measurement (creatinine, phosphate) Simple enzyme activity	High-throughput analysers
Ligand assay (usually immunoassay)	Specific proteins Hormones Drugs	Increasingly available for POCT or high-throughput analysers
Chromatography: gas chromatography (GC), high-performance liquid chromatography (HPLC), thin-layer chromatography (TLC)	Organic compounds	Therapeutic drug monitoring (TDM)
Mass spectroscopy (MS)	Drugs Vitamins Organic compounds	Screening for drugs of misuse Vitamins Biochemical metabolites
Spectrophotometry, turbidimetry, nephelometry, fluorimetry	Haemoglobin derivatives Specific proteins Immunoglobulins	Xanthochromia Lipoproteins Paraproteins
Electrophoresis	Proteins Some enzymes	Paraproteins Isoenzyme analysis
Atomic absorption (AA) **Inductively coupled plasma/mass spectroscopy (ICP-MS)**	Trace elements and metals	Quantitation of heavy metals
Molecular diagnostics	Nucleic acid quantification and/or sequence	Inherited and somatic cell variants (Ch. 3) Genetic polymorphisms (Ch. 3) Variations in rates of drug metabolism (Ch. 2) Microbial diagnosis (Ch. 7)

19.2 How to interpret urea and electrolytes results*

Sodium

- Largely reflects changes in water balance
- See 'Hypernatraemia' and 'Hyponatraemia'

Potassium

- May reflect K shifts in and out of cells
- Low levels usually mean excessive losses (gastrointestinal or renal)
- High levels usually mean renal dysfunction
- See 'Hypokalaemia' and 'Hyperkalaemia'

Chloride

- Generally changes in parallel with plasma Na
- Low in metabolic alkalosis
- High in some forms of metabolic acidosis

Bicarbonate

- Abnormal in acid–base disorders
- See Box 19.18

Urea

- Increased with a fall in glomerular filtration rate (GFR), reduced renal perfusion or urine flow rate, and in high protein intake or catabolic states

Creatinine

- Increased with a fall in GFR, in individuals with high muscle mass, and with some drugs
- See Figure 18.2

*The term urea and electrolytes (U&Es) refers to urea, electrolytes and creatinine. In some countries this is abbreviated to EUC (electrolytes/urea/creatinine).

Water and electrolyte homeostasis

Total body water (TBW) is approximately 60% of body weight in an adult male, although the proportion is somewhat more for infants and less for women. In a 70 kg man, TBW is therefore about 40 L. Approximately 25 L is located inside cells (the intracellular fluid or ICF), while the remaining 15 L is in the extracellular fluid (ECF) compartment (see Fig. 19.1). Most of the ECF (approximately 12 L) is interstitial fluid, which is within the tissues but outside cells, whereas the remainder (about 3 L) is in the plasma compartment.

The ion composition between the main body fluid compartments intracellularly and extracellularly is illustrated in Figure 19.1. The dominant positively charged ion (cation) within cells is potassium, whereas phosphates and negatively charged proteins constitute the major intracellular negatively charged ions (anions). In the ECF the dominant cation is sodium, while chloride and, to a lesser extent, bicarbonate are the most important ECF anions. An important difference between the intravascular (plasma) and interstitial compartments of the ECF is that only plasma contains significant concentrations of protein.

The major force maintaining the difference in cation concentrations between the ICF and ECF is the sodium–potassium pump (Na,K-activated adenosine triphosphatase, ATPase), which is present in all cell membranes. Maintenance of these gradients is essential for many cell processes, including the excitability of conducting tissues such as nerve and muscle. The difference in protein content between the plasma and the interstitial fluid compartment is maintained by the impermeability of the capillary wall to protein. This protein concentration gradient (the colloid osmotic, or oncotic, pressure of the plasma) contributes to the balance of forces across the capillary wall that favour fluid retention within the plasma compartment.

The concentration of sodium in the ECF plays a pivotal role in determining plasma osmolality and thereby controlling intracellular volume through changes in water balance between the intracellular and extracellular space. In contrast, plasma volume is largely controlled by total body sodium, which determines volume change. Therefore, disturbances in water homeostasis typically present with biochemical abnormalities such as hyponatraemia or hypernatraemia, whereas disturbances in sodium homeostasis present with hypervolaemia or hypovolaemia as the result of expansion or contraction of ECF volume, respectively.

Fig. 19.1 Normal distribution of body water and electrolytes. Schematic representation of volume (L = litres) and composition (dominant ionic species only shown) of the intracellular fluid (ICF) and extracellular fluid (ECF) in a 70 kg male. The main difference in composition between the plasma and interstitial fluid (ISF) is the presence of appreciable concentrations of protein in the plasma but not the ISF. The Na/K differential is maintained by the Na,K-adenosine triphosphatase (ATPase) pump.

Sodium homeostasis

Most of the body's sodium is located in the ECF, where it is by far the most abundant cation. Accordingly, total body sodium is the principal determinant of ECF volume. Sodium intake varies widely between individuals, ranging between 50 and 250 mmol/24 hrs. The kidneys can compensate for these wide variations in sodium intake by increasing excretion of sodium when there is sodium overload, and retaining sodium in the presence of sodium depletion, to maintain normal ECF volume and plasma volume.

Functional anatomy and physiology

The functional unit for renal excretion is the nephron, which is illustrated in Figure 19.2. Blood undergoes ultrafiltration in the glomerulus, generating a fluid that is free from cells and protein, and which resembles plasma in its electrolyte composition. This is delivered into the renal tubules, where reabsorption of water and various electrolytes occurs. (More detail on the structure and function of the glomerulus is given in Ch. 18.) The glomerular filtration rate (GFR) is approximately 125 mL/min (equivalent to 180 L/24 hrs) in a normal adult. Over 99% of the filtered fluid is reabsorbed into the blood in the peritubular capillaries during its passage through successive segments of the nephron, mainly because of tubular reabsorption of sodium. The processes mediating sodium reabsorption, and the factors that regulate it, are key to understanding clinical disturbances and pharmacological interventions of sodium and fluid balance.

The nephron can be divided into four different functional segments in terms of sodium and water reabsorption (see Fig. 19.2).

Proximal renal tubule

About 65% of the filtered sodium load is reabsorbed in the proximal renal tubule. The cellular mechanisms are complex but some of the key features are shown in panel A of Figure 19.2. The key to sodium reabsorption from the luminal fluid rests on the basolateral (blood-side) of the cell, where large numbers of Na,K-ATPase pumps are present (black circle), which

Late distal tubule

Fig. 19.2 Anatomy of the nephron and principal transport mechanisms in different parts of the renal tubule. The apical membrane of tubular cells is the side facing the lumen and the basolateral membrane is the side facing the blood. Black circles indicate active transport pumps linked to ATP hydrolysis and other symbols indicate ion channels and transporter molecules (see text for more details). Details of the proportion of sodium reabsorbed, water permeability and sites of action for different classes of diuretics are shown. A. At the same site, acetazolamide inhibits carbonic anhydrase (CA), which, by reducing production of hydrogen ions by proximal tubular cells, inhibits sodium–hydrogen exchange through the NHE-3 transporter (pink circle). Loop diuretics block the NKCC2 transporter (white cylinder) in the loop of Henle B, whereas thiazide diuretics block the NCCT channel (orange cylinder) in the early distal tubule C. Amiloride and spironolactone block the ENaC channel (blue doughnut) in the late distal tubule and collecting ducts D. See text for further details and abbreviations. (aa = afferent arteriole; ea = efferent arteriole; md = macula densa)

transport sodium from the cells into the blood. This creates a low concentration of sodium within the cell that drives the passive reabsorption of sodium from the lumen into the epithelial cell. Transporters in the apical membrane are then able to couple sodium transport to the entry of various organic molecules, including glucose, amino acids, phosphate and others. An example of this is shown in Figure 19.2, where the reabsorption of Na is coupled to the reabsorption of glucose via the sodium-glucose co-transporter 2 (SGLT2) transport protein (yellow circle). Entry of sodium into the tubular cells at this site is also linked to secretion of H^+ ions, through the sodium–hydrogen exchanger (NHE-3) (pink circle). This relates to a complicated system responsible for bicarbonate reabsorption where HCO_3^- ions in the lumen are combined with H^+ ions to form carbonic acid (H_2CO_3). The H_2CO_3 is broken down to form H_2O and CO_2 in a reaction catalysed by carbonic anhydrase (CA) present on the luminal membrane of the tubular cell. The CO_2 and H_2O are then freely able to diffuse into the tubular cell. Within the tubular cell, H_2CO_3 is generated from H_2O and CO_2 by intracellular CA. The H_2CO_3 then dissociates spontaneously to produce H^+ ions, which are transported into the lumen by the NHE-3 transporter, and HCO_3^- ions, which are transported into the blood. This allows for almost complete reabsorption of bicarbonate in the proximal tubule. In addition, a large component of the transepithelial flux of sodium, water and other dissolved solutes occurs through gaps *between* the cells (the 'shunt' pathway). Overall, fluid and electrolyte reabsorption is almost isotonic in this segment, as water reabsorption is matched very closely to sodium fluxes, such that the osmolality of fluid passing into the loop of Henle is very similar to that of plasma. A component of this water flow also passes *through* the cells, via aquaporin-1 (AQP1) water channels (see Fig. 19.5), which are not sensitive to hormonal regulation. Acetazolamide and SGLT2 inhibitors both act on this segment to promote sodium excretion by their effects on carbonic anhydrase and the SGLT2 protein, respectively.

Loop of Henle

The thick ascending limb of the loop of Henle reabsorbs a further 25% of the filtered sodium but is impermeable to water, resulting in dilution of the luminal fluid, as illustrated in panel B in Figure 19.2. Again, the primary driving force is the Na,K-ATPase on the basolateral cell membrane (black circle), which creates a low intracellular concentration of sodium, but in this segment, sodium entry through the Na,K,2Cl (NKCC2, white cylinder) allows electroneutral entry of these ions into the renal tubular cell by balancing transport of cations (Na^+/K^+) with anions (Cl^-). Some of the potassium accumulated inside the cell recirculates across the apical membrane back into the lumen through the ROMK potassium channel (white circle), providing a continuing supply of potassium to match the high concentrations of sodium and chloride in the lumen. Due to this, a small positive transepithelial potential difference exists in the lumen of this segment relative to the interstitium, and this serves to drive cations such as sodium, potassium, calcium and magnesium between the cells, forming a reabsorptive shunt pathway. Loop diuretics like furosemide inhibit sodium reabsorption in this segment by inhibiting the NKCC2 transporter.

Early distal renal tubule

The early distal tubule (also called distal convoluted tubule) is responsible for reabsorption of about 7% of the filtered sodium load, as shown in panel C in Figure 19.2. This is again primarily driven by the activity of the basolateral Na,K-ATPase (black circle). In this segment, entry of sodium into the cell from the luminal fluid occurs via the NCCT sodium–chloride co-transport carrier (orange cylinder). This segment is also impermeable to water, resulting in further dilution of the luminal fluid. There is no significant transepithelial flux of potassium in this segment, but calcium is reabsorbed in exchange for sodium, where a basolateral sodium–calcium exchanger (blue cylinder) leads to low intracellular concentrations of calcium, promoting calcium entry from the luminal fluid through a calcium channel (blue ellipse). Thiazide diuretics inhibit sodium reabsorption in this segment by inhibiting the NCCT transporter.

Late distal renal tubule and collecting ducts

The late distal tubule and cortical collecting duct are anatomically and functionally continuous (panel D in Fig. 19.2). Here, sodium entry from the luminal fluid into principal cells occurs through the epithelial sodium channel (ENaC), generating a substantial lumen-negative transepithelial potential difference. This sodium flux into the tubular cells is balanced by secretion of potassium and hydrogen ions into the lumen and by reabsorption of chloride ions. Potassium passes into the luminal fluid down its electrochemical gradient, through an apical potassium channel (ROMK) in the principal cells (white circle). Hydrogen ion secretion is mediated by an H^+-ATPase (black triangle) located on the luminal membrane of the α-intercalated cells. Beta-intercalated cells secrete bicarbonate and both cell types participate in the excretion of ammonia and ammonium. The distal tubule and collecting duct have a variable permeability to water, depending on circulating levels of arginine vasopressin (AVP, also known as antidiuretic hormone, ADH). All ion transport processes in this segment are stimulated by the steroid hormone aldosterone, which can increase sodium reabsorption to a maximum of 2%–3% of the filtered sodium load. Amiloride and spironolactone both reduce sodium reabsorption in this segment by inhibiting the activity of the ENaC transporter (blue doughnut), either directly, as in the case of amiloride, or by inhibiting the effects of aldosterone, as is the case with spironolactone.

Regulation of sodium transport

The amount of sodium excreted by the kidney is dependent on the filtered load of sodium (which is principally determined by GFR) and the control of tubular sodium reabsorption. Several interrelated mechanisms serve to maintain whole-body sodium balance, and hence ECF volume, by matching urinary sodium excretion to sodium intake (Fig. 19.3), and controlling those two processes.

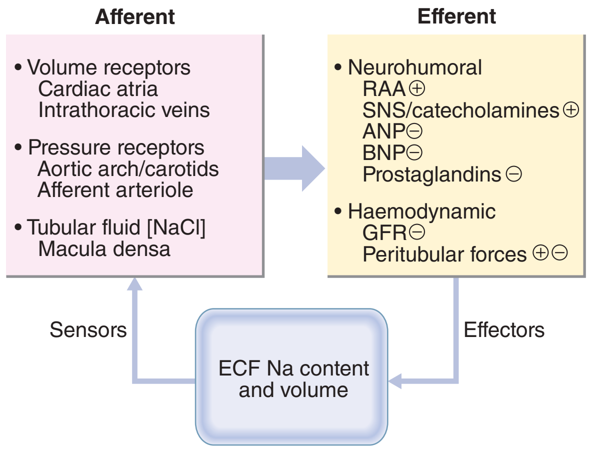

Fig. 19.3 Mechanisms involved in the regulation of sodium transport. ⊕ indicates an effect to stimulate Na reabsorption and hence reduce Na excretion, while ⊖ indicates an effect to inhibit Na reabsorption and hence increase Na excretion. (ANP = atrial natriuretic peptide; BNP = brain natriuretic peptide; ECF = extracellular fluid; GFR = glomerular filtration rate; RAA = renin–angiotensin–aldosterone system; SNS = sympathetic nervous system)

Important sensing mechanisms include volume receptors in the cardiac atria and the intrathoracic veins, as well as pressure receptors located in the central arterial tree (aortic arch and carotid sinus) and the afferent arterioles within the kidney. A further afferent signal is generated within the kidney itself: the enzyme renin is released from specialised smooth muscle cells in the walls of the afferent and efferent arterioles, at the point where they make contact with the early distal tubular cells of the macula densa to form the juxtaglomerular apparatus (see Fig. 19.2). Renin release is stimulated by:

- reduced perfusion pressure in the afferent arteriole
- increased sympathetic nerve activity
- decreased sodium chloride concentration in the distal tubular fluid.

Renin acts on the peptide substrate, angiotensinogen (which is produced by the liver), to produce angiotensin I, which is cleaved by angiotensin-converting enzyme (ACE), largely in the pulmonary capillary bed, to produce angiotensin II. Angiotensin II has multiple actions: it stimulates proximal tubular sodium reabsorption and release of aldosterone from the zona glomerulosa of the adrenal cortex and causes vasoconstriction of small arterioles (see Fig. 20.19). Aldosterone amplifies sodium retention by its action on the cortical collecting duct. The net effect of activation of the renin–angiotensin system is to raise blood pressure and cause sodium and water retention, thereby correcting hypovolaemia.

Changes in GFR alter peritubular hydrostatic pressure and oncotic pressure in opposite directions, resulting in a change in sodium reabsorption. In particular, with hypovolaemia, and a reduction in hydrostatic pressure and an increase in oncotic pressure, there is an increase in sodium reabsorption.

The sympathetic nervous system also acts to increase sodium retention, both through haemodynamic mechanisms (afferent arteriolar vasoconstriction and GFR reduction) and by direct stimulation of proximal tubular sodium reabsorption. In contrast, other humoral mediators, such as the natriuretic peptides (atrial natriuretic peptide and brain natriuretic peptide), which inhibit sodium reabsorption, contribute to natriuresis during periods of sodium and volume excess.

Increases in sodium intake cause hypervolaemia, which increases renal perfusion and GFR and suppresses renin production through increased delivery of sodium into the macula densa. This sets in motion a train of events opposite to those that occur in hypovolaemia, to cause an increase in sodium excretion.

Presenting problems in sodium balance

When the balance of sodium intake and excretion is disturbed, any tendency for plasma sodium concentration to change is usually corrected by the osmotic mechanisms controlling water balance. As a result, disorders in sodium balance present chiefly as alterations in the ECF volume, resulting in hypovolaemia or hypervolaemia, rather than as an alteration in plasma sodium concentration. Clinical manifestations of altered ECF volume are illustrated in Box 19.3.

Hypovolaemia

Hypovolaemia is defined as a reduction in circulating blood volume. The most common causes are loss or sequestration of sodium-containing fluids and acute blood loss, as summarised in Box 19.4.

Pathogenesis

Loss of sodium-containing fluid triggers the changes in renal sodium handling and activation of the renin–angiotensin system that were described earlier in this chapter. Loss of whole blood, as in acute haemorrhage, is another cause of hypovolaemia, and elicits the same mechanisms for the conservation of sodium and water as loss of sodium-containing fluid.

Clinical assessment

Hypovolaemia is primarily a clinical diagnosis, based on characteristic symptoms such as thirst, dizziness and weakness along with characteristic clinical signs (see Box 19.3) in the context of a relevant precipitating illness.

Investigations

Serum sodium concentrations do not reflect total body sodium and are therefore not helpful in making the diagnosis of hypovolaemia. The GFR is usually maintained unless the hypovolaemia is very severe or prolonged, but urinary flow rate is reduced because of activation of sodium- and water-retaining mechanisms in the nephron. Serum creatinine, which reflects GFR, is usually normal, but serum urea concentration is typically elevated due to a low urine flow rate, which is accompanied by increased tubular reabsorption of urea. Similarly, serum uric acid may also rise, reflecting increased reabsorption in the proximal renal tubule. The urine sodium concentration appropriately falls, and sodium excretion may reduce to less than 0.1% of the filtered sodium load.

19.3 Clinical features of hypovolaemia and hypervolaemia

	Hypovolaemia	Hypervolaemia
Symptoms	Thirst Dizziness on standing Weakness	Ankle swelling Abdominal swelling Breathlessness
Signs	Postural hypotension Tachycardia Dry mouth Reduced skin turgor Reduced urine output Weight loss Delirium, stupor	Peripheral oedema Raised JVP Pulmonary crepitations Pleural effusion Ascites Weight gain Hypertension (sometimes)

(JVP = jugular venous pressure)

19.4 Causes of hypovolaemia

Mechanism	Examples
Inadequate sodium intake	Environmental deprivation, inadequate therapeutic replacement
Gastrointestinal sodium loss	Vomiting, diarrhoea, nasogastric suction, external fistula
Skin sodium loss	Excessive sweating, burns
Renal sodium loss	Diuretic therapy, mineralocorticoid deficiency, tubulointerstitial disease
Internal sequestration*	Bowel obstruction, peritonitis, pancreatitis, crush injury
Reduced blood volume	Acute blood loss

*A cause of circulatory volume depletion, although total body sodium and water may be normal or increased.

Management

Management of sodium and volume depletion has two main components:

- treat the cause where possible, to stop ongoing salt and volume losses
- replace the salt and water deficits, and provide ongoing maintenance requirements, usually by intravenous fluid replacement when depletion is severe.

Intravenous fluid therapy

Intravenous fluid therapy can be used to maintain water, sodium and potassium intake when the patient is fasting, such as during an acute illness or post-operatively. If any deficits or continuing pathological losses are identified, additional fluid and electrolytes will be required. In prolonged periods of fasting (more than a few days), attention also needs to be given to providing sufficient caloric and nutritional intake to prevent excessive catabolism of body energy stores. The daily maintenance requirements for water and electrolytes in a typical adult are shown in Box 19.5, and the composition of some widely available intravenous fluids is given in Box 19.6. The choice of fluid and the rate of administration depend on the clinical circumstances, as assessed at the bedside and from laboratory data, as described in Box 19.7.

The choice of intravenous fluid therapy in the treatment of significant hypovolaemia relates to the concepts in Figure 19.1. If fluid containing neither sodium nor protein is given, it will distribute in the body fluid compartments in proportion to the normal distribution of total body water. For example, administration of 1 L of 5% dextrose contributes little (approximately 3/40 of the infused volume) towards expansion of the plasma volume, which makes this fluid unsuitable for restoring the circulation and perfusion of vital organs. Intravenous infusion of an isotonic (normal) saline solution, on the other hand, is more effective at expanding the ECF, although only a small proportion (about 3/15) of the infused volume actually contributes to plasma volume.

Whilst it would appear that solutions containing plasma proteins (colloids) would be better retained within the vascular space and be more effective at correcting hypovolaemia than protein-free fluids (crystalloids), clinical studies have not shown any advantage of giving albumin-containing infusions in the treatment of acute hypovolaemia and indeed have demonstrated increased morbidity related to their use. Therefore, crystalloids are the fluid of choice for resuscitation in acute hypovolaemia. More studies, however, are required to clarify the most appropriate crystalloid in this situation, given that normal saline can cause a mild metabolic acidosis, perhaps related to excessive chloride loading, whereas ‘balanced solutions’, such as Hartmann’s, may cause a mild hyponatraemia, as their composition is slightly hypotonic.

Hypervolaemia

Hypervolaemia is the result of sodium and water excess and is rare in patients with normal cardiac and renal function, since the kidney has a

19.5 Basic daily water and electrolyte requirements

	Requirement per kg	Typical 70 kg adult
Water	35–45 mL/kg	2.45–3.15 L/24 hrs
Sodium	1.5–2 mmol/kg	105–140 mmol/24 hrs
Potassium	1.0–1.5 mmol/kg	70–105 mmol/24 hrs

19.6 Composition of some isotonic intravenous fluids

Fluid	D-glucose	Calories	Na^+ (mmol/L)	Cl^- (mmol/L)	Other (mmol/L)
5% dextrose	50 g	200	0	0	0
Normal (0.9%) saline	0	0	154	154	0
Hartmann's solution	0	0	131	111	K^+ 5 Ca^{2+} 2 $Lactate^-$ 29

19.7 How to assess fluid and electrolyte balance in hospitalised patients

Step 1: assess clinical volume status

- Examine patient for signs of hypovolaemia or hypervolaemia (see Box 19.3)
- Check daily weight change

Step 2: review fluid balance chart

- Check total volumes IN and OUT on previous day (IN–OUT is positive by ~400 mL in normal balance, reflecting insensible fluid losses of ~800 mL and metabolic water generation of ~400 mL)
- Check cumulative change in daily fluid balance over previous 3–5 days
- Correlate chart figures with weight change and clinical volume status to estimate net fluid balance

Step 3: assess ongoing fluid losses

- Check losses from gastrointestinal tract and surgical drains
- Estimate increased insensible losses (e.g. in fever) and internal sequestration ('third space')

Step 4: check plasma U&Es (see Box 19.2)

- Check plasma Na as marker of relative water balance
- Check plasma K as a guide to extracellular K balance
- Check HCO_3 as a clue to acid–base disorder
- Check urea and creatinine to monitor renal function

Step 5: prescribe appropriate intravenous fluid replacement therapy

- Replace basic water and electrolytes each day (see Box 19.5)
- Allow for anticipated oral intake and pathological fluid loss
- Adjust amounts of water (if IV, usually given as isotonic 5% dextrose), sodium and potassium according to plasma electrolyte results

(IV = intravenous; U&Es = urea and electrolytes)

large capacity to increase renal excretion of sodium and water via the homeostatic mechanisms described earlier in the chapter.

Pathogenesis

The most common systemic disorders responsible for hypervolaemia are outlined in Box 19.8. In cardiac failure, cirrhosis and nephrotic syndrome, sodium retention occurs in response to circulatory insufficiency caused by the primary disorder, as illustrated in Figure 19.4. The pathophysiology is different in kidney failure, when the primary cause of volume expansion is the profound reduction in GFR impairing sodium and water excretion, while secondary tubular mechanisms are of lesser importance. In primary hyperaldosteronism (Conn syndrome), the pathophysiology also differs, in that increased secretion of aldosterone directly stimulates sodium reabsorption.

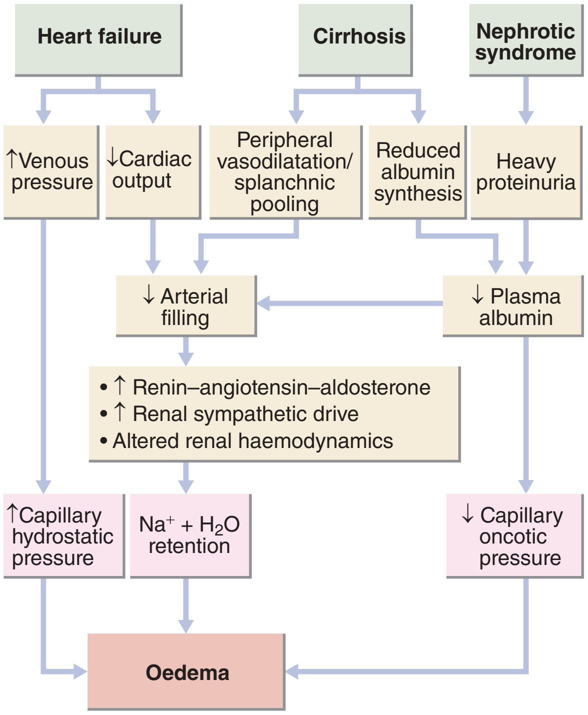
Clinical assessment

Peripheral oedema is the most common physical sign of hypervolaemia since the excess fluid leaks out of the capillaries to expand the interstitial compartment of the ECF. This is particularly the case in nephrotic syndrome and chronic liver disease, in which hypoalbuminaemia is a prominent feature. The main exception is Conn syndrome, which presents with hypertension and often hypokalaemia, but in which peripheral oedema is unusual.

19.8 Causes of sodium and water excess

Mechanism	Examples
Impaired renal function	Primary renal disease
Primary hyperaldosteronism*	Conn syndrome
Secondary hyperaldosteronism (see Fig. 19.5)	Congestive cardiac failure Cirrhotic liver disease Nephrotic syndrome Protein-losing enteropathy Malnutrition Idiopathic/cyclical oedema Renal artery stenosis*

*Conditions in this box *other than* primary hyperaldosteronism and renal artery stenosis are typically associated with generalised oedema.



Heart failure
Cirrhosis
Nephrotic syndrome
↑Venous pressure
↓Cardiac output
Peripheral vasodilatation/ splanchnic pooling
Reduced albumin synthesis
Heavy proteinuria
↓ Arterial filling
↓ Plasma albumin
• ↑ Renin–angiotensin–aldosterone
• ↑ Renal sympathetic drive
• Altered renal haemodynamics
↑Capillary hydrostatic pressure
$Na^+ + H_2O$ retention
↓ Capillary oncotic pressure
Oedema

Fig. 19.4 Secondary mechanisms causing sodium excess and oedema in cardiac failure, cirrhosis and nephrotic syndrome. Primary renal retention of Na and water may also contribute to oedema formation when glomerular filtration rate is significantly reduced (see Box 19.8).

Investigations

Although hypervolaemia is accompanied by an excess of total body sodium, serum sodium concentrations tend to be normal due to the accompanying water retention. Serum concentrations of potassium are normal except in Conn syndrome, where there is hypokalaemia due to the increased aldosterone production. Creatinine, GFR and urea are usually normal, unless the underlying cause of hypervolaemia is renal failure. General investigations may reveal evidence of cardiac, renal or liver disease.

Management

The management of hypervolaemia involves several components:

- specific treatment directed at the underlying cause, such as ACE inhibitors in heart failure and glucocorticoids in minimal change nephropathy
- restriction of dietary sodium (to 50–80 mmol/24 hrs) to match the diminished excretory capacity
- fluid restriction.

Diuretic therapy

Diuretics play a pivotal role in the treatment of hypervolaemia due to salt and water retention and in hypertension. They act by inhibiting sodium reabsorption at various locations along the nephron (see Fig. 19.2). Their potency and adverse effects relate to their mechanism and site of action.

Carbonic anhydrase inhibitors Acetazolamide is a carbonic anhydrase inhibitor that inhibits intracellular production of H^+ ions in the proximal tubule, reducing the fraction of sodium reabsorption that is exchanged for H^+ by the apical membrane sodium–hydrogen exchanger. It is a weak diuretic but is seldom used clinically for this purpose, since only a small fraction of proximal sodium reabsorption uses this mechanism, and much of the sodium that is not reabsorbed in the proximal tubule can be reabsorbed by downstream segments of the nephron. Its use is also complicated by metabolic acidosis due to reduction in proximal bicarbonate reabsorption.

Sodium glucose co-transporter 2 inhibitors Inhibitors of the sodium-dependent glucose transporter 2 (SGLT2), such as dapagliflozin, empagliflozin and canagliflozin, simultaneously block glucose and sodium reabsorption in the proximal tubule. They have mild diuretic properties and by reducing sodium reabsorption are able to reduce tubuloglomerular feedback. They were developed to lower blood glucose in the treatment of diabetes (Ch. 18), but are now also used in chronic kidney disease (see page 632) and heart failure.

Loop diuretics Loop diuretics, such as furosemide, inhibit sodium reabsorption in the thick ascending limb of the loop of Henle, by blocking the action of the apical membrane NKCC2 co-transporter. Because this segment reabsorbs a large fraction of the filtered sodium, these drugs are potent diuretics and are commonly used in diseases associated with significant oedema. Loop diuretics cause excretion not only of sodium (and with it, water) but also of potassium. This occurs chiefly because of delivery of increased amounts of sodium to the late distal tubule and cortical collecting ducts, where sodium reabsorption is associated with secretion of potassium, and is amplified if circulating aldosterone levels are high.

Thiazide diuretics Thiazide diuretics inhibit sodium reabsorption in the early distal tubule by blocking the NCCT co-transporter in the apical membrane. Since this segment reabsorbs a much smaller fraction of the filtered sodium, these are less potent than loop diuretics but are widely used in the treatment of hypertension and less severe oedema. Like loop diuretics, thiazides increase excretion of potassium through delivery of increased amounts of sodium to the late distal tubule and collecting duct. They are the diuretics that are most likely to be complicated by the development of hyponatraemia (p. 666).

Potassium-sparing diuretics Potassium-sparing diuretics act on the late distal renal tubule and cortical collecting duct segment to inhibit sodium reabsorption. Since sodium reabsorption and potassium secretion are linked at this site, the reduced sodium reabsorption is accompanied by reduced potassium secretion. The apical sodium channel ENaC (see Fig. 19.2) is blocked by amiloride and triamterene, while spironolactone and eplerenone also act at this site by blocking binding of aldosterone to mineralocorticoid receptors, thereby blocking ENaC activity.

Osmotic diuretics These act independently of a specific transport mechanism. As they are freely filtered at the glomerulus but not reabsorbed by any part of the tubular system, they retain fluid osmotically within the tubular lumen and limit the extent of sodium reabsorption in multiple segments. Mannitol is the most commonly used osmotic diuretic. It is given by intravenous infusion to achieve short-term diuresis in conditions such as cerebral oedema.

Clinical use of diuretics

The following principles should be observed when using diuretics:

- Use the minimum effective dose. When commencing diuretics or increasing the dose, monitor fluid status and increase the dose until the desired effect is achieved.
- Use for as short a period of time as necessary.
- Monitor regularly for adverse effects.

The choice of diuretic is determined by the potency required, the presence of coexistent conditions and the side-effect profile.

Adverse effects encountered with the most frequently used classes of diuretic (loop drugs and thiazide drugs) are summarised in Box 19.9. Volume depletion and electrolyte disorders are the most common, as predicted from their mechanism of action. The metabolic side-effects listed are rarely of clinical significance and may reflect effects on K^+ channels that influence insulin secretion. Since most drugs from these classes are sulphonamides, there is a relatively high incidence of hypersensitivity reactions and occasional idiosyncratic side-effects in a variety of organ systems.

The side-effect profile of the potassium-sparing diuretics differs in several important respects from that of other diuretics. The disturbances in potassium, magnesium and acid–base balance are in the opposite direction, so that normal or increased levels of potassium and magnesium are found in the blood, and there is a tendency to metabolic acidosis, especially when renal function is impaired.

An important feature of the most commonly used diuretic drugs (furosemide, thiazides and amiloride) is that they act on their target molecules from the luminal side of the tubular epithelium. Since they are highly protein-bound in the plasma, very little reaches the urinary fluid by glomerular filtration, but there are active transport mechanisms for secreting organic acids and bases, including these drugs, across the proximal tubular wall into the lumen, resulting in adequate drug concentrations being delivered to later tubular segments. This secretory process may be impaired by certain other drugs and by accumulated organic anions as occurs in chronic kidney disease and chronic liver failure, leading to resistance to diuretics. The transport protein is also responsible for the

19.9 Adverse effects of loop-acting and thiazide diuretics

Renal side-effects

- Hypovolaemia
- Hyponatraemia
- Hypokalaemia
- Metabolic alkalosis
- Hyperuricaemia
- Hypomagnesaemia
- Hypercalciuria (loop)
- Hypocalciuria (thiazide)

Metabolic side-effects

- Glucose intolerance/hyperglycaemia
- Hyperlipidaemia

Miscellaneous side-effects

- Hypersensitivity reactions
- Erectile dysfunction
- Acute pancreatitis/cholecystitis (thiazide)

secretion of uric acid, so the use of these diuretics can competitively inhibit this process and result in gout.

Diuretic resistance refers to the inability to adequately enhance fluid and sodium excretion to alleviate volume overload, oedema or congestion, even when diuretic doses are increased to their maximum effective level. This phenomenon can occur due to several factors:

- Renal impairment: A decrease in renal blood flow (RBF) reduces the amount of diuretic delivered to the kidneys, while a decline in GFR decreases sodium delivery to the tubules. Both reductions in RBF and GFR can contribute to diuretic resistance. Additionally, elevated levels of organic acids may inhibit tubular secretion of diuretics.
- Hypoproteinemia: Since loop diuretics bind to albumin, low protein levels increase their distribution in the body and reduce their availability for renal secretion. Moreover, proteinuria can further compromise the diuretic effect by causing secreted diuretics to bind to filtered albumin in the tubular fluid.
- Reduced oral bioavailability: Poor absorption of oral diuretics can limit their effectiveness.
- Activation of sodium-retaining mechanisms: Compensatory mechanisms that promote sodium retention can counteract the effects of diuretics.

To manage this condition, patients may require higher doses of diuretics, short-term intravenous (IV) therapy or a combination of diuretics that target different segments of the nephron.

Either a loop or a thiazide drug can be combined with a potassium-sparing drug, and all three classes can be used together for short periods, with carefully supervised clinical and laboratory monitoring. In certain cases, diuretics may be administered alongside an albumin infusion to enhance protein binding and improve tubular secretion. However, it is important to note that evidence supporting this approach is limited, and albumin infusions carry their own risks.

Water homeostasis

Daily water intake can vary from about 500 mL to several litres a day. About 800 mL of water is lost daily through the stool, sweat and the respiratory tract (insensible losses) and about 400 mL is generated daily through oxidative metabolism (metabolic water). The kidneys are chiefly responsible for adjusting water excretion to balance intake, endogenous production and losses to maintain total body water content and serum osmolality within the reference range of 280–296 mOsmol/kg.

Functional anatomy and physiology

While regulation of total ECF volume is principally achieved through renal control of sodium excretion, mechanisms exist to allow for the excretion of urine that is hypertonic or hypotonic in relation to plasma to maintain constant plasma osmolality.

These functions are largely achieved by the loop of Henle and the collecting ducts (see Fig. 19.2). The countercurrent configuration of flow in adjacent limbs of the loop (Fig. 19.5) involves osmotic movement of water from the descending limbs and reabsorption of solute from neighbouring ascending limbs, to set up a gradient of osmolality from isotonic (like plasma) in the renal cortex to hypertonic (around 1200 mOsmol/kg) in the inner part of the medulla. At the same time, the fluid emerging from the thick ascending limb is hypotonic compared to plasma because it has been diluted by the reabsorption of sodium, but not water, from the thick ascending limb and is further diluted in the early distal tubule. As this dilute fluid passes from the cortex through the collecting duct system to the renal pelvis, it traverses the medullary interstitial gradient of osmolality set up by the operation of the loop of Henle, and water is able to be reabsorbed. Whether water is reabsorbed at this point via aquaporin ducts inserted into the collecting duct to concentrate the urine or whether the duct becomes impermeable to water allowing for dilute

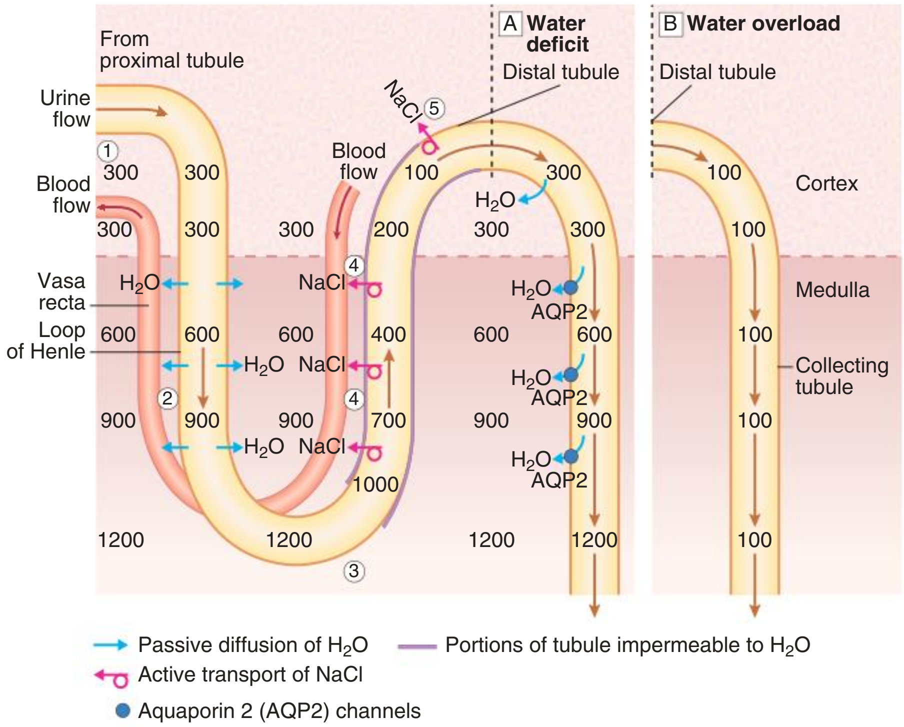


Fig. 19.5 **Mechanisms of renal water handling**. (1) Filtrate from the proximal tubule is isosmotic to plasma and cortical interstitial fluid. (2) Water moves down its osmotic gradient, concentrating the filtrate but not diluting the interstitium, as the vasa recta carries away the water. (3) The filtrate is at its highest concentration at the bend of the loop and therefore the surrounding medulla is also concentrated. (4) NaCl is pumped out of the filtrate in the thick ascending limb and early distal tubule, increasing the interstitial fluid osmolality. (5) The filtrate has a concentration of 100 mOsmol/kg as it leaves the early distal tubule. **A** In the face of water deficit, vasopressin levels rise, causing AQP2 channels to migrate to the luminal side of the cell membrane increasing water permeability of the collecting ducts, resulting in osmotic reabsorption of water. **B** In the situation of water overload, vasopressin secretion is suppressed, AQP2 channels are held intracellularly, rendering the collecting ducts impermeable to water, resulting in production of a dilute urine.

urine to be excreted depends on the presence or absence of the circulating level of vasopressin, respectively. Vasopressin is released by the posterior pituitary gland under conditions of increased plasma osmolality or hypovolaemia.

- When water intake is high and plasma osmolality is normal or low–normal (see Fig. 19.5B), vasopressin levels are suppressed and the collecting ducts remain impermeable to water. The luminal fluid osmolality remains low, resulting in the excretion of a dilute urine (minimum osmolality approximately 50 mOsmol/kg in a healthy young person).
- When water intake is restricted and plasma osmolality is high (see Fig. 19.5A), or in the presence of significant plasma volume depletion, vasopressin levels rise. This causes water permeability of the collecting ducts to increase through binding of vasopressin to the V2 receptor, which enhances collecting duct water permeability through the insertion of AQP2 channels into the luminal cell membrane. This results in osmotic reabsorption of water along the entire length of the collecting duct, with maximum urine osmolality approaching that in the medullary tip (up to 1200 mOsmol/kg).

Parallel to these changes in vasopressin release are changes in water-seeking behaviour triggered by the sensation of thirst, which also becomes activated as plasma osmolality rises.

In summary, for adequate dilution of the urine there must be:

- adequate solute delivery to the loop of Henle and early distal tubule
- normal function of the loop of Henle and early distal tubule
- absence of vasopressin in the circulation.

If any of these processes is faulty, water retention and hyponatraemia may result.

Conversely, to achieve concentration of the urine there must be:

- adequate solute delivery to the loop of Henle
- normal function of the loop of Henle
- vasopressin release into the circulation
- vasopressin action on the collecting ducts.

Failure of any of these steps may result in inappropriate water loss and hypernatraemia.

Presenting problems in regulation of osmolality

Changes in plasma osmolality are mainly determined by changes in serum sodium concentration and its associated anions. As outlined above, changes in sodium concentration usually occur because of disturbances in water balance, either because there is a relative excess of body water compared to total body sodium (hyponatraemia) or a relative lack of body water compared to total body sodium (hypernatraemia). Abnormalities of water balance can result from disturbances in urinary concentration or dilution.

If extracellular osmolality falls, water flows across cell membranes, causing cell swelling, whereas cell shrinkage occurs when osmolality rises. Brain cells and therefore cerebral function are particularly sensitive to such volume changes and can result in increased intracerebral pressure and reduced cerebral perfusion.

Hyponatraemia

Hyponatraemia is defined as a serum Na < 135 mmol/L. It is a common electrolyte abnormality with many potential underlying causes, as summarised in Box 19.10.

Pathophysiology

In all cases, hyponatraemia is caused by greater retention of water relative to sodium. The causes are best categorised according to associated changes in the ECF volume (see Box 19.10).

19.10 Causes of hyponatraemia

Volume status	Examples
Hypovolaemic	Renal sodium losses: Diuretic therapy (especially thiazides) Adrenocortical failure Gastrointestinal sodium losses: Vomiting Diarrhoea Skin sodium losses: Burns
Euvolaemic	Primary polydipsia Excessive electrolyte-free water infusion SIADH (see Box 19.11) Hypothyroidism
Hypervolaemic	Congestive cardiac failure Cirrhosis Nephrotic syndrome Chronic kidney disease (during free water intake)

(SIADH = syndrome of inappropriate antidiuretic hormone (vasopressin) secretion)

19.11 Causes and diagnosis of syndrome of inappropriate antidiuretic hormone secretion (SIADH)

Causes

- Tumours
- Central nervous system disorders: stroke, trauma, infection, psychosis, porphyria
- Pulmonary disorders: pneumonia, tuberculosis, obstructive lung disease
- Drugs: anticonvulsants, psychotropics, antidepressants, cytotoxics, oral hypoglycaemic agents, opiates
- Idiopathic

Diagnosis

- Low plasma sodium concentration (typically < 130 mmol/L)
- Low plasma osmolality (< 275 mOsmol/kg)
- Urine osmolality not minimally low (typically > 100 mOsmol/kg)
- Urine sodium concentration not minimally low (> 30 mmol/L)
- Low–normal plasma urea, creatinine, uric acid
- Clinical euvolaemia
- Absence of adrenal, thyroid, pituitary or renal insufficiency
- No recent use of diuretics
- Exclusion of other causes of hyponatraemia (see Box 19.10)
- Appropriate clinical context (above)

Hyponatraemia with hypovolaemia

In this situation there is depletion of sodium and water, but the sodium deficit exceeds the water deficit, causing hypovolaemia and hyponatraemia (see Box 19.3). The cause of sodium loss is usually apparent, and common examples are shown in Box 19.10.

Hyponatraemia with euvolaemia

In this situation there are no major disturbances of body sodium content, and the patient is clinically euvolaemic. Excess body water may be the result of abnormally high intake, either orally (primary polydipsia) or because of medically infused fluids (as intravenous dextrose solutions, or by absorption of sodium-free bladder irrigation fluid after prostatectomy).

Water retention also occurs in the syndrome of inappropriate secretion of antidiuretic hormone, or vasopressin (SIADH). In this condition, an endogenous source of vasopressin (either cerebral or tumour-derived) promotes water retention by the kidney in the absence of an appropriate physiological stimulus (Box 19.11). The clinical diagnosis requires the patient to be euvolaemic, with no evidence of cardiac, renal or hepatic disease potentially associated with hyponatraemia. Other non-osmotic stimuli that cause release of vasopressin (pain, stress, nausea) should also be excluded. Supportive laboratory findings are shown in Box 19.11.

Hyponatraemia with hypervolaemia

In this situation, excess water retention is associated with sodium retention and volume expansion, as in heart failure, liver disease or kidney disease. Reduced effective circulating volume initially activates the renin–angiotensin–aldosterone system (RAAS) to increase sodium and water reabsorption in an attempt to fix the perceived reduction in circulating volume. With ongoing reduction in effective circulating volume, vasopressin is released to further restore effective volume causing hyponatraemia.

Clinical assessment

Hyponatraemia is often asymptomatic but can also be associated with profound disturbances of cerebral function, manifesting as anorexia, nausea, vomiting, delirium, lethargy, seizures and coma. The likelihood of symptoms occurring is related to the speed at which hyponatraemia develops rather than the severity of hyponatraemia. This is because water rapidly flows into cerebral cells when plasma osmolality falls acutely, causing them to become swollen and ischaemic. However, when hyponatraemia develops gradually, cerebral neurons have time to respond by reducing intracellular osmolality, through excreting potassium and reducing synthesis of intracellular organic osmolytes (Fig. 19.6). The osmotic gradient favouring water movement into the cells is thus reduced and symptoms are avoided. This process takes about 24–48 hours and hyponatraemia is therefore classified as acute (< 48 hrs) and chronic (> 48 hrs). Hyponatraemia can also be defined as mild (130–135 mmol/L), moderate (125–129 mmol/L) or severe (< 124 mmol/L), based on biochemical findings or on the degree of severity of symptoms (Box 19.12).

Investigations

An algorithm for the clinical assessment of patients with hyponatraemia is shown in Figure 19.7. Artefactual causes of hyponatraemia should be considered in all cases. These include severe hyperlipidaemia or hyperproteinaemia, when the aqueous fraction of the serum specimen is reduced because of the volume occupied by the macromolecules (although this artefact is dependent on the assay technology). Transient hyponatraemia may also occur due to osmotic shifts of water out of cells during hyperosmolar states caused by acute hyperglycaemia or by mannitol infusion, but in these cases plasma osmolality is normal, or even high.

No change in cerebral cell size
Cerebral swelling → cerebral oedema

Fig. 19.6 **Hyponatraemia and the brain.** Numbers represent osmolality (osmo) in mOsmol/kg.

When these conditions have been excluded, serum and urine electrolytes and osmolality (see Fig. 19.7) are usually the only tests required to clarify the underlying cause. Hypovolaemic hyponatraemia is characterised by a low urinary sodium concentration (< 30 mmol/L) when there are extrarenal causes of sodium loss and high urinary sodium concentration (> 30 mmol/L) in patients with excessive renal sodium loss.

Measurement of vasopressin is not generally helpful in distinguishing between different categories of hyponatraemia. This is because concentrations of vasopressin are raised both in hypovolaemic states and in most chronic hypervolaemic states, as the impaired circulation in those disorders activates vasopressin release through non-osmotic mechanisms. Indeed, patients with these disorders may have higher circulating vasopressin (ADH) levels than patients with SIADH. The only disorders listed in Box 19.10 in which vasopressin is suppressed are primary polydipsia and iatrogenic water intoxication, where the hypo-osmolar state inhibits vasopressin release from the pituitary. Plasma vasopressin measurements are no longer used in routine practice since it is unstable, and they have been replaced by measurements of copeptin. This is a peptide derived from the carboxyl terminal of the vasopressin precursor and acts as a surrogate for vasopressin. Copeptin measurements can be useful in the differential diagnosis of patients with the combination of hyponatraemia and polyuria.

Management

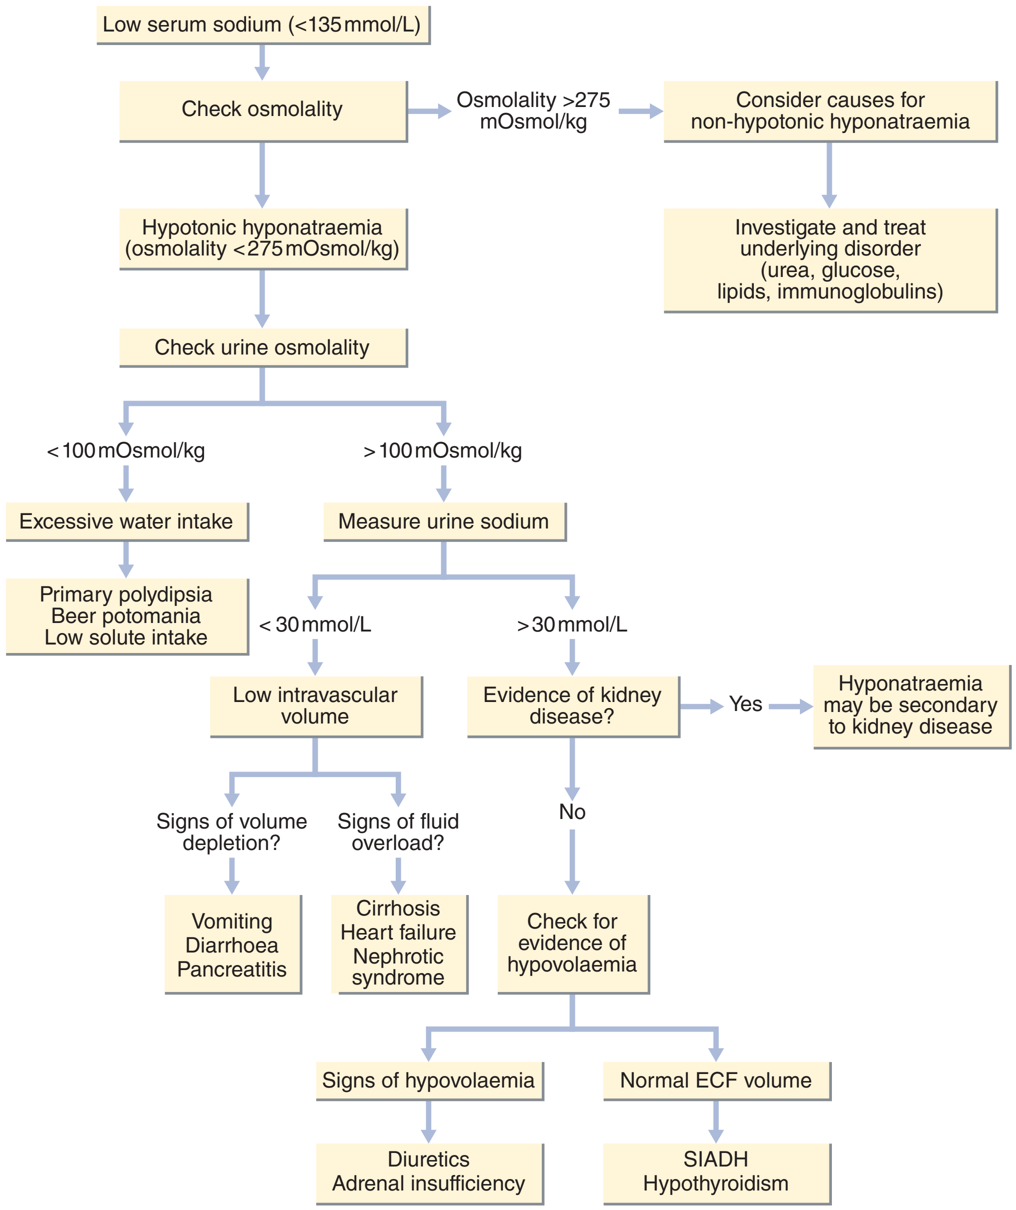
The treatment of hyponatraemia is critically dependent on its rate of development, severity, presence of symptoms and underlying cause. If hyponatraemia has developed rapidly (< 48 hrs) and there are signs of cerebral oedema, such as obtundation or convulsions, sodium levels should be restored rapidly to normal by infusion of hypertonic (3%) sodium chloride. A common approach is to give an initial bolus of 150 mL over 20 minutes, which may be repeated once or twice over the initial hours of observation, depending on the neurological response and rise in plasma sodium.

Rapid correction of hyponatraemia that has developed more slowly (> 48 hrs) can be hazardous, since brain cells adapt to slowly developing hypo-osmolality by reducing the intracellular osmolality, thus maintaining normal cell volume (see Fig. 19.6). Under these conditions, an abrupt increase in extracellular osmolality can lead to water shifting out of neurons, abruptly reducing their volume and causing them to detach from their myelin sheaths. The resulting 'myelinolysis' can produce permanent structural and functional damage to mid-brain structures and may be fatal. The rate of correction of the plasma Na concentration in chronic asymptomatic hyponatraemia should not exceed 10 mmol/L/24 hrs, and an even slower rate is generally safer.

The underlying cause should also be treated. For hypovolaemic patients, this involves controlling the source of sodium loss and administering intravenous saline if clinically warranted. Patients with euvolaemic

i 19.12 Symptoms and severity of hyponatraemia

Severity	Serum sodium	Symptoms
Mild	130–135 mmol/L	None
Moderate	125–129 mmol/L	Nausea Delirium Headache
Severe	< 124 mmol/L	Vomiting Somnolence Seizures Coma Cardiorespiratory arrest



Low serum sodium (<135 mmol/L)
Check osmolality
Osmolality >275 mOsmol/kg
Consider causes for non-hypotonic hyponatraemia
Investigate and treat underlying disorder (urea, glucose, lipids, immunoglobulins)
Hypotonic hyponatraemia (osmolality <275 mOsmol/kg)
Check urine osmolality
< 100 mOsmol/kg
> 100 mOsmol/kg
Excessive water intake
Measure urine sodium
Primary polydipsia
Beer potomania
Low solute intake
< 30 mmol/L
> 30 mmol/L
Low intravascular volume
Evidence of kidney disease?
Yes
Hyponatraemia may be secondary to kidney disease
Signs of volume depletion?
Signs of fluid overload?
No

Normal ECF volume
Diuretics
Adrenal insufficiency
SIADH
Hypothyroidism

Fig. 19.7 Algorithm for the diagnosis of hyponatraemia. (ECF = extracellular fluid; SIADH = syndrome of inappropriate antidiuretic hormone (vasopressin) secretion)

hyponatraemia generally respond to fluid restriction in the range of 600–1000 mL/24 hrs, accompanied where possible by withdrawal of the precipitating stimulus (such as drugs causing SIADH). In patients with persistent hyponatraemia due to prolonged SIADH, oral urea therapy (30–45 g/day) can be used, which provides a solute load to promote water excretion. Oral vasopressin receptor antagonists such as tolvaptan may also be used to block the vasopressin-mediated component of water retention in a range of hyponatraemic conditions, but concerns exist about the risk of overly rapid correction of hyponatraemia with these agents. Hypervolaemic patients with hyponatraemia need treatment of the underlying condition, accompanied by cautious use of diuretics in conjunction with strict fluid restriction. Potassium-sparing diuretics may be particularly useful in this context when there is significant secondary hyperaldosteronism.

Hypernatraemia

Hypernatraemia is defined to exist when the serum Na is > 145 mmol/L. It occurs because there is a deficit of water relative to sodium. The causes are summarised in Box 19.13, grouped according to any associated disturbance of total body sodium and water content.

i 19.13 Causes of hypernatraemia

Volume status	Examples
Hypovolaemic	Renal sodium and water loss: Diuretic therapy (especially osmotic diuretic, or loop diuretic during water restriction) Glycosuria (hyperglycaemic hyperosmolar state) Gastrointestinal sodium and water loss: Colonic diarrhoea Skin sodium and water loss: Excessive sweating
Euvolaemic	Arginine vasopressin deficiency (AVP-D; previously known as cranial diabetes insipidus) and arginine vasopressin resistance (AVP-R; previously known as nephrogenic diabetes insipidus)*
Hypervolaemic	Enteral or parenteral feeding Intravenous or oral salt administration Chronic kidney disease (during water restriction)

*Hypovolaemia can occur in arginine vasopressin deficiency/resistance if water intake is restricted.

Pathophysiology

Whatever the underlying cause, sustained hypernatraemia generally occurs because of an impaired thirst mechanism or responsiveness to thirst or inadequate concentration of the urine in the face of a restricted water intake. Regardless of fluid status, hypernatraemia occurs because there is a relative lack of total body water in comparison to sodium. This is generally due to a lack of maximal concentration of urine in the presence of water restriction.

Patients are clinically categorised based on their fluid status, as it is a clinical variable we can assess. They may exhibit low, normal or high total body sodium levels, corresponding to hypovolaemia, euvolaemia or hypervolaemia, respectively. In any of these states, if their water content is disproportionately lower than their sodium levels, they will present with hypernatraemia.

For example, hypernatraemia can complicate conditions where there is hypovolaemia due to excessive loss of fluid in excess of sodium from the kidneys, where an adequate medullary concentration gradient cannot be generated in the kidney (see Fig. 19.5) due to low GFR or loop diuretic therapy. In contrast, patients suffering from a lack of vasopressin effect because of pituitary damage (arginine vasopressin deficiency (AVP-D), previously cranial diabetes insipidus) or because the collecting duct cells are unable to respond to vasopressin (arginine vasopressin resistance (AVP-R), previously nephrogenic diabetes insipidus) are likely to be euvolaemic unless water intake is restricted.

Clinical assessment

Patients with significant hypernatraemia generally have reduced cerebral function, either as a primary problem or as a consequence of the hypernatraemia itself, which results in dehydration of neurons and brain shrinkage. In the presence of an intact thirst mechanism and preserved capacity to obtain and ingest water, hypernatraemia may not progress very far. If adequate water is not obtained, dizziness, delirium, weakness and, ultimately, coma and death can result.

As outlined above, copeptin can be used in the diagnosis of water regulation disorders as a surrogate marker of vasopressin release. It is used in this regard to distinguish between AVP-D and AVP-R.

Management

Treatment of hypernatraemia depends on both the rate of development and the underlying cause. If there is reason to think that the condition has developed rapidly, neuronal shrinkage may be acute, and relatively rapid correction may be attempted. This can be achieved by infusing an appropriate volume of intravenous fluid (isotonic 5% dextrose or hypotonic 0.45% saline) at an initial rate of 50–70 mL/hr. In older, institutionalised patients, however, it is more likely that the disorder has developed slowly, and extreme caution should be exercised in lowering plasma sodium to avoid the risk of cerebral oedema. Where possible, the underlying cause should also be addressed (see Box 19.13).

Older adult patients are predisposed, in different circumstances, to both hyponatraemia and hypernatraemia, and a high index of suspicion of these electrolyte disturbances is appropriate in older patients with recent alterations in behaviour (Box 19.14).

19.14 Hyponatraemia and hypernatraemia in old age

- **Decline in GFR:** older patients are predisposed to both hyponatraemia and hypernatraemia, mainly because, as glomerular filtration rate declines with age, the capacity of the kidney to dilute or concentrate the urine is impaired.
- **Low solute intake:** older patients may reduce solute intake, which can lead to hyponatraemia.
- **Diuretics:** increased prescription of diuretics in older patients, particularly thiazides, can lead to hyponatraemia.
- **Vasopressin release:** water retention is aggravated by any condition that stimulates vasopressin release, especially heart failure. Moreover, the vasopressin response to non-osmotic stimuli may be brisker in older subjects.
- **Inadequate water intake:** in older patients this can occur due to physical restrictions preventing access to drinks and/or blunted thirst. Both are frequently present in patients with advanced dementia or following a severe stroke. This can lead to hypernatraemia.
- **Dietary salt:** hypernatraemia is aggravated if dietary supplements or medications with a high sodium content (especially effervescent preparations) are administered.

Potassium homeostasis

Potassium is the major intracellular cation (see Fig. 19.1), and the steep concentration gradient for potassium across the cell membrane of excitable cells plays an important part in generating the resting membrane potential and allowing the propagation of the action potential that is crucial to normal functioning of nerve, muscle and cardiac tissues. Control of body potassium balance is described below.

Functional anatomy and physiology

The kidneys normally excrete some 90% of the daily intake of potassium, typically 80–100 mmol/24 hrs. Potassium is freely filtered at the glomerulus; around 65% is reabsorbed in the proximal tubule and a further 25% in the thick ascending limb of the loop of Henle. Little potassium is transported in the early distal tubule, but a significant secretory flux of potassium into the urine occurs in the late distal tubule and cortical collecting duct to ensure that the amount removed from the blood is proportional to the ingested load.

The mechanism for potassium secretion in the distal parts of the nephron is shown in panel D of Figure 19.2. Movement of potassium from blood to lumen is dependent on active uptake across the basal cell membrane by the Na,K-ATPase, followed by diffusion of potassium through the ROMK channel into the tubular fluid. The electrochemical gradient for potassium movement into the lumen is contributed to both by the high intracellular potassium concentration and by the negative luminal potential difference relative to the blood.

Several factors influence the rate of potassium secretion. Luminal influences include the rate of sodium delivery and fluid flow through the late distal tubule and cortical collecting ducts. This is a major factor responsible for the increased potassium loss that accompanies diuretic treatment. Agents interfering with the generation of the negative luminal potential also impair potassium secretion, and this is the basis of reduced potassium secretion associated with potassium-sparing diuretics such as amiloride. Factors acting on the blood side of this tubular segment include plasma potassium and pH, such that hyperkalaemia and alkalosis both enhance potassium secretion directly. However, the most important factor in the acute and chronic adjustment of potassium secretion to match metabolic potassium load is aldosterone.

As shown in Figure 19.8, a negative feedback relationship exists between the plasma potassium concentration and aldosterone. In addition to its regulation by the RAAS (see Fig. 20.19), aldosterone is released from the adrenal cortex in direct response to an elevated plasma potassium. Aldosterone then acts on the kidney to enhance potassium secretion, hydrogen secretion and sodium reabsorption, in the late distal tubule and cortical collecting ducts. The resulting increase in excretion of potassium maintains plasma potassium within a narrow range (3.5–5.0 mmol/L). Factors that reduce angiotensin II levels may indirectly affect potassium balance by blunting the rise in aldosterone that would otherwise be provoked by hyperkalaemia. This accounts for the increased risk of hyperkalaemia during therapy with ACE inhibitors and related drugs.

Presenting problems in potassium homeostasis

Changes in the distribution of potassium between the ICF and ECF compartments can alter plasma potassium concentration, without any overall change in total body potassium content. Potassium is driven into the cells by extracellular alkalosis and by several hormones, including insulin, catecholamines (through the β_2-receptor) and aldosterone. Any of these

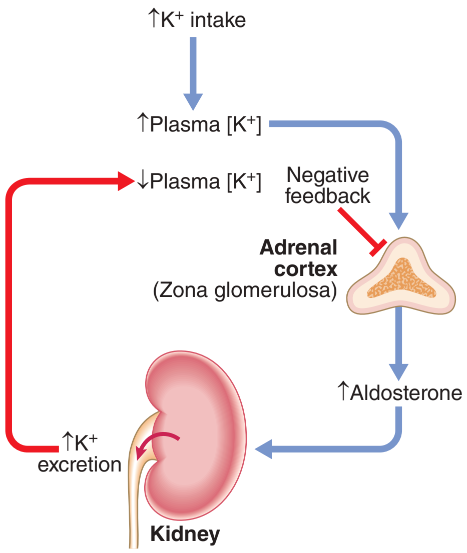

Fig. 19.8 Feedback control of plasma potassium concentration.

factors can produce hypokalaemia, whereas extracellular acidosis, lack of insulin and insufficiency or blockade of catecholamines or aldosterone can cause hyperkalaemia due to efflux of potassium from the intracellular compartment.

Hypokalaemia

Hypokalaemia is a common electrolyte disturbance and is defined as existing when serum K^+ falls below 3.5 mmol/L. The main causes of hypokalaemia are shown in Box 19.15.

Pathophysiology

Hypokalaemia is generally indicative of abnormal potassium loss from the body, through either the kidney or the gastrointestinal tract. Renal causes of hypokalaemia can be divided into those with and those without hypertension. Hypokalaemia in the presence of hypertension may be due to increased aldosterone secretion in Conn syndrome or a genetic variant affecting sodium channels in the distal nephron (Liddle syndrome). Excessive intake of liquorice or treatment with carbenoxolone may result in a similar clinical picture, due to inhibition of the renal 11βHSD2 enzyme, which inactivates cortisol in peripheral tissues.

If blood pressure is normal or low, hypokalaemia can be classified according to the associated change in acid–base balance. Inherited defects in tubular transport should be suspected when hypokalaemia occurs in association with hypotension and alkalosis, provided that diuretic use has been excluded. One such disease is Bartter syndrome, in which sodium reabsorption in the thick ascending limb of Henle is defective, usually due to a loss-of-function variant of the *NKCC2* transporter. The clinical and biochemical features are similar to those in chronic treatment with furosemide. In Gitelman syndrome there is a loss-of-function variant affecting the NCCT transporter in the early distal tubule. The clinical and biochemical features are similar to chronic thiazide treatment. Note that while both Bartter and Gitelman syndromes are characterised by hypokalaemia and hypomagnesaemia, urinary calcium excretion is increased in Bartter syndrome but decreased in Gitelman syndrome, analogous to the effects of the loop and thiazide diuretics, respectively, on calcium transport (see Box 19.9).

If hypokalaemia occurs in the presence of a normal blood pressure and metabolic acidosis, renal tubular acidosis (proximal or 'classical' distal) should be suspected.

When hypokalaemia is due to potassium wasting through the gastrointestinal tract, the cause is usually obvious clinically. In some cases, when there is occult induction of vomiting, hypokalaemia is characteristically associated with metabolic alkalosis, due to loss of gastric acid. If, however, potassium loss has occurred through the surreptitious use of aperients, the hypokalaemia is generally associated with metabolic acidosis. In both cases, urinary potassium excretion is low unless there is significant extracellular volume depletion, which can raise urinary potassium levels by stimulating aldosterone production.

19.15 Causes of hypokalaemia

Cause	Other features and comment
Reduced intake	Urine $K^+ < 20–30$ mmol/24 hrs
Dietary deficiency	
Potassium-free intravenous fluids	
Redistribution into cells	
Alkalosis	Caused by flux of K^+ into cells
Insulin	
Catecholamines	
β-adrenergic agonists	
Hypokalaemic periodic paralysis	
Increased urinary excretion	Urine $K^+ > 20–30$ mmol/24 hrs
Activation of mineralocorticoid receptor:	
Conn syndrome	Associated with hypertension with alkalosis
Cushing syndrome	
Glucocorticoid excess	
Carbenoxolone/liquorice	
Genetic disorders:	
Liddle syndrome	Associated with hypertension with alkalosis
Bartter syndrome	Associated with alkalosis and hypomagnesaemia
Gitelman syndrome	
Renal tubular acidosis	Inherited and acquired forms; associated with high serum chloride. Type 2 associated with glycosuria, aminoaciduria and phosphaturia
Type 1 (distal)	
Type 2 (proximal)	
Acetazolamide	Associated with acidosis
Diuresis:	
Associated with acidosis	Increased sodium delivery to distal tubule
Loop diuretics	
Thiazides	
Recovery from acute tubular necrosis	
Recovery from renal obstruction	
Increased gastrointestinal loss	Urine $K^+ < 20–30$ mmol/L
Upper gastrointestinal tract:	
Vomiting	Loss of gastric acid Associated with metabolic alkalosis
Nasogastric aspiration	
Lower gastrointestinal tract:	
Diarrhoea	Associated with metabolic acidosis
Laxative abuse	
Villous adenoma	
Bowel obstruction/fistula	
Ureterosigmoidostomy	

Hypokalaemia can also be caused by redistribution of potassium into cells as outlined above or as the result of K^+ flux into muscle in hypokalaemic periodic paralysis, which is associated with variants in several genes that regulate transmembrane ion flow into muscle cells. Finally, reduced dietary intake of potassium can contribute to hypokalaemia but is seldom the only cause, except in extreme cases.

Clinical assessment

Patients with mild hypokalaemia (plasma K^+ 3.0–3.5 mmol/L) are generally asymptomatic, but more profound reductions in plasma potassium often lead to muscular weakness and associated tiredness. Ventricular ectopic beats or more serious arrhythmias may occur and the arrhythmogenic effects of digoxin may be potentiated. Typical electrocardiogram (ECG) changes occur, affecting the T wave in particular. Functional bowel obstruction may occur due to paralytic ileus. Long-standing hypokalaemia may cause renal tubular damage (hypokalaemic nephropathy) and can interfere with the tubular response to vasopressin (AVP-R), resulting in polyuria and polydipsia.

Investigations

Measurement of plasma electrolytes, bicarbonate, urine potassium and sometimes of plasma calcium and magnesium is usually sufficient to establish the diagnosis. If the diagnosis remains unclear, plasma renin should be measured. Levels are low in patients with primary hyperaldosteronism and other forms of mineralocorticoid excess but raised in other causes of hypokalaemia. Measurement of urinary potassium may also be helpful; if the kidney is the route of potassium loss, the urine potassium is high (> 30 mmol/24 hrs), whereas if potassium is being lost through the gastrointestinal tract, the kidney retains potassium, resulting in a lower urinary potassium (generally < 20 mmol/24 hrs). It should be noted, however, that if gastrointestinal fluid loss is also associated with hypovolaemia, activation of the renin–angiotensin–aldosterone system may occur, causing increased loss of potassium in the urine.

The cause of hypokalaemia may remain unclear despite the above investigations when urinary potassium measurements are inconclusive, and the history is incomplete or unreliable. Many such cases are associated with metabolic alkalosis, and in this setting the measurement of urine chloride concentration can be helpful. A low urine chloride (< 30 mmol/L) is characteristic of vomiting (spontaneous or self-induced, in which chloride is lost in HCl in the vomit), while a urine chloride > 40 mmol/L suggests diuretic therapy (acute phase) or a tubular disorder such as Bartter or Gitelman syndromes. Differentiation between occult diuretic use and primary tubular disorders can be achieved by performing a screen of urine for diuretic drugs and genetic screening.

Management

Treatment of hypokalaemia involves first determining the cause and correcting this where possible. If the problem is mainly one of redistribution of potassium into cells, reversal of the process responsible may be sufficient to restore plasma potassium without providing supplements. In most cases, however, some form of potassium replacement will be required. This can generally be achieved with slow-release potassium chloride tablets, but in more acute circumstances intravenous potassium chloride may be necessary. The rate of administration depends on the severity of hypokalaemia and the presence of cardiac or neuromuscular complications but should generally not exceed 10 mmol of potassium per hour. In patients with severe, life-threatening hypokalaemia, infusion rates of up to 20 mmol/hr can be used with continuous cardiac monitoring.

In the less common situation where hypokalaemia occurs in the presence of metabolic acidosis, alkaline salts of potassium, such as potassium bicarbonate, can be given by mouth. If magnesium depletion is also present, replacement of magnesium may also be required, since low cellular magnesium can promote tubular potassium secretion, causing ongoing urinary losses. In some circumstances, potassium-sparing diuretics, such as amiloride, can assist in the correction of hypokalaemia, hypomagnesaemia and metabolic alkalosis, especially when renal loss of potassium is the underlying cause.

Hyperkalaemia

Hyperkalaemia is a common electrolyte disorder, which is defined as existing when serum K^+ is > 5 mmol/L. The causes of hyperkalaemia are summarised in Box 19.16.

Pathophysiology

It is important to remember that hyperkalaemia can be artefactual due to haemolysis of blood specimens during collection or in vitro, or due to release of potassium from platelets in patients with thrombocytosis.

True hyperkalaemia, however, can occur either because of redistribution of potassium between the ICF and ECF, or because potassium intake exceeds excretion. Redistribution of potassium from the ICF to the ECF may take place in the presence of systemic acidosis, or when the circulating levels of insulin, catecholamines and aldosterone are reduced, or when the effects of these hormones are blocked.

19.16 Causes of hyperkalaemia

Cause	Other features and comment
Artefactual	
Haemolysis during venepuncture	Release of intracellular K^+ during sample collection, transit or clotting
Haemolysis in vitro	
Thrombocytosis/leucocytosis	
Increased intake	
Dietary potassium	
Potassium-containing intravenous fluids	
Redistribution from cells	
Acidosis	Caused by flux of intracellular K^+ into plasma
Insulin deficiency	
Severe hyperglycaemia	
β-blockers	
Hyperkalaemic periodic paralysis	
Rhabdomyolysis	
Severe haemolysis	
Tumour lysis syndrome	
Reduced urinary excretion	
Reduced glomerular filtration:	
Acute kidney injury	Plasma creatinine typically > 500 μmol/L (5.67 mg/dL)
Chronic kidney disease	
Reduced mineralocorticoid receptor activation:	
Addison disease	
Congenital adrenal hyperplasia	
Isolated aldosterone deficiency	
ACE inhibitors	Both reduce aldosterone levels
Angiotensin-receptor blockers	
Calcineurin inhibitors	All block the mineralocorticoid receptor
Spironolactone	
Eplerenone	
Heparin	Inhibits aldosterone production
Inhibitors of renin production:	
Non-steroidal anti-inflammatory drugs	
β-blockers	
Tubulointerstitial disease:	
Interstitial nephritis	
Diabetic nephropathy	
Obstructive uropathy	
Other:	
Amiloride	Blocks K^+ exchange in distal tubule
Gordon syndrome	Direct effect on K^+ transport in renal tubule

High dietary potassium intake may contribute to hyperkalaemia but is seldom the only explanation unless renal excretion mechanisms are impaired. The mechanism of hyperkalaemia in acute kidney injury and chronic kidney disease is impaired excretion of potassium into the urine as the result of a reduced GFR. In addition, acute kidney injury can be associated with severe hyperkalaemia when there is an increased potassium load, such as in rhabdomyolysis or in sepsis, particularly when acidosis is present. In chronic kidney disease, adaptation to moderately elevated plasma potassium levels commonly occurs. However, acute rises in potassium triggered by excessive dietary intake, hypovolaemia or drugs (see below) may occur and destabilise the situation.

Hyperkalaemia can also occur when tubular potassium secretion is impaired, even with a normal GFR. This impairment may result from low aldosterone levels, as seen in conditions like Addison disease, hyporeninaemic hypoaldosteronism or inherited disorders such as congenital isolated hypoaldosteronism, which involves defects in aldosterone biosynthesis. Additionally, pseudohypoaldosteronism type 2 (Gordon syndrome), caused by variants in the *WNK2* and *WNK4* genes, leads to reduced potassium secretion in the renal tubules.

Drug-induced causes include ACE inhibitors, angiotensin-receptor blockers (ARBs), non-steroidal anti-inflammatory drugs (NSAIDs) and β-adrenoceptor antagonists (β-blockers). In aldosterone deficiency or aldosterone resistance, hyperkalaemia may be associated with acid retention, giving rise to the pattern of hyperkalaemic distal ('type 4') renal tubular acidosis.

In another group of conditions, tubular potassium secretion is impaired as the result of aldosterone resistance. This can occur in a variety of diseases in which there is inflammation of the tubulointerstitium, such as systemic lupus erythematosus; following renal transplantation; during treatment with potassium-sparing diuretics; and in several inherited disorders of tubular transport.

Clinical assessment

Mild to moderate hyperkalaemia (<6.5 mmol/L) is usually asymptomatic. More severe hyperkalaemia can present with progressive muscular weakness, but sometimes there are no symptoms until cardiac arrest occurs. The typical ECG changes are shown on page 657. Peaking of the T wave is an early ECG sign, but widening of the QRS complex presages a dangerous cardiac arrhythmia. However, these characteristic ECG findings are not always present, even in severe hyperkalaemia.

Investigations

Measurement of electrolytes, creatinine and bicarbonate, when combined with clinical assessment, usually provides the explanation for hyperkalaemia. In aldosterone deficiency, plasma sodium concentration is characteristically low, although this can occur with many causes of hyperkalaemia. Addison disease should be excluded unless there is an obvious alternative diagnosis.

Management

Treatment of hyperkalaemia depends on its severity and the rate of development, but opinions vary as to what level of serum potassium constitutes severe hyperkalaemia and requires urgent treatment. Patients who have potassium concentrations <6.5 mmol/L in the absence of neuromuscular symptoms or ECG changes can be treated with a reduction of potassium intake and correction of predisposing factors. However, in acute and/or severe hyperkalaemia (plasma potassium >6.5–7.0 mmol/L), more urgent measures must be taken (Box 19.17). The first step should be infusion of 10 mL 10% calcium gluconate to stabilise conductive tissue membranes (calcium has the opposite effect to potassium on conduction of an action potential). Measures to shift potassium from the ECF to the ICF should also be applied, as they generally have a rapid effect and may avert arrhythmias. Ultimately, a means of removing potassium from the body is generally necessary. When renal function is reasonably preserved, loop diuretics (accompanied by intravenous saline if hypovolaemia is present) may be effective. In renal failure, dialysis may be required. Ion exchange resins, such as Calcium Resonium (which can be given orally or rectally) and oral sodium polystyrene sulfonate (SPS), have traditionally been used to bind and excrete gastrointestinal potassium. There are concerns, however, about SPS's lack of proven efficacy and safety, with a number of reports of intestinal necrosis associated with its use. Newer cation exchange resins, which include sodium zirconium cyclosilicate and patiromer sorbitex calcium, have been developed. These are safe and effective treatments for hyperkalaemia and are preferred to SPS, where available.

19.17 Treatment of severe hyperkalaemia

Objective	Therapy
Stabilise cell membrane potential[1]	IV calcium gluconate (10 mL of 10% solution)
Shift K^+ into cells	Inhaled β_2-adrenoceptor agonist IV glucose (50 mL of 50% solution) and 5–10 IU rapidly acting insulin IV sodium bicarbonate[2]
Remove K^+ from body	IV furosemide and normal saline[3] Ion-exchange resin orally Dialysis

[1] If severe hyperkalaemia (K^+ typically > 6.5 mmol/L).
[2] If acidosis present.
[3] If adequate residual renal function.
(IV = intravenous)

Acid–base homeostasis

The pH of arterial plasma is normally 7.40, corresponding to an H^+ concentration of 40 nmol/L, and under normal circumstances H^+ concentrations do not vary outside the range of 37–45 nmol/L (pH 7.35–7.43). Abnormalities of acid–base balance can occur in a wide range of diseases. Increases in H^+ concentration cause acidosis with a decrease in pH, whereas decreases in H^+ concentration cause alkalosis with a rise in pH.

Functional anatomy and physiology

A variety of physiological mechanisms maintain pH of the ECF within narrow limits. The first is the action of blood and tissue buffers, of which the most important involves reaction of H^+ ions with bicarbonate to form carbonic acid, which, under the influence of the enzyme carbonic anhydrase (CA), dissociates to form CO_2 and water:

$$CO_2 + H_2O \underset{CA}{\leftrightarrow} H_2CO_3 \rightleftharpoons H^+ + HCO_3^-$$

This buffer system is important because bicarbonate is present at a relatively high concentration in ECF (21–29 mmol/L), and two of its key components are under physiological control: CO_2 by the lungs, and bicarbonate by the kidneys. These relationships are illustrated in Figure 19.9 (a form of the Henderson–Hasselbalch equation).

Respiratory control of acid–base balance

Respiratory compensation for acid–base disturbances can occur quickly. In response to acid accumulation, pH changes in the brainstem stimulate ventilatory drive, which reduces PCO_2 and subsequently increases pH. Conversely, systemic alkalosis leads to inhibition of ventilation, causing

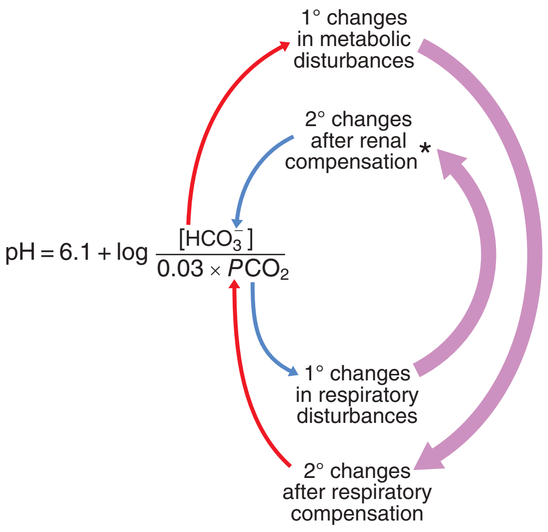

Fig. 19.9 Relationship between pH, PCO2 (in mmHg) and plasma bicarbonate concentration (in mmol/L). *Note that changes in HCO_3^- concentration are also part of the renal correction for sustained metabolic acid–base disturbances as long as the kidney itself is not the cause of the primary disturbance.

a rise in PCO_2 and reduction in pH, although it should be noted that this mechanism has limited capacity to change pH because hypoxia provides an alternative stimulus to drive ventilation.

The kidneys provide a third line of defence against disturbances of arterial pH. When acid accumulates due to chronic respiratory or metabolic (non-renal) causes, the kidneys have the capacity to enhance urinary excretion of acid, effectively increasing the plasma bicarbonate.

Renal control of acid–base balance

Regulation of acid–base balance occurs at several sites in the kidney. The proximal tubule reabsorbs about 85% of the filtered bicarbonate ions through the mechanism illustrated in panel A in Figure 19.2. This is dependent on the enzyme carbonic anhydrase, which is present both in the cytoplasm of the proximal tubular cells and on the luminal surface of the brush border membranes. The system has a high capacity for reabsorption of filtered bicarbonate but does not lead to significant acidification of the luminal fluid.

Distal nephron segments also have an important role in bicarbonate reabsorption and acid excretion. Dissociation of H_2CO_3 occurs in the distal tubular cells, under the influence of carbonic anhydrase generating H^+ ions and HCO_3^- ions. The H^+ ions are secreted into the lumen by an H^+-ATPase in the α-intercalated cells of the cortical collecting duct and the outer medullary collecting duct cells and the HCO_3 passes across the basolateral membrane into the blood. Within the tubular lumen, H^+ combines with hydrogen phosphate HPO_4^{2-} in the distal tubular lumen to form dihydrogen phosphate $H_2PO_4^-$, which is excreted in the urine with sodium. Similarly, H^+ combines with NH_3 in the luminal fluid to form ammonium (NH_4^+) ions, which are trapped and excreted in the urine combined with chloride ions. The NH_3 necessary for this reaction is generated in tubular cells by the enzyme glutaminase, which acts on the amino acid glutamine. Both of these buffers help to prevent the urinary pH falling below 5, which would create an unfavourable gradient that would stop further secretion of H^+ ions into the urine.

Titratable acid and ammonium excretion removes approximately 1 mmol/kg of hydrogen ions from the body per day, which equates to the non-volatile acid load arising from the metabolism of dietary protein. The slightly alkaline plasma pH of 7.4 (H^+ 40 nmol/L) that is maintained during health can be accounted for by the kidney's ability to generate an acidic urine (typically pH 5–6 (H^+ 1000–10 000 nmol/L), in which the net daily excess of metabolic acid produced by the body can be excreted.

Presenting problems in acid–base balance

Patients with disturbances of acid–base balance may present clinically either with the effects of tissue malfunction due to disturbed pH (such as altered cardiac and central nervous system function), or with secondary changes in respiration that occur as a response to the underlying metabolic change (such as Kussmaul respiration during metabolic acidosis). The clinical picture is often dominated by the underlying cause rather than the acid–base abnormality itself. Frequently, acid–base disturbances only become evident when the venous plasma bicarbonate concentration is measured and found to be abnormal, or when blood gas analysis shows abnormalities in pH, PCO_2 or bicarbonate.

The most common patterns of abnormality in blood gas parameters are shown in Box 19.18. Interpretation of arterial blood gases in respiratory failure is described in Box 17.16.

In metabolic disturbances, respiratory compensation is almost immediate, so that the predicted compensatory change in PCO_2 is achieved soon after the onset of the metabolic disturbance. In respiratory disorders, on the other hand, a small initial change in bicarbonate occurs as a result of chemical buffering of CO_2, chiefly within red blood cells, but over days and weeks the kidney achieves further compensatory changes in bicarbonate concentration as a result of chronic adjustments in acid secretory capacity. When the clinically obtained acid–base parameters do not accord with the predicted compensation shown, a mixed acid–base disturbance should be suspected.

Metabolic acidosis

Metabolic acidosis occurs when an acid other than carbonic acid (due to CO_2 retention) accumulates in the body, resulting in a fall in the plasma bicarbonate. The causes of metabolic acidosis are summarised in Box 19.19, subdivided into two categories, depending on whether the anion gap is normal or raised. When plasma bicarbonate falls, another anion needs to take its place. This is either chloride (normal anion gap) or an unmeasured anion (raised anion gap). The causes are discussed in more detail below.

Pathophysiology

Metabolic acidosis with a normal anion gap occurs when there is poisoning with or therapeutic infusion of a chloride-containing acid such as hydrochloric acid or ammonium chloride or when there is a primary loss of bicarbonate from the ECF (via the gastrointestinal tract or from the kidneys).

Renal tubular acidosis (RTA) can be caused by a defect in one of three processes:

- impaired bicarbonate reabsorption in the proximal tubule (proximal RTA)
- impaired acid secretion in the late distal tubule or cortical collecting duct intercalated cells (classical distal RTA)
- impaired sodium reabsorption in the late distal tubule or cortical collecting duct, which is associated with reduced secretion of both potassium and H^+ ions (hyperkalaemic distal RTA).

Various subtypes of RTA are recognised and the most common causes are shown in Box 19.20. The inherited forms of RTA are due to variants in the genes that regulate acid or bicarbonate transport in the renal tubules (see Fig. 19.2).

Acidosis with an increased anion gap is mostly seen in ketoacidosis, lactic acidosis and late kidney failure, where there is endogenous

i 19.18 Principal patterns of acid–base disturbance

Disturbance	Blood H^+	Primary change	Compensatory response	Predicted compensation
Metabolic acidosis	> 40[1]	$HCO_3^- < 24$ mmol/L	$PCO_2 < 5.33$ kPa[2]	PCO_2 fall in kPa = 0.16 × HCO_3^- fall in mmol/L
Metabolic alkalosis	< 40[1]	$HCO_3^- > 24$ mmol/L	$PCO_2 > 5.33$ kPa[2,3]	PCO_2 rise in kPa = 0.08 × HCO_3^- rise in mmol/L
Respiratory acidosis	> 40[1]	$PCO_2 > 5.33$ kPa[2]	$HCO_3^- > 24$ mmol/L	Acute: HCO_3^- rise in mmol/L = 0.75 × PCO_2 rise in kPa Chronic: HCO_3^- rise in mmol/L = 2.62 × PCO_2 rise in kPa
Respiratory alkalosis	< 40[1]	$PCO_2 < 5.33$ kPa[2]	$HCO_3^- < 24$ mmol/L	Acute: HCO_3^- fall in mmol/L = 1.50 × PCO_2 fall in kPa Chronic: HCO_3^- fall in mmol/L = 3.75 × PCO_2 fall in kPa

[1] H^+ of 40 nmol/L = pH of 7.40.
[2] PCO_2 of 5.33 kPa = 40 mmHg.
[3] PCO_2 does not rise above 7.33 kPa (55 mmHg) because hypoxia then intervenes to drive respiration.

19.19 Causes of metabolic acidosis

Disorder	Mechanism
Normal anion gap	
Ingestion or infusion of inorganic acid	Therapeutic infusion of or poisoning with NH_4Cl, HCl
Gastrointestinal HCO_3^- loss	Loss of HCO_3^- in diarrhoea, small bowel fistula, urinary diversion procedure
Renal tubular acidosis (RTA)	Urinary loss of HCO_3^- in proximal RTA; impaired tubular acid secretion in distal RTA
Increased anion gap	
Endogenous acid load	
Diabetic ketoacidosis	Accumulation of ketones[1] with hyperglycaemia
Starvation ketosis	Accumulation of ketones without hyperglycaemia
Alcoholic ketoacidosis	
Lactic acidosis	Shock, liver disease, drugs
Kidney disease	Accumulation of organic acids
Exogenous acid load	
Aspirin poisoning	Accumulation of salicylate[2]
Methanol poisoning	Accumulation of formate
Ethylene glycol poisoning	Accumulation of glycolate, oxalate

[1] Ketones include acid anions acetoacetate and β-hydroxybutyrate.
[2] Salicylate poisoning is also associated with respiratory alkalosis due to direct ventilatory stimulation.

19.20 Causes of renal tubular acidosis

Proximal renal tubular acidosis (type II RTA)

- Inherited:
  - Fanconi syndrome
  - Cystinosis
  - Wilson disease
- Paraproteinaemia:
  - Myeloma
  - Amyloidosis
- Heavy metal toxicity:
  - Lead, cadmium and mercury poisoning
- Drugs:
  - Carbonic anhydrase inhibitors
  - Ifosfamide
- Primary hyperparathyroidism

Classical distal renal tubular acidosis (type I RTA)

- Inherited
- Autoimmune diseases:
  - Systemic lupus erythematosus
  - Sjögren syndrome
- Hyperglobulinaemia
- Primary hyperparathyroidism
- Toxins and drugs:
  - Toluene
  - Lithium
  - Amphotericin

Hyperkalaemic distal renal tubular acidosis (type IV RTA)

- Hypoaldosteronism (primary or secondary)
- Obstructive nephropathy
- Renal transplant rejection
- Drugs:
  - Amiloride
  - Spironolactone

production of anions distinct from Cl^- and HCO_3^-. Ketoacidosis is caused by insulin deficiency and is exacerbated by catecholamine and stress hormone excess, which combine to cause lipolysis and the formation of acidic ketones (acetoacetate, 3-hydroxybutyrate and acetone). The most common cause of ketoacidosis is diabetic ketoacidosis (DKA); its aetiology and management are discussed in Chapter 21. Starvation ketoacidosis occurs when there is reduced food intake in situations of high glucose demand, such as in neonates, and in pregnant or breastfeeding women. In alcoholic ketoacidosis, there is usually a background of chronic malnutrition and a recent alcohol binge. Two subtypes of lactic acidosis have been defined:

- *type I*, due to tissue hypoxia and peripheral generation of lactate, as in patients with circulatory failure and shock
- *type II*, due to impaired metabolism of lactate, as in liver disease or by a number of drugs and toxins, including metformin, which inhibit lactate metabolism.

Metabolic acidosis with an increased anion gap may also be a consequence of exogenous acid loads from poisoning with aspirin, methanol or ethylene glycol. Typically, metabolic acidosis in chronic kidney disease is associated with a normal anion gap until late in the disease process, when the gap widens due to the lack of excretion of anions such as phosphate, sulphate and urate.

Clinical assessment

Normal anion gap metabolic acidosis is usually due either to bicarbonate loss in diarrhoea, where the clinical diagnosis is generally obvious, or to RTA. Although some forms of RTA are inherited, it may also be an acquired disorder, and in these circumstances the discovery of metabolic acidosis may serve as an early clue to the underlying diagnosis. The presentation of increased anion gap acidosis is usually dominated by clinical features of the underlying disease, such as uncontrolled diabetes mellitus, kidney failure or shock, or may be suggested by the clinical history of starvation, alcoholism or associated symptoms, such as visual complaints in methanol poisoning.

Investigations

The different types of metabolic acidosis can be distinguished by blood gas measurements, along with measurements of creatinine, electrolytes and bicarbonate. Under normal circumstances, the anion gap, defined as the numerical difference between the main measured cations ($Na^+ + K^+$) and the anions ($Cl^- + HCO_3^-$) is about 5–11 mmol/L. This gap is normally made up of various unmeasured anions, such as phosphate and sulphate, as well as albumin. RTA should be suspected when there is a hyperchloraemic acidosis with a normal anion gap in the absence of gastrointestinal disturbance. The diagnosis can be confirmed by finding an inappropriately high urine pH (> 5.5) in the presence of systemic acidosis. Sometimes, distal RTA may be incomplete, such that the plasma bicarbonate concentration may be normal. In this case, an acid challenge test can be performed by administration of an acid load in the form of ammonium chloride to reduce plasma bicarbonate. The diagnosis of incomplete distal RTA can be confirmed if the urine pH fails to fall below 5.3 in the presence of a low bicarbonate.

The different subtypes of RTA can be differentiated by various biochemical features. Patients with proximal and distal RTA often present with features of profound hypokalaemia, while type IV RTA is associated with hyperkalaemia. Proximal RTA is frequently associated with urinary wasting of amino acids, phosphate and glucose (Fanconi syndrome), as well as bicarbonate and potassium. Patients with this disorder can lower the urine pH when the acidosis is severe and plasma bicarbonate levels have fallen below 16 mmol/L, since distal H^+ secretion mechanisms are intact. In the classical form of distal RTA, however, acid accumulation is relentless and progressive, resulting in mobilisation of calcium from bone and osteomalacia with hypercalciuria, renal stone formation and nephrocalcinosis. Potassium is also lost in classical distal RTA, while it is retained in hyperkalaemic distal RTA.

Investigations in patients with raised anion gap metabolic acidosis show features of the underlying cause, such as reduced GFR in kidney failure and raised urine or blood ketones in ketoacidosis. In DKA, blood glucose is raised, while in starvation and alcoholic acidosis blood glucose is not elevated and may be low. Measurement of plasma lactate is helpful in the diagnosis of lactic acidosis when values are increased over the normal maximal level of 2 mmol/L.

Management

The first step in management of metabolic acidosis is to identify and correct the underlying cause when possible (see Box 19.19). This may involve controlling diarrhoea, treating diabetes mellitus, correcting shock, stopping drugs that might cause the condition or using dialysis to remove toxins. Since metabolic acidosis is frequently associated with sodium and water depletion, resuscitation with intravenous fluids is often needed. In alcoholism and starvation ketosis, intravenous glucose is indicated. By stimulating endogenous insulin secretion, this will reverse hepatic ketone production. Malnourished patients may also require thiamin, potassium, magnesium and phosphate supplements. Use of intravenous bicarbonate in metabolic acidosis is controversial. Because rapid correction of acidosis can induce hypokalaemia or a fall in plasma ionised calcium, the use of bicarbonate infusions is best reserved for situations where the underlying disorder cannot be readily corrected and acidosis is severe ($H^+ > 100$ nmol/L, pH < 7.00) or associated with evidence of tissue dysfunction.

The acidosis in RTA can sometimes be controlled by treating the underlying cause (see Box 19.20) but usually supplements of sodium and potassium bicarbonate are also necessary in types I and II RTA to achieve a target plasma bicarbonate level of > 18 mmol/L and normokalaemia. In type IV RTA, loop diuretics, thiazides or fludrocortisone (as appropriate to the underlying diagnosis) may be effective in correcting the acidosis and the hyperkalaemia.

Metabolic alkalosis

Metabolic alkalosis is characterised by an increase in the plasma bicarbonate concentration and the plasma pH (see Box 19.18). There is a compensatory rise in PCO_2 due to hypoventilation, but this is limited by the need to avoid hypoxia. Classical causes include Conn syndrome, Cushing syndrome and glucocorticoid therapy. Occasionally, overuse of antacid salts for treatment of dyspepsia produces a similar pattern.

Pathophysiology

Metabolic alkalosis is best classified according to the accompanying changes in ECF volume. Hypovolaemic metabolic alkalosis is the most common pattern. This can be caused by sustained vomiting, in which acid-rich fluid is lost directly from the body, or by treatment with loop diuretics or thiazides. In the case of sustained vomiting, loss of gastric acid is the immediate cause of the alkalosis, but several factors act to sustain or amplify this in the context of volume depletion (Fig. 19.10). Loss of sodium and fluid leads to hypovolaemia and secondary hyperaldosteronism, triggering proximal sodium bicarbonate reabsorption and additional acid secretion by the distal tubule. Hypokalaemia occurs due to potassium loss in the vomitus and by the kidney as the result of secondary hyperaldosteronism, and itself is a stimulus to acid secretion. Additionally, the compensatory rise in PCO_2 further enhances tubular acid secretion. The net result is sustained metabolic alkalosis with an inappropriately acid urine, which cannot be corrected until the deficit in circulating volume has been replaced.

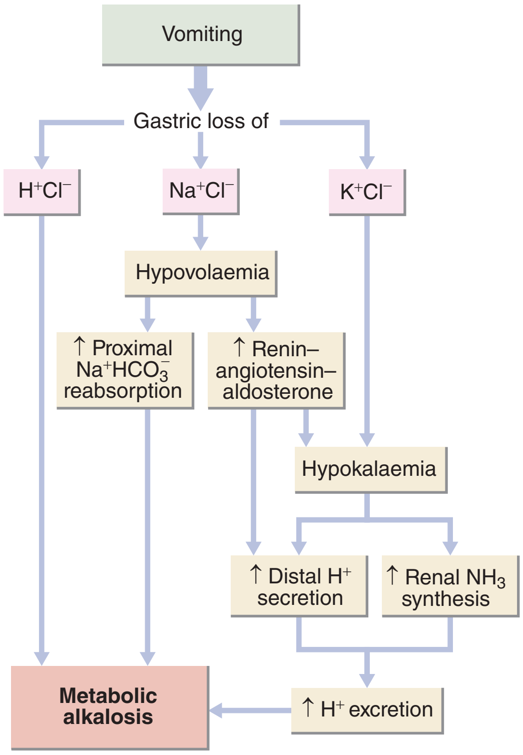

Fig. 19.10 Generation and maintenance of metabolic alkalosis during prolonged vomiting. Loss of H^+Cl^- generates metabolic alkalosis, which is maintained by renal changes.

Normovolaemic (or hypervolaemic) metabolic alkalosis occurs when bicarbonate retention and volume expansion occur simultaneously.

Clinical assessment

Clinically, apart from manifestations of the underlying cause, there may be few symptoms or signs related to alkalosis itself. When the rise in systemic pH is abrupt, however, plasma ionised calcium falls and signs of increased neuromuscular irritability, such as tetany, may develop.

Investigations

The diagnosis can be confirmed by measurement of electrolytes and arterial blood gases.

Management

Metabolic alkalosis with hypovolaemia can be corrected by intravenous infusions of 0.9% saline with potassium supplements. This reverses the secondary hyperaldosteronism and allows the kidney to excrete the excess alkali in the urine. Management of metabolic alkalosis in the absence of hypovolaemia should focus on management of the underlying endocrine cause such as Conn syndrome, Cushing syndrome or corticosteroid excess.

Respiratory acidosis

Respiratory acidosis occurs when there is accumulation of CO_2 due to type II respiratory failure. This results in a rise in the PCO_2, with a compensatory increase in plasma bicarbonate concentration, particularly when the disorder is of long duration and the kidney has fully developed its capacity for increased acid excretion.

This acid–base disturbance can arise from lesions anywhere along the neuromuscular pathways from the brain to the respiratory muscles that result in impaired ventilation. It can also arise during intrinsic lung disease if there is significant mismatching of ventilation and perfusion.

Clinical features are primarily those of the underlying cause of the respiratory disorder, such as paralysis, chest wall injury or chronic obstructive lung disease, but the CO_2 accumulation may itself lead to drowsiness that further depresses respiratory drive.

Management involves correction of causative factors where possible, but ultimately ventilatory support may be necessary.

Respiratory alkalosis

Respiratory alkalosis develops when there is a period of sustained hyperventilation, resulting in a reduction of PCO_2 and increase in plasma pH. If the condition is sustained, renal compensation occurs, such that tubular acid secretion is reduced, and the plasma bicarbonate falls.

Respiratory alkalosis is usually of short duration, occurring in anxiety states or as the result of over-vigorous assisted ventilation. It can be prolonged in the context of pregnancy, pulmonary embolism, chronic liver disease and ingestion of certain drugs such as salicylates that directly stimulate the respiratory centre in the brainstem.

Clinical features are those of the underlying cause, but agitation associated with perioral and digital tingling may also occur, as alkalosis promotes the binding of calcium to albumin, resulting in a reduction in ionised calcium concentrations. In severe cases, Trousseau sign and Chvostek sign may be positive, and tetany or seizures can occur.

Management involves correction of identifiable causes, reduction of anxiety, and a period of rebreathing into a closed bag to allow CO_2 levels to rise.

Mixed acid–base disorders

It is not uncommon for more than one disturbance of acid–base metabolism to be present at the same time in the same patient: for example, a respiratory acidosis due to narcotic overdose with metabolic alkalosis due to vomiting. In these situations, the arterial pH will represent the net effect of all primary and compensatory changes. Indeed, the pH may be normal, but the presence of underlying acid–base disturbances can be gauged from concomitant abnormalities in the PCO_2 and bicarbonate concentration.

In assessing these disorders, all clinical influences on the patient's acid–base status should be identified, and reference should be made to the table of predicted compensation given in Box 19.18. If the compensatory change is discrepant from the rules of thumb provided, more than one disturbance of acid–base metabolism may be suspected.

Calcium homeostasis

Disorders of calcium homeostasis are discussed in Chapter 20 and bone disease is discussed in Chapter 25.

Magnesium homeostasis

Magnesium is mainly an intracellular cation. It is important to the function of many enzymes, including the Na,K-ATPase, and can regulate both potassium and calcium channels. Its overall effect is to stabilise excitable cell membranes.

Functional anatomy and physiology

Renal handling of magnesium involves filtration of free plasma magnesium at the glomerulus (about 70% of the total), with extensive reabsorption (50%–70%) in the loop of Henle and other parts of the proximal and distal renal tubule. Magnesium reabsorption is also enhanced by parathyroid hormone (PTH).

Presenting problems in magnesium homeostasis

Disturbances in magnesium homeostasis usually occur because of increased loss of magnesium through the gut or kidney or inability to excrete magnesium normally in patients with renal impairment.

Hypomagnesaemia

Hypomagnesaemia is defined as existing when plasma magnesium concentrations are below the reference range of 0.75–1.0 mmol/L (1.5–2.0 mEq/L).

Pathophysiology

Hypomagnesaemia usually reflects magnesium depletion (Box 19.21), which can be caused by excessive magnesium loss from the gastrointestinal tract (notably in chronic diarrhoea) or the kidney (during prolonged use of loop diuretics). Excessive alcohol ingestion can cause magnesium depletion through both gut and renal losses. Some inherited tubular transport disorders, such as Gitelman and Bartter syndromes, can also result in urinary magnesium wasting. Magnesium depletion has important effects on calcium homeostasis because magnesium is required for the normal secretion of PTH in response to a fall in serum calcium, and because hypomagnesaemia causes end-organ resistance to PTH.

Clinical assessment

Mild degrees of hypomagnesaemia may be asymptomatic, but more severe hypomagnesaemia may be associated with symptoms of hypocalcaemia, such as tetany, cardiac arrhythmias (notably torsades de pointes), central nervous excitation and seizures, vasoconstriction and hypertension. Hypomagnesaemia and magnesium depletion are also associated (through uncertain mechanisms) with hyponatraemia and hypokalaemia, which may contribute to some of the clinical manifestations.

19.21 Causes of hypomagnesaemia

Mechanism	Examples
Inadequate intake	Starvation Malnutrition Alcoholism Parenteral nutrition
Excessive losses	
Gastrointestinal	Prolonged vomiting/nasogastric aspiration Chronic diarrhoea/laxative abuse Malabsorption Small bowel bypass surgery Fistulae Proton pump inhibitors
Urinary	Diuretic therapy Alcohol Tubulotoxic drugs: Gentamicin Cisplatin Herceptin Volume expansion Diabetic ketoacidosis Post-obstructive diuresis Recovery from acute tubular necrosis Inherited tubular transport defect: Bartter syndrome Gitelman syndrome Primary renal magnesium wasting
Miscellaneous	Acute pancreatitis Foscarnet therapy Proton pump inhibitor therapy Hungry bone syndrome Diabetes mellitus

Management

The underlying cause should be identified and treated where possible. When symptoms are present, the treatment of choice is intravenous magnesium chloride at a rate not exceeding 0.5 mmol/kg in the first 24 hours. If intravenous access is not feasible, magnesium sulphate can be given intramuscularly. Oral magnesium salts have limited effectiveness due to poor absorption and may cause diarrhoea. If hypomagnesaemia is caused by diuretic treatment, adjunctive use of a potassium-sparing agent can also help by reducing magnesium loss into the urine.

Hypermagnesaemia

This is a much less common abnormality than hypomagnesaemia. Predisposing conditions include acute kidney injury, chronic kidney disease and adrenocortical insufficiency. The condition is generally precipitated in patients at risk from an increased intake of magnesium, or from the use of magnesium-containing medications, such as antacids, laxatives and enemas.

Clinical features include bradycardia, hypotension, reduced consciousness and respiratory depression.

Management involves ceasing all magnesium-containing drugs and reducing dietary magnesium intake, improving renal function if possible, and promoting urinary magnesium excretion using a loop diuretic with intravenous hydration, if residual renal function allows. Calcium gluconate may be given intravenously to ameliorate cardiac effects. Dialysis may be necessary in patients with poor renal function.

Phosphate homeostasis

Inorganic phosphate (mainly present as HPO_4^{2-}) is intimately involved in cell energy metabolism, intracellular signalling and bone and mineral homeostasis (Ch. 25). The normal plasma concentration is 0.8–1.4 mmol/L (2.48–4.34 mg/dL).

Functional anatomy and physiology

Phosphate is freely filtered at the glomerulus and approximately 65% is reabsorbed by the proximal tubule, through an apical sodium–phosphate co-transport carrier. A further 10%–20% is reabsorbed in the distal tubules, leaving a fractional excretion of some 10% to pass into the urine, usually as $H_2PO_4^-$. Proximal reabsorption is decreased by PTH, fibroblast growth factor 23 (FGF23), volume expansion, osmotic diuretics and glucose infusion.

Presenting problems in phosphate homeostasis

The following section deals primarily with conditions that cause acute disturbances in serum phosphate concentrations. Chronic disorders that are accompanied by phosphate depletion, such as osteomalacia and hypophosphataemic rickets, are discussed in Chapter 25. Acute kidney injury and chronic kidney disease, which are associated with hyperphosphataemia, are discussed below and also in Chapter 18.

Hypophosphataemia

Hypophosphataemia is defined as existing when serum phosphate values fall below 0.8 mmol/L (2.48 mg/dL). The causes are shown in Box 19.22, subdivided into the underlying pathogenic mechanisms.

Pathophysiology

Phosphate may redistribute into cells during periods of increased energy utilisation (such as refeeding after a period of starvation) and during systemic alkalosis. However, severe hypophosphataemia usually represents an overall body deficit due to either inadequate intake or absorption through the gut, or excessive renal losses, most notably in primary hyperparathyroidism or as the result of acute plasma volume expansion, osmotic diuresis and diuretics acting on the proximal renal tubule. Less common causes include inherited defects of proximal sodium–phosphate co-transport and tumour-induced osteomalacia due to ectopic production of the hormone FGF23.

Clinical assessment

The clinical features of phosphate depletion are wide-ranging, reflecting the involvement of phosphate in many aspects of metabolism. Defects appear in the blood (impaired function and survival of all cell lineages), skeletal muscle (weakness, respiratory failure), cardiac muscle (congestive cardiac failure), smooth muscle (ileus), central nervous system (decreased consciousness, seizures and coma) and bone (osteomalacia and rickets in severe prolonged hypophosphataemia).

19.22 Causes of hypophosphataemia

Mechanism	Examples
Redistribution into cells	Refeeding after starvation Respiratory alkalosis Treatment for diabetic ketoacidosis
Inadequate intake or absorption	Malnutrition Malabsorption Chronic diarrhoea Phosphate binders Antacids Vitamin D deficiency or resistance
Increased renal excretion	Hyperparathyroidism Extracellular fluid volume expansion with diuresis Osmotic diuretics Fanconi syndrome Familial hypophosphataemic rickets Tumour-induced hypophosphataemic rickets

Investigations

Measurement of creatinine, electrolytes, phosphate, albumin, calcium and alkaline phosphatase should be performed. In selected cases, measurement of PTH and 25(OH)D and FGF23 may be helpful. The combination of hypophosphataemia and hypercalcaemia suggests primary hyperparathyroidism, which should be further investigated by measurements of PTH. The combination of hypophosphataemia with raised FGF23 levels and normal levels of 25(OH)D suggests either hereditary hypophosphataemic rickets or tumour-induced osteomalacia.

Management

Management of hypophosphataemia due to decreased dietary intake or excessive losses involves administering oral phosphate supplements and high-protein/high-dairy dietary supplements that are rich in naturally occurring phosphate. Intravenous treatment with sodium or potassium phosphate salts can be used in critical situations, but there is a risk of precipitating hypocalcaemia and metastatic calcification. Management of primary hyperparathyroidism is discussed in Chapter 18 and of hypophosphataemic rickets in Chapter 25.

Hyperphosphataemia

Hyperphosphataemia is most commonly caused by acute kidney injury or chronic kidney disease. Rarely, hyperphosphataemia can occur in association with hypercalcaemia in the inherited disorder tumoral calcinosis due to loss-of-function variants in *FGF23* or *GALTN3*.

Pathophysiology

In acute kidney injury and chronic kidney disease, the primary cause is reduced phosphate excretion as the result of a low GFR. In contrast, the hyperphosphataemia in hypoparathyroidism and pseudohypoparathyroidism is due to increased tubular phosphate reabsorption. Redistribution of phosphate from cells into the plasma can also be a contributing factor in the tumour lysis syndromes and other catabolic states. Phosphate accumulation can be aggravated in any of these conditions if the patient takes phosphate-containing preparations or inappropriate vitamin D therapy.

Clinical assessment

The clinical features relate to hypocalcaemia and metastatic calcification, particularly in chronic kidney disease with tertiary hyperparathyroidism, when a high calcium–phosphate product occurs. Tumoral calcinosis is characterised by musculoskeletal pain due to deposition of calcium and phosphate in the joints and soft tissues.

Management

Hyperphosphataemia in patients with kidney disease should be treated with dietary phosphate restriction and the use of oral phosphate binders. Hyperphosphataemia in hypoparathyroidism and pseudohypoparathyroidism does not usually require treatment. Hyperphosphataemia associated with tumour lysis syndromes and catabolic states can be treated with intravenous normal saline, which is given to promote phosphate excretion.

Lipids and lipoprotein metabolism

The three main biological classes of lipid are:

- cholesterol, composed of hydrocarbon rings
- triglycerides (TGs), composed of glycerol esterified to three fatty acid chains
- phospholipids, composed of a hydrophobic ‘tail’ consisting of two long-chain fatty acids esterified to glycerol with a hydrophilic head containing a phosphate group.

Poorly water-soluble lipids need to be absorbed from the gastrointestinal tract and transported throughout the body. This is achieved by incorporating lipids within lipoproteins. Plasma cholesterol and TGs are clinically important because they are major treatable risk factors for atherosclerotic cardiovascular disease (ASCVD). Furthermore, severe hypertriglyceridaemia predisposes to acute pancreatitis.

Functional anatomy and physiology

Lipids are transported and metabolised by apolipoproteins, which combine with lipids to form spherical or disc-shaped lipoproteins, consisting of a hydrophobic core and a less hydrophobic coat (Fig. 19.11). Some apolipoproteins also act as enzyme co-factors or cell receptor ligands. Variations in lipid and apolipoprotein composition result in distinct classes of lipoprotein that perform specific metabolic functions.

Processing of dietary lipid

Intestinal absorption of dietary lipids is described in Chapter 22. The most salient features relevant to lipid metabolism are summarised in Figure 19.12. Enterocytes extract mono- and diglycerides and free fatty acids from intestinal micelles. Intracellular re-esterification forms TGs, which are combined with a truncated form of apolipoprotein B (Apo B48) as it is synthesised. Intestinal cholesterol from dietary and biliary sources is also absorbed via a specific intestinal membrane

Fig. 19.12 **Absorption, transport and storage of lipids**. Pathways of lipid transport are shown; in addition, cholesterol ester transfer protein exchanges triglyceride and cholesterol ester between very low-density lipoprotein/chylomicrons and high-/low-density lipoprotein, and free fatty acids released from peripheral lipolysis can be taken up in the liver. (ABCA1/ABCG1 = adenosine triphosphate-binding cassette A1/G1; Apo = apolipoprotein; BA = bile acids; C = cholesterol; CE = cholesterol ester; FFA = free fatty acids; HDL = mature high-density lipoprotein; HL = hepatic lipase; HMGCoAR = hydroxy-methyl-glutaryl-co-enzyme A reductase; IDL = intermediate-density lipoprotein; iHDL = immature high-density lipoprotein; LCAT = lecithin cholesterol acyl transferase; LDL = low-density lipoprotein; LDLR = low-density lipoprotein receptor (Apo B100 receptor); LPL = lipoprotein lipase; PCSK9 = proprotein convertase subtilisin kexin 9; SRB1 = scavenger receptor B1; TG = triglyceride; VLDL = very low-density lipoprotein)

transporter termed NPC1L1. These processes produce chylomicrons containing TG and cholesterol ester that are secreted into blood via the lymphatics and thoracic duct. On entering the blood stream, nascent chylomicrons are modified by further exchange of apolipoproteins and lipids.

Chylomicron TGs are hydrolysed by lipoprotein lipase on the endothelium of tissue capillary beds. The local release of fatty acids provides substrate for energy utilisation or storage as TG in adipose and other tissues. The residual 'remnant' chylomicron is avidly cleared by hepatic receptors including low-density lipoprotein receptors (LDLRs), which recognise Apo E on the remnant lipoproteins. Complete absorption of dietary lipids takes about 6–10 hours, so chylomicrons are usually undetectable in the plasma after a 12-hour fast.

Dietary determinants of plasma cholesterol concentrations are mainly saturated and *trans*-unsaturated fatty acids, which reduce LDLR activity (see below). Dietary cholesterol has surprisingly modest effects on plasma cholesterol levels. Plant sterols and cholesterol absorption inhibitors reduce the re-utilisation of both dietary and biliary cholesterol. Dietary determinants of plasma TG concentrations are complex. Excessive intake of carbohydrate, fat or alcohol may contribute to increased plasma TG by different mechanisms. Hereditary deficiencies in the absorption and transport of lipids may result in low plasma levels of lipids and fat-soluble vitamins such as A, D, E and K.

Endogenous lipid synthesis

In the fasting state, the liver is the major source of plasma lipids (see Fig. 19.12).

The liver acquires lipids by uptake, synthesis or conversion from other macronutrients. These lipids are secreted as very low-density lipoproteins (VLDLs), which are rich in TG. They differ from chylomicrons in that VLDLs are less massive and contain full-length Apo B100. Within the circulation, VLDLs undergo metabolic processing similar to that of chylomicrons. Hydrolysis of VLDL TG releases fatty acids to tissues and converts VLDLs into 'remnant' intermediate-density lipoproteins (IDLs). Most IDLs are rapidly cleared by LDLRs in the liver, but some are processed by hepatic lipase, which removes TG and most materials other than Apo B100, and free and esterified cholesterol, thereby producing LDL. The catabolism of TG-rich chylomicrons and VLDL by lipoprotein lipase is modulated by factors including Apo C2 and C3 on the surface of these particles.

Cholesterol transport

LDL particles act as a source of cholesterol for cells and tissues (see Fig. 19.12). LDL cholesterol is internalised via the LDLR. Homeostatic control of intracellular cholesterol levels is coordinated by sterol regulatory element binding protein (SREBP) via several mechanisms. Decline in SREBP down-regulates expression of LDLR and reduces the synthesis and activity of the rate-limiting enzyme for cholesterol synthesis, hydroxy-methyl-glutaryl-co-enzyme A (HMGCoA) reductase. Intracellular free cholesterol concentrations are maintained within a narrow range by the inhibitory effects of LDL on expression of LDLR, and control of cholesterol absorption, synthesis and esterification. Counterintuitively, an accompanying increase in an important regulator of LDLR levels, proprotein convertase subtilisin kexin 9 (PCSK9), targets LDLR for degradation thereby modulating its half-life.

A subpopulation of LDL acquires apolipoprotein (a), a genetically controlled apolipoprotein, leading to the hepatic formation of lipoprotein (a) (Lp(a)). This lipoprotein is absent from most animal species. Lp(a) transports oxidised phospholipid. Its broader role is unknown, but it is an independent risk factor for ASCVD.

Peripheral tissues are guarded against excessive cholesterol accumulation by high-density lipoproteins (HDLs; see Fig. 19.12). Lipid-poor Apo A1 (derived from the liver, intestine and other sources) accepts cellular cholesterol and phospholipid from the specific membrane transporter ATP-binding cassette A1 (ABCA1). This produces small HDLs that can accept more free cholesterol from cholesterol-rich membrane 'rafts' via ABCG1. The accepted cholesterol is esterified by lecithin cholesterol acyl transferase (LCAT) in these small HDLs. The process maintains an uptake gradient which remodels the particle into a mature spherical HDL. These HDLs release their cholesterol to the liver and other cholesterol-requiring tissues via the scavenger receptor B1 (SRB1). Much of the cholesterol required for steroid hormone production is derived from HDL.

Cholesterol ester transfer protein (CETP) in plasma transfers cholesterol from HDLs or LDLs to VLDLs or chylomicrons in exchange for TG. When TG is elevated, the action of CETP may reduce HDL cholesterol and remodel LDLs into 'small, dense' LDL particles that may be more atherogenic towards the blood-vessel wall.

Lipids and cardiovascular disease

Plasma lipoprotein levels are major modifiable risk factors for atherosclerotic cardiovascular disease (ASCVD). Increased levels of atherogenic lipoproteins (especially low-density lipoprotein (LDL) and Lp(a), but also intermediate-density lipoprotein (IDL), and possibly chylomicron remnants) contribute to the development of atherosclerosis. Lp(a) is an independent causal risk factor for ASCVD as well as aortic stenosis.

Following chemical modifications such as oxidation, apolipoprotein B (Apo B)-containing lipoproteins are no longer cleared by the usual low-density lipoprotein receptor (LDLR) pathway. They trigger a self-perpetuating inflammatory response, during which they are taken up by macrophage 'scavenger receptors' to form foam cells in atherosclerotic lesions. They also have an adverse effect on endothelial function. Conversely, high-density lipoprotein (HDL) may counteract some components of the inflammatory response, including expression of vascular adhesion molecules by the endothelium. Low HDL cholesterol levels (HDL-C) are usually associated with triglyceride (TG) elevation, thereby confounding associations between HDL-C and/or TG with atherosclerosis.

Investigations

Lipid measurements are usually performed for the following reasons:

- screening for primary or secondary prevention of ASCVD
- investigation of patients with clinical features of lipid disorders and their relatives, known as cascade testing
- monitoring of response to diet, weight management and medications.

Convenient, non-fasting measurements of total cholesterol (TC) and HDL cholesterol (HDL-C) allow estimation of non-HDL cholesterol (non-HDLC, calculated as TC – HDL-C). A 12-hour fasting sample is required to standardise TG measurement and allow calculation of LDL cholesterol (LDL-C) according to the Friedewald or other formulae. Friedewald calculation of LDL-C can become unreliable when TG levels exceed 4 mmol/L (350 mg/dL), so more robust formulae such as the Martin/Hopkins calculation are gaining acceptance. Measurements of non-HDLC or Apo B100 may assess risk of ASCVD more accurately than LDL-C, particularly when TG levels are increased. Formal diagnosis of hypertriglyceridaemia and calculation of LDL-C via formulae require a 12-hour fast, but non-fasting non-HDL and TG levels offer convenient markers of cardiovascular risk. Elevated levels of TG, which are common in obesity, diabetes mellitus and insulin resistance, are frequently associated with low HDL and increased 'small, dense' LDL.

Pre-analytical factors, such as recent illness, may affect cholesterol, LDL-C and HDL-C temporarily. Plasma levels decrease (whilst TG levels increase) in proportion to severity of the episode. Results that will affect major decisions, such as initiation of drug therapy, should be confirmed with a repeat measurement.

Presenting problems in lipid metabolism

Hyperlipidaemia can occur in association with various diseases and drugs, as summarised in Box 19.23. Overt or subclinical hypothyroidism may cause hypercholesterolaemia. Measurement of thyroid function is warranted in most cases, even in the absence of typical symptoms and signs. Once secondary causes are excluded, primary lipid abnormalities may be classified according to the predominant lipid problem: hypercholesterolaemia, hypertriglyceridaemia or mixed hyperlipidaemia (Box 19.24). Although monogenic disorders are encountered in all three categories, most cases are due to polygenic variants interacting with environmental factors. The clinical features and complications of dyslipidaemia vary somewhat between these causes.

Hypercholesterolaemia

Polygenic hypercholesterolaemia is the most common cause of a mild to moderate increase in LDL-C (see Box 19.24). Physical signs, such as corneal arcus and xanthomata, may be found in this as well as other forms of hyperlipidaemia (see p. 656–657). The risk of cardiovascular disease is proportional to the degree of LDL-C (or Apo B) elevation, but is modified by other major risk factors, including high TG and high Lp(a).

Familial hypercholesterolaemia (FH) is a more severe disorder with a prevalence of approximately 0.4% in most populations. Its usual cause is loss-of-function variants affecting the *LDLR* gene, which results in an autosomal co-dominant pattern of inheritance. A similar syndrome can arise with loss-of-function variants in the ligand-binding domain of Apo B100 or gain-of-function variants in *PCSK9*, which promote LDLR degradation. Pathological variants can be detected in one of these three genes by genetic testing in about 70% of patients with FH. Most patients with FH have LDL-C levels that are approximately twice as high as unaffected subjects of the same age and gender. FH may be accompanied by xanthomas of the Achilles or extensor digitorum tendons (p. 565), which are strongly suggestive of FH. The onset of corneal arcus before age 45 years is also suggestive of this condition. Identification of an index case of FH (the first case of FH in a family) should trigger genetic and biochemical screening of other family members, which is a cost-effective method for case detection. Affected individuals should be managed from childhood (Box 19.25) because FH accelerates the risk of premature ASCVD by 20–40 years.

Homozygous FH is rare, but more likely in populations in which there is a 'founder' gene effect or consanguineous marriage. Homozygosity results in more extensive xanthomas and precocious ASCVD, often in childhood. Hyperalphalipoproteinaemia refers to increased levels of HDL-C. This condition rarely causes cardiovascular disease, but it may reflect HDL dysfunction, so it should not be regarded as universally benign.

Familial combined hyperlipidaemia and dysbetalipoproteinaemia may present with the pattern of predominant hypercholesterolaemia (see 'Mixed hyperlipidaemia' below).

19.23 Causes of secondary hyperlipidaemia

Secondary hypercholesterolaemia

Moderately common

- Drugs:
    - Diuretics
    - Ciclosporin
    - Glucocorticoids
    - Androgens
    - Antiretroviral agents
- Hypothyroidism
- Pregnancy
- Cholestatic liver disease (possibly in the form of lipoprotein X)

Less common

- Nephrotic syndrome
- Anorexia nervosa
- Porphyria
- Hyperparathyroidism

Secondary hypertriglyceridaemia

Common

- Type 2 diabetes mellitus
- Chronic kidney disease
- Abdominal obesity
- Excess alcohol
- Hepatocellular disease
- Drugs:
    - β-blockers
    - Retinoids
    - Glucocorticoids
    - Antiretroviral agents

Hypertriglyceridaemia

Hypertriglyceridaemia is usually polygenic (see Box 19.24) or secondary. Common causes include medications (such as β-blockers and retinoids), hepatic impairment, type 2 diabetes mellitus, impaired glucose tolerance, central obesity or other manifestations of insulin resistance, renal impairment, excess alcohol intake, and reduced absorption of bile acids.

19.25 Familial hypercholesterolaemia in adolescence

- **Statin treatment:** may be required from the age of about 10. It does not compromise normal growth and maturation.
- **Smoking:** patients should be strongly advised not to smoke.
- **Adherence to medication:** critically important to the success of treatment. Simple regimens should be used and education and support provided.

19.24 Classification of hyperlipidaemia

Disease	Elevated lipid results	Elevated lipoprotein	CHD risk	Pancreatitis risk
Predominant hypercholesterolaemia				
Polygenic (majority)	TC ± TG	LDL ± VLDL	+	–
Familial hypercholesterolaemia (LDLR defect, defective Apo B100, increased function of *PCSK9*)	TC ± TG	LDL ± VLDL	+++	–
Hyperalphalipoproteinaemia	TC ± TG	HDL	–	–
Predominant hypertriglyceridaemia				
Polygenic (majority)	TG	VLDL ± LDL	Variable	+
Lipoprotein lipase deficiency	TG ≫ TC	Chylo	?	+++
Familial hypertriglyceridaemia	TG > TC	VLDL ± chylo	?	++
Mixed hyperlipidaemia				
Polygenic (majority)	TC + TG	VLDL + LDL	Variable	+
Familial combined hyperlipidaemia*	TC and/or TG	LDL and/or VLDL	++	+
Dysbetalipoproteinaemia*	TC and/or TG	IDL	+++	+

*Familial combined hyperlipidaemia and dysbetalipoproteinaemia may also present as predominant hypercholesterolaemia or predominant hypertriglyceridaemia.

(Apo B100 = apolipoprotein B100; CHD = coronary heart disease; chylo = chylomicrons; HDL = high-density lipoprotein; IDL = intermediate-density lipoprotein; LDL = low-density lipoprotein; LDLR = low-density lipoprotein receptor; TC = total cholesterol; TG = triglycerides; VLDL = very low-density lipoprotein)

+ = slightly increased risk; ++ = increased risk; +++ = greatly increased risk; ? = risk unclear

It is often accompanied by post-prandial hyperlipidaemia and reduced HDL-C, both of which may contribute to ASCVD risk. Excessive intake of alcohol or dietary fat, or other exacerbating factors, may precipitate a massive increase in TG levels, which, if they exceed 10 mmol/L (880 mg/dL), may pose a risk of acute pancreatitis.

Monogenic forms of hypertriglyceridaemia also occur due to loss-of-function variants in the genes encoding lipoprotein lipase, or Apo C2, which coordinate the lipolytic breakdown of TG-rich lipoproteins. These cause recessively inherited severe hypertriglyceridaemia which may present in childhood with episodes of acute abdominal pain or pancreatitis. In common with other causes of severe hypertriglyceridaemia, hepatomegaly, lipaemia retinalis and eruptive xanthomas may occur (p. 565). Familial hypertriglyceridaemia may also be inherited due to loss-of-function variants in the *APOA5* gene, which encodes a co-factor that is essential for lipoprotein lipase activity. These conditions are not particularly responsive to routine drug therapy. Conversely, loss-of-function variants for genes encoding ANGPTL 3 and 4, or Apo C3, may increase lipoprotein lipase activity. These changes are associated with lower TG levels and decreased risk of ASCVD. Novel therapies based on inhibition of these gene products are showing promise as novel triglyceride-lowering agents.

Familial combined hyperlipidaemia and dysbetalipoproteinaemia may present with the pattern of predominant hypertriglyceridaemia (see 'Mixed hyperlipidaemia', below).

Mixed hyperlipidaemia

The point of differentiation between predominant hyperlipidaemias and mixed hyperlipidaemia is poorly defined. The term 'mixed' usually implies the presence of hypertriglyceridaemia, as well as an increase in LDL-C or IDL. Treatment of massive hypertriglyceridaemia may improve TG faster than cholesterol, thus temporarily mimicking mixed hyperlipidaemia.

Primary mixed hyperlipidaemia is usually polygenic and, like predominant hypertriglyceridaemia, often occurs in association with type 2 diabetes mellitus, impaired glucose tolerance, central obesity or other manifestations of insulin resistance. Both components of mixed hyperlipidaemia may contribute to the risk of ASCVD.

Familial combined hyperlipidaemia is a term used to identify an inherited tendency towards the over-production of atherogenic Apo B-containing lipoproteins. It results in elevation of cholesterol, TG or both in different family members at different times. It is associated with an increased risk of ASCVD, but it does not produce any pathognomonic physical signs. In practice, this relatively common condition is substantially modified by factors such as age and weight. It may not be a monogenic condition, but rather one end of a heterogeneous spectrum that overlaps insulin resistance.

Dysbetalipoproteinaemia (also referred to as type 3 hyperlipidaemia, broad-beta dyslipoproteinaemia or remnant hyperlipidaemia) involves accumulation of approximately equimolar levels of cholesterol and TG. It is caused by homozygous inheritance of the Apo E2 allele, which is the isoform least avidly recognised by the LDLR. In conjunction with other exacerbating factors, such as obesity or diabetes, it leads to accumulation of atherogenic IDL and chylomicron remnants. Premature ASCVD is common, as is peripheral vascular disease. It may also result in the formation of palmar xanthomas, tuberous xanthomas or tendon xanthomas.

Several rare conditions have been described (Box 19.26). They provide important insights into lipid metabolism and its impact on risk of ASCVD. Fish-eye disease, Apo A1 Milano and lecithin cholesterol acyl transferase (LCAT) deficiency demonstrate that very low HDL-C levels do not necessarily cause ASCVD, but Apo A1 deficiency, and possibly Tangier disease, demonstrate that low HDL-C can be atherogenic under some circumstances. PCSK9 gain-of-function and autosomal recessive *FH* variants reveal the importance of proteins that chaperone the LDLR. Sitosterolaemia and cerebrotendinous xanthomatosis demonstrate that sterols other than cholesterol can cause xanthomas and ASCVD, while *PCSK9* loss-of-function mutations, abetalipoproteinaemia and hypobetalipoproteinaemia suggest that low levels of Apo B-containing lipoproteins reduce the risk of ASCVD. Gastrointestinal and hepatic symptoms may arise from impaired transport of lipid from intestine or liver in the latter two conditions. The extremely low levels of plasma lipid levels which accompany these conditions may lead to fat-soluble vitamin deficiency (vitamins A, D, E and K). The vitamin E deficiency may result in neurological sequelae. On the other hand, low levels of LDL cholesterol due to reduced PCSK9 activity are not associated with adverse outcomes, suggesting the aggressive reduction on LDL-C does not pose safety issues.

i 19.26 Miscellaneous and rare forms of hyperlipidaemia

Condition	Lipoprotein pattern	CVD risk
Tangier disease	Very low HDL, low TC	+
Apo A1 deficiency	Very low HDL	++
Apo A1 Milano	Very low HDL	–
Fish-eye disease	Very low HDL, high TG	–
LCAT deficiency	Very low HDL, high TG	?
Autosomal recessive FH	Very high LDL	++
Sitosterolaemia	High plant sterols including sitosterol	+
Cerebrotendinous xanthomatosis	Bile acid defect (cholestanol accumulation)	+
PCSK9 loss of function	Low LDL	–
Severe cholestasis	Lipoprotein x	–

+ = slightly increased risk; ++ = increased risk
(CVD = cardiovascular disease; FH = familial hypercholesterolaemia; HDL = high-density lipoprotein; LCAT = lecithin cholesterol acyl transferase; LDL = low-density lipoprotein; PCSK9 = proprotein convertase subtilisin kexin 9; TC = total cholesterol; TG = triglycerides)

Principles of management

Assessment of ASCVD risk, treatment of all modifiable risk factors and optimisation of lifestyle, especially diet and physical activity, are central to management in all cases. Lipid-lowering therapies have a key role in the prevention of ASCVD because of their ability to prevent progression and promote stabilisation of atherosclerotic plaque. Patients with the greatest absolute risk of ASCVD derive the greatest absolute benefit from treatment. On the other hand, benefits are cumulative, so early intervention and sustained adherence offer major benefits.

Public health organisations recommend thresholds for the introduction of lipid-lowering therapy based on the identification of patients in very high-risk categories, or those calculated to be at high absolute risk according to algorithms or tables. The large epidemiological studies on which risk assessment is based should be recalibrated for the local population, where possible. The decision to commence lipid-lowering therapy takes lipid concentrations into account along with other risk factors and age. The benefit of even modest sustained reductions accumulates over time. Public health guidelines reflect local differences as well as common themes. Recent modifications include additional clinical input for risk calculation tables, expanded lists of risk-enhancing factors, consideration of socio-economic factors, use of coronary calcium scores in intermediate-risk patients and adoption of more aggressive LDL-C treatment goals. Secondary prevention target levels for LDL-C are less than 1.4 mmol/L, whilst extreme/very high-risk cases may warrant an LDL target below 1.0 mmol/L.

Non-pharmacological management

Patients with lipid abnormalities should receive medical counselling about activity and diet couched in terms of practical dietary and culinary advice:

- replace sources of saturated and trans-unsaturated fat and cholesterol with alternative foods, such as lean meat, low-fat dairy products, polyunsaturated spreads and low-glycaemic-index carbohydrates

- reduce energy-dense foods such as fats and soft drinks, while increasing physical activity and exercise to maintain or lose weight
- increase consumption of cardioprotective and nutrient-dense foods, such as vegetables, unrefined carbohydrates, fish, pulses, nuts, legumes and fruits
- adjust alcohol consumption, reducing intake if excessive (> 2 standard drinks per day) or if associated with hypertension, hypertriglyceridaemia or central obesity
- achieve additional benefits with preferential intake of foods containing lipid-lowering nutrients such as n-3 fatty acids, dietary fibre and plant sterols
- reduce intake of saturated and trans-unsaturated fat to less than 7%–10% of total energy and that of cholesterol to < 250 mg/day.
- adopt cuisines which are both palatable and healthy, such as a Mediterranean style diet
- avoid fad diets high in saturated fats style because they may drastically elevate LDL-C.

These measures should achieve a response within 3–4 weeks but dietary adjustment may need to be introduced gradually. Although hyperlipidaemia in general, and hypertriglyceridaemia in particular, can be very responsive to these measures, LDL-C reductions are often only modest in routine clinical practice. Explanation, encouragement and persistence are often required to assist patient adherence. Even minor weight loss can substantially reduce cardiovascular risk, especially in centrally obese patients.

All other modifiable cardiovascular risk factors should be assessed and treated. If possible, intercurrent drug treatments that adversely affect the lipid profile should be replaced.

Pharmacological management

The main diagnostic categories provide a useful framework for management and the selection of first-line pharmacological treatments (Fig. 19.13). Depending on the response, treatment with more than one drug may be required. Advances in understanding the genetic factors that regulate lipid metabolism have led to the identification of several new lipid-lowering agents. Monoclonal antibodies and antisense mRNA therapies directed against PCSK9 are already used in clinical practice, whereas antisense mRNA directed against angiopoietin-like 3 (ANGPTL3) and apolipoprotein C3 *(APOC3)* are under investigation for the treatment of hypertriglyceridaemia and selected cases of hypercholesterolaemia.

Hypercholesterolaemia

The drugs used in the treatment of hypercholesterolaemia target the pathways responsible for cholesterol synthesis, its absorption from the diet, or its clearance from the circulation. Homeostatic mechanisms orchestrated by sterol regulatory element binding protein (SREBP) maintain intracellular cholesterol concentrations, explaining the synergism of combination therapy and the blunting of statin, ezetimibe and resin monotherapy. The PCSK9 response to SREBP is paradoxical because it reverses the SREBP-induced increase in LDLRs. As such, PCSK9 may represent a 'fine tuning' mechanism for intracellular cholesterol homeostasis. The consequences are summarised in Figure 19.14.

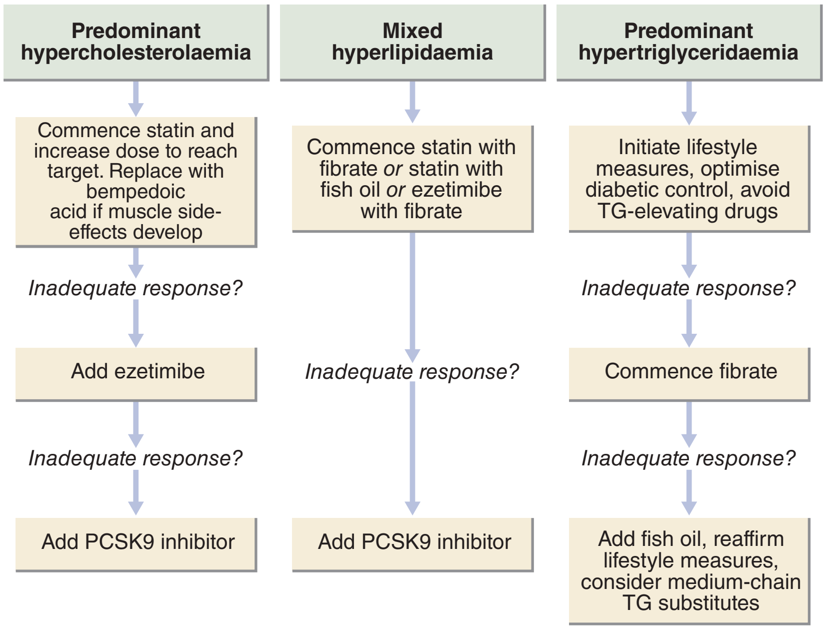
Statins

Statins reduce cholesterol synthesis by inhibiting the 3-hydroxy-3-methylglutaryl coenzyme A (HMGCoA) reductase enzyme. The reduction in cholesterol synthesis up-regulates production of the LDLR, which increases clearance of LDL and its precursor IDL, resulting in a secondary reduction in LDL synthesis. Statins reduce LDL-C by up to 60%, reduce TG by up to 40% and increase HDL-C by up to 10%. They also reduce the concentration of intermediate metabolites including isoprenes, which may lead to other effects such as suppression of the inflammatory response. There is clear evidence of protection against total and coronary mortality, stroke and cardiovascular events across the spectrum of ASCVD.

Statins are generally well tolerated and serious side-effects are infrequent. Liver chemistry abnormalities and muscle problems, such as myalgia, asymptomatic increase in creatine kinase (CK), myositis and, infrequently, rhabdomyolysis, are the most common. Side-effects are more likely in older adults and in patients who are debilitated or receiving other drugs that interfere with statin degradation, which usually involves cytochrome P450 3A4 or glucuronidation.

Bempedoic acid

Bempedoic acid provides an alternative agent with which to suppress hepatic cholesterol synthesis. It is administered as a prodrug which is activated in the liver, but not in muscle. The active form inhibits ATP citrate lyase resulting in reduced cholesterol synthesis. This reduces LDL-C



Predominant hypercholesterolaemia

Fig. 19.14 **Mechanism of action for cholesterol-lowering drugs.** Traditional cholesterol-lowering drugs such as statins and ezetimibe lower intracellular cholesterol, causing activation of sterol regulatory element binding protein (SREBP), which increases expression of sterol responsive genes, particularly LDLR, leading to lower plasma LDL. Activation of SREBP also stimulates cholesterol synthesis and absorption, which may blunt the therapeutic response to these drugs. SREBP also fine-tunes the restoration of intracellular cholesterol by up-regulating PCSK9, which assists degradation of LDLRs. Inhibitors of PCSK9 do not affect intracellular cholesterol but instead work by causing LDLR to accumulate at the cell surface, thereby removing cholesterol bound to LDL from the circulation. (HMGCoA = hydroxy-methyl-glutaryl-co-enzyme A; HMGCoAR = hydroxy-methyl-glutaryl-co-enzyme A reductase; LDL = low-density lipoprotein; LDLR = low-density lipoprotein receptor; PCSK9 = proprotein convertase subtilisin kexin 9)

by about 30%, with significant reduction in ASCVD outcomes, but no increase in muscle side-effects.

PCSK9 inhibitors

Inhibitors have been developed that eliminate proprotein convertase subtilisin/kexin type 9 (PCSK9), a proprotein that degrades the LDLR. This causes levels of LDLR to increase, which markedly reduces LDL-C by clearing LDL from the circulation. The PCSK9 inhibitors currently available are the monoclonal antibodies (Mab) evolocumab and alirocumab, which are administered subcutaneously every 2–4 weeks, and the PCSK9 antisense mRNA inclisiran, which is administered subcutaneously every 6 months. These drugs are all highly effective. Reductions in LDL-C of about 50%–60% have been observed with these agents in patients who have not responded adequately to standard lipid-lowering therapy. The reduction has been accompanied by a decline in the risk of ASCVD events of about 15% within 2 years. The reason PCSK9 inhibitors are so highly effective is that they do not lower intracellular levels of cholesterol and hence do not trigger the compensatory mechanisms that blunt the effect of other cholesterol-lowering medications. The PCSK9 inhibitors act synergistically with statins and ezetimibe and lower lipoprotein (a) by mechanisms that are unclear.

Ezetimibe

Ezetimibe inhibits the activity of the intestinal mucosal transporter NPC1L1, which is responsible for absorption of dietary and biliary cholesterol. The resulting depletion of hepatic cholesterol up-regulates hepatic LDLR production. This mechanism of action is synergistic with the effect of statins. Monotherapy in a 10 mg/day dose reduces LDL-C by 15%–20%. Slightly greater (17%–25%) incremental LDL-C reduction occurs when ezetimibe is added to statins or bempedoic acid. Ezetimibe is well tolerated, with proven efficacy for a beneficial effect on ASCVD endpoints. Plant sterol-supplemented foods, which also reduce cholesterol absorption, lower LDL-C by 7%–15%.

Bile acid-sequestering resins

The use of colestyramine, colestipol and colesevelam is declining. They prevent the reabsorption of bile acids, thereby increasing de novo bile acid synthesis from hepatic cholesterol. The resultant depletion of hepatic cholesterol up-regulates LDLR activity and reduces LDL-C in a manner that is synergistic with the action of statins.

Novel lipid-lowering therapy

Small interfering messenger RNA (siRNA) strategy used to eliminate PCSK9 by means of inclisiran can be directed against other atherogenic targets such as Lp(a). Olpasiran and pelacarsen are two such agents with potent capacity to reduce Lp(a) by over 70%. Their clinical efficacy is currently under assessment. Likewise, evinacumab and siRNA methods can reduce ANGPTL3. This reduces both TG and LDLC. The clinical efficacy of these agents is also under review, but it appears that ANGPTL3 inhibitors may have a unique mechanism of action that utilises an alternative clearance pathway for LDLC. Oral versions of PCSK9 inhibitors and Lp(a)-lowering agents are also under development. Gene editing techniques are also being applied to targets such as PCSK9, ANGPTL3 and Lp(a). In these instances, the aim is to silence the gene, rather than modify the gene product.

Combination therapy

In many patients, treatment of predominant hypercholesterolaemia can be achieved by diet plus the use of a statin in sufficient doses to achieve target LDL-C levels. Patients who do not reach LDL-C targets on the maximum tolerated statin dose, or who are intolerant of statins, may receive plant sterols, ezetimibe, PCSK9 inhibitors, bempedoic acid or resins. Ezetimibe is safe and effective in combination with a statin or bempedoic acid because the mechanisms of action of individual therapies complement each other while blunting each other's compensatory mechanisms. The judicious use of combination therapy, particularly ezetimibe plus statin, may assist long-term adherence.

Hypertriglyceridaemia

Predominant hypertriglyceridaemia can be treated with one of the TG-lowering drugs described below, in combination with lifestyle measures such as weight reduction, reduction in alcohol consumption and optimisation of glycaemic control.

Fibrates

Fibrates stimulate peroxisome proliferator-activated receptor (PPAR) alpha, which controls the expression of gene products that mediate the metabolism of TG and HDL. As a result, synthesis of fatty acids, TG and VLDL is reduced, while that of lipoprotein lipase, which catabolises TG, is enhanced. In addition, production of Apo A1 and ABC A1 is up-regulated leading to an increase in HDL-C. Consequently, fibrates reduce TG by up to 50% and increase HDL-C by up to 20%, but LDL-C changes are variable.

Fewer large-scale trials have been conducted with fibrates than with statins. Reduced rates of cardiovascular disease have been reported with fibrate therapy in the subgroup of patients with low HDL-C levels and elevated TG (TG $>$2.3 mmol/L (200 mg/dL)). More recently, pemafibrate failed to show cardiovascular benefit, possibly due to its lack of effect on Apo B levels. Fibrates are usually well tolerated but share a similar side-effect profile to statins. In addition, they may increase the risk of cholelithiasis and prolong the action of anticoagulants. Accumulating evidence suggests that some may also have a protective effect against diabetic microvascular complications.

Highly polyunsaturated long-chain n-3 fatty acids

These include eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA), which comprise approximately 30% of the fatty acids in marine oil. EPA and DHA inhibit TG and VLDL formation. Intakes of more than 2 g of n-3 fatty acid (equivalent to 6 g of most forms of fish oil) per day lower TG in a dose-dependent fashion. Up to 50% reduction in TG may be achieved with 15 g marine oil per day. Changes in HDL-C are variable but marine oils do not usually reduce LDL-C. Marine oil fatty acids have also been shown to inhibit platelet aggregation and modulate cardiac arrhythmia in animal models. Dietary and pharmacological trials suggested that n-3 fatty acids may reduce mortality from coronary heart disease. A benefit of purified EPA compared to mineral oil was reported in the REDUCE-IT trial amongst hypertriglyceridaemic patients, but the benefit correlated with plasma EPA level rather than TG response. A modest increase in the risk of atrial fibrillation has recently been reported in association with marine oil supplements. Dietary fish consumption is the preferred option for the general population.

Patients with predominant hypertriglyceridaemia who do not respond to lifestyle intervention can be treated with fibrates or n-3 fatty acids, depending on individual response and tolerance. Fibrates and fish oil should be accompanied by lifestyle measures, optimisation of diabetic control, reduction of alcohol intake and avoidance of drugs that raise triglycerides.

Massive hypertriglyceridaemia may require more aggressive limitation of dietary fat intake ($<$10%–20% energy as fat). Any degree of insulin deficiency should be corrected because insulin is required for optimal activity of lipoprotein lipase. The initial target for patients with massive hypertriglyceridaemia is TG $<$10 mmol/L (880 mg/dL), to reduce the risk of acute pancreatitis. The treatments listed above may not be sufficient to achieve this goal.

Novel triglyceride-lowering therapy

Small interfering messenger RNA (siRNAs) or antisense oligonucleotides (ASOs) to inhibit the production of Apo C3 or ANGPTL3 work by diminishing one or other of these negative modulators of lipoprotein and endothelial lipases. This augments the action of these lipolytic enzymes. Both agents achieve impressive response rates, often sufficient to achieve TG levels less than 10 mmol/L. Plozasiran, directed against Apo C3, has been shown to prevent acute pancreatitis. Effects differ in that anti-ANGPTL3 has greater LDLC and HDLC lowering capability. This may reflect unmasking of an alternative LDL uptake pathway because anti-ANGPTL3 has been effective in reducing LDL in patients with homozygous FH.

Mixed hyperlipidaemia

Mixed hyperlipidaemia can be difficult to treat. First-line therapy with statins alone is unlikely to achieve target levels, once fasting TGs exceed approximately 4 mmol/L (350 mg/dL). Fibrates are first-line therapy for dysbetalipoproteinaemia, but they may not control the cholesterol component in other forms of mixed hyperlipidaemia. Combination therapy is often required. Effective combinations include:

- statin plus fenofibrate (recognising that the risk of myopathy is increased with gemfibrozil, but fenofibrate is relatively safe in this regard)
- statin plus marine oil when TG is not too high
- fibrate plus ezetimibe when LDL-C is not too high.

Monitoring of therapy

The effects of lipid-lowering therapy should be assessed after 6 weeks (12 weeks for fibrates). At this point, it is prudent to review side-effects, lipid response (see target levels above), creatine kinase (CK) and liver function tests. During longer-term follow-up, adherence to treatment, review of concomitant medications, diet and exercise should be assessed, with monitoring of waist circumference, weight, blood pressure and lipid levels. The presence of cardiovascular symptoms or signs should be noted, and absolute risk of atherosclerotic cardiovascular risk assessed periodically. Effective lipid-lowering therapy may be associated with a paradoxical, and as yet unexplained, increase in coronary calcium score.

It is not necessary to perform routine checks of CK and liver function unless symptoms occur, or if statins are used in combination with fibrates, or other drugs that may interfere with their clearance. Mild disturbance of liver function tests may indicate metabolism-associated fatty liver disease (MAFLD), which is not a contraindication to continuation of treatment. If myalgia or weakness occurs in association with CK elevation over 5–10 times the upper limit of normal, or if sustained alanine aminotransferase (ALT) elevation more than 2–3 times the upper limit of normal occurs, treatment should be discontinued and alternative therapy sought.

The principles of the management of dyslipidaemia can be applied broadly, but the objectives of treatment in old age (Box 19.27) and the safety of pharmacological therapy in pregnancy (Box 19.28) warrant special consideration.

19.27 Management of hyperlipidaemia in old age

- **Prevalence of atherosclerotic cardiovascular disease:** greatest in old age.
- **Associated cardiovascular risk:** lipid levels become less predictive, as do other risk factors apart from age itself.
- **Benefit of statin therapy:** maintained up to the age of 80 years but evidence is lacking beyond this.
- **Life expectancy and statin therapy:** lives saved by intervention are associated with shorter life expectancy than in younger patients, and so the impact of statins on quality-adjusted life years is smaller in old age.
- **Lipid-lowering interventions aspire to preserve cognitive function:** whilst this is yet to be proven for current agents, patients may be reassured that the effects on cognitive function are not detrimental. Suggestions to the contrary are ill-informed.

19.28 Dyslipidaemia in pregnancy

- **Lipid metabolism:** lipid and lipoprotein levels increase during pregnancy. This includes an increase in low-density lipoprotein cholesterol, which resolves postpartum. Remnant dyslipidaemia and hypertriglyceridaemia may be exacerbated during pregnancy.
- **Treatment:** dyslipidaemia is rarely thought to warrant urgent treatment so pharmacological therapy is usually contraindicated when conception or pregnancy is anticipated. Teratogenicity has been reported with systemically absorbed agents, and non-absorbed agents may interfere with nutrient bioavailability.
- **Monitoring:** while still uncommon among women of child-bearing age, cardiovascular disease is increasing in prevalence. Pre-conception cardiovascular review should be considered for women at high risk to optimise medications for pregnancy and to ensure that the patient will be able to withstand the demands of pregnancy and labour.

Fig. 19.15 **Pathophysiology of inherited metabolic disorders.** Inherited metabolic disorders cause disease either because there is lack of synthesis of an essential metabolite as the result of enzyme deficiency, or because there is accumulation of a toxic metabolite upstream of the deficient enzyme.

Inherited metabolic disorders

Inherited metabolic disorders are a large group of rare genetic diseases which result in disordered cellular metabolism. The majority are caused by variants in single genes that code for enzymes, leading to defective or absent enzyme activity. This leads to: (1) the accumulation of toxic metabolites that lie upstream within the pathway or (2) an inability to synthesise essential metabolites that are required for cellular function (Fig. 19.15). Most disorders are autosomal recessive.

Newborn screening programmes, the availability of specific therapies, increased access to genetic testing and the recognition of attenuated, later-onset forms has led to a significant increase in the incidence and prevalence of inherited metabolic disorders, many of which are treatable. Treatment options are rapidly expanding with the use of gene therapies, RNA-based therapies and precision medicine techniques.

Disorders of amino acid metabolism

Inherited disorders of amino acid metabolism usually present in the neonatal period, but some disorders, especially of amino acid transport, may not present until later in life.

Phenylketonuria

The early identification via newborn screening and successful dietary treatment of babies with phenylketonuria (PKU) has profoundly changed the outcome of this disorder, with patients now expected to live normal lives. PKU is caused by loss-of-function variants in the *PAH* gene, which encodes phenylalanine hydroxylase, an enzyme required for the degradation of phenylalanine, an essential amino acid. Undegraded phenylalanine accumulates, causing direct neurotoxicity and profound neurodevelopmental disability. Treatment involves lifelong adherence to a low-phenylalanine diet with additional amino acid and micronutrient dietary supplements. Early and adequate dietary treatment prevents major neurodisability, and lifelong adherence is thought to prevent psychiatric morbidity and improve cognitive function. Treatment with sapropterin, which acts as a co-factor for phenylalanine hydroxylase, has been shown to reduce blood phenylalanine concentrations and increase phenylalanine tolerance in adults and children with PKU. However, its use is limited to patients with milder variants as well as by cost.

Maternal phenylketonuria syndrome, causing microcephaly, developmental delay and cardiac defects, is caused by exposure of the developing fetus to high levels of phenylalanine. Strict dietary adherence, both preconception and during pregnancy, prevents any deleterious effects in the offspring.

Homocystinuria

Homocystinuria is usually caused by variants in the *CBS* gene, leading to impaired activity of the enzyme cystathionine beta-synthase. This prevents homocysteine degradation and causes toxic accumulation of homocysteine and methionine (upstream of the metabolic block). Multiple body systems are affected, including the central nervous system (developmental delay, intellectual development disorder, seizures and psychiatric disturbance); skeleton (tall stature, osteoporosis); eye (ectopia lentis – lens displacement) and cardiovascular system (arterial and venous thromboembolic disease). The phenotypic spectrum is extremely variable, and adults may present later in life, often with thromboembolic disease. Treatment aims to reduce homocysteine levels – through vitamin B_6 (pyridoxine) – which acts as a co-factor to increase CBS enzyme activity, betaine, folate and vitamin B_{12} (to utilise the alternative homocysteine remethylation pathway) and consumption of a low-methionine diet. Early treatment and good adherence can prevent many of the expected complications.

Disorders of the urea cycle

Ammonia is generated by metabolism in all organs and transported to the liver for disposal by the urea cycle. Defects in any of the six urea cycle enzymes prevents normal ammonia degradation and can lead to life-threatening hyperammonaemia.

Ornithine tricarboxylase deficiency

Ornithine tricarboxylase (OTC) deficiency is the most common urea cycle disorder and is an X-linked recessive disorder. Males often have severe neonatal disease, but the phenotypic spectrum, especially among women, is extremely wide. It may present later in life, often following a physiological stress such as trauma, surgery or post-partum. Acute hyperammonaemia may present as unexplained encephalopathy, often with early respiratory alkalosis. If unrecognised, it can rapidly lead to cerebral oedema and death. Severe, neonatal onset disease can be treated by liver transplantation (the donated liver has normal enzyme activity). Later-onset disease can be managed with a protein-restricted diet, arginine supplementation and urea-scavenging medication (sodium benzoate and sodium or glycerol phenylbutyrate) to promote nitrogen excretion via alternative pathways.

Disorders of carbohydrate metabolism

Galactosaemia

Inherited variations in the *GALT* gene, causing loss of function of the enzyme galactose-1-phosphate uridyl transferase, lead to galactosaemia and an inability to metabolise galactose. In countries that do not screen newborns for galactosaemia, patients usually present with neonatal crisis, with life-threatening liver and kidney failure, diarrhoea and cataracts, often complicated by fulminant sepsis. Treatment is with a lactose- and galactose-free diet. This effectively prevents acute symptoms, but even with treatment there is almost always neuropsychological impairment, and many patients exhibit slowly progressive neurological dysfunction over time. Premature ovarian failure occurs in almost all affected women.

Glycogen storage diseases

Glycogen storage diseases are a group of rare disorders that result from inherited defects in one of the many enzymes responsible for the formation, mobilisation or breakdown of glycogen, or of utilisation of glucose. The classification and enzyme defects responsible are summarised in Box 19.29. While glycogen storage disease type II (Pompe) is listed in this box, it is caused by deficiency in α-glucosidase which is a lysosomal enzyme responsible for degradation of glycogen. Accordingly, it is now classified as a lysosomal storage disease. The specific enzyme defect and degree of enzyme deficiency predicts symptomology and age of onset. Management is based upon avoidance of fasting, dietary modifications with frequent administration of carbohydrates and carefully managed exercise programmes to avoid hypoglycaemia. Enzyme replacement therapy is available for the treatment of Pompe disease.

Disorders of mitochondrial energy metabolism

During fasting or increased energy demand, fatty acid oxidation is an important source of mitochondrial energy production. Inherited variants causing loss of function in many of the enzymes involved in fatty acid oxidation and electron transfer within mitochondria have been identified. Many disorders have a catastrophic neonatal presentation, with hypoketotic hypoglycaemia, encephalopathy and liver dysfunction. Attenuated adult-onset forms are increasingly recognised, often with episodes of severe, acute rhabdomyolysis and/or progressive myopathy. Common precipitants in adulthood are endurance exercise events, such as running marathons, and alcohol. Management centres on the avoidance of fasting and provision of a regular carbohydrate energy source, with or without dietary modification of long-chain or medium-chain fats. Examples include carnitine palmitoyltransferase 2 (CPT2) deficiency, very long-chain acyl-CoA dehydrogenase (VLCAD) deficiency, medium-chain acyl-CoA dehydrogenase (MCAD) deficiency and multiple acyl-CoA dehydrogenase (MADD) deficiency. Late onset MADD is often fully reversible with riboflavin supplementation, which acts as a co-factor to the electron transfer flavoprotein complex.

Lysosomal storage disorders

The lysosome is an organelle responsible for the breakdown and resynthesis of macromolecules – essentially recycling and waste disposal – within the cell. Variants in genes encoding specific lysosomal enzymes cause loss of enzymatic function and the accumulation of undegraded or partially degraded macromolecules within the lysosome, eventually leading to tissue damage in multiple body systems (Box 19.30). Biologic therapies with recombinant enzyme replacement therapy (ERT) have been developed to correct the metabolic defect and slow disease progression. The greatest benefit of ERT is seen with early treatment, but it does not penetrate the blood–brain barrier and is ineffective in treating neurological manifestations of disease. Some diseases appear mo re amenable to therapy than others. As ever, there is usually a spectrum of disease severity depending on the degree of residual enzyme function, and treating partial-loss-of-function variants with small molecule therapies to improve trafficking or support enzyme function, or as substrate reduction therapy, has shown promise as an alternative therapeutic strategy.

The porphyrias

These disorders are caused by enzymatic defects in the haem biosynthesis pathway. Most are partial loss of function, with autosomal dominant inheritance and variable penetrance. Diagnosis relies on the detection of

i 19.29 Glycogen storage diseases*

Type	Enzyme/transporter deficiency	Major phenotype	Clinical features/complications	Other names
0	Glycogen synthase	Liver	Fasting ketotic hypoglycaemia, postprandial lactic acidaemia	
Ia	Glucose-6-phosphatase	Liver Kidney	Infantile hypoglycaemia, ketosis, lactic acidosis and hepatomegaly. Long-term risk of hepatic adenoma and hepatocellular carcinoma	Von Gierke
Ib	Glucose-6-phosphate transporter deficiency	Liver Kidney Immunological	Infantile hypoglycaemia, ketosis, lactic acidosis and hepatomegaly with neutrophil dysfunction and colitis	
II	Alpha-glucosidase	Muscle Heart Brain	Hypotonia, hypertrophic cardiomyopathy and developmental delay in infancy. Proximal myopathy and respiratory muscle weakness in adulthood	Pompe
III	Glycogen debrancher	Muscle Heart Liver	Infantile hepatomegaly and hypoglycaemia. Rhabdomyolysis, myopathy and cardiomyopathy in adulthood	Coris/Forbes
IV	Glycogen brancher	Muscle Brain Liver	Hepatomegaly, liver failure, myopathy	Anderson
V	Myophosphorylase	Muscle	Exercise intolerance, 'second wind' phenomenon and rhabdomyolysis	McArdle
VI	Glycogen phosphorylase	Liver	Hepatomegaly	Hers
VII	Muscle phosphofructokinase	Muscle	Exercise intolerance, rhabdomyolysis	Tarui
IX	Glycogen phosphorylase kinase	Liver Muscle	Hypoglycaemia Hepatomegaly	
X	Phosphoglycerate mutase	Muscle	Exercise intolerance, rhabdomyolysis	
XI	GLUT-2	Liver Kidney	Hypoglycaemia, tubular dysfunction, hepatosplenomegaly, bone disease	Fanconi–Bickel

*Some rarer causes of glycogen storage disease have not been included in this box.

19.30 Lysosomal storage diseases*

Disease	Enzyme deficiency	Inheritance	Clinical features	Treatment
Fabry disease 1	Alpha-galactosidase	XLR	Acroparaesthesia, angiokeratoma, corneal verticillata Kidney disease (proteinuria and progressive CKD) Cardiomyopathy and arrhythmias Stroke and white matter changes	Enzyme replacement therapy Small molecule chaperone (amenable variants)
Gaucher disease	Glucocerebrocidase	AR	Hepatosplenomegaly Bone marrow infiltration and skeletal disease Thrombocytopenia Infantile neuronopathic form	Enzyme replacement therapy (not for neuronopathic disease) Substrate reduction therapies
Mucopolysaccharidoses	Eight different enzymes involved in the degradation of glycosaminoglycans	AR	Vary dependent on syndrome Skeletal, joint, valvular disease Characteristic facies Intellectual disability	Enzyme replacement therapy for MPSI; MPSII; MPS IV Limited by lack of efficacy in CNS disease
Niemann–Pick type C	Disorder of cholesterol and glycolipid trafficking	AR	Highly variable: progressive liver disease and neurological disease in childhood. Neuropsychiatric symptoms in adulthood. Vertical supranuclear gaze palsy is a classical sign	Miglustat may slow progression of functional decline in juvenile/adult-onset forms
Pompe disease	Alpha-glucosidase	AR	Hypotonia, hypertrophic cardiomyopathy and developmental delay in infancy. Limb girdle myopathy and respiratory muscle weakness in adulthood	Enzyme replacement therapy

*More than 70 lysosomal storage diseases are recognised; multiple rarer types have been described which are not included in this box.
(AR = autosomal recessive; CKD = chronic kidney disease; CNS = central nervous system; MPS = mucopolysaccharidosis; XLR = X-linked recessive)

19.31 Diagnostic biochemical findings in the porphyrias

	Biochemical abnormalities (protect specimens from light)		
Condition	**Urine**	**Blood**	**Faeces**
Acute intermittent porphyria	ALA ↑ PBG		
Hereditary coproporphyria	ALA PBG ↑ Copro III		↑ Copro III
Variegate porphyria	ALA PBG ↑ Copro III		↑ Proto IX
Erythropoietic protoporphyria		↑ Proto IX	↑ Proto IX
Porphyria cutanea tarda	↑ Uro I		

(ALA = delta-aminolaevulinic acid; Copro III = coproporphyrin III; PBG = porphobilinogen; Proto IX = protoporphorin IX; Uro I = uroporphyrin I)

characteristic biochemical metabolites, as well as genetic variants and/or enzyme activity levels (Box 19.31)

Acute porphyrias (the neurovisceral form) are characterised by acute attacks of abdominal/pelvic pain and neuropathic symptoms, with neuropsychiatric symptoms, tachycardia, hypertension and hyponatraemia. Classically, the urine is pigmented and darkens on exposure to light. The most common form is acute intermittent porphyria, caused by variants in *PBGD*, which encodes the enzyme porphobilinogen deaminase. Attacks are provoked by a relative depletion of haem, which removes the negative feedback regulation of the haem production pathway and stimulates haem biosynthesis. This results in the accumulation of δ-aminolaevulinic acid (ALA) and porphobilinogen (PBG) pre-cursors upstream of the metabolic block. ALA causes direct neurotoxicity. Urgent testing of urine for the presence of ALA and/or PBG will confirm the presence of an acute attack and can be useful to differentiate between acute porphyria attacks and other causes.

Attacks can be provoked by fasting, trauma, intercurrent infection, alcohol, drugs, the menstrual cycle and hormonal contraceptives. A list of safe drugs can be found at www.drugs-porphyria.org. Cyclical attacks in menstruating women can respond to suppression of the menstrual cycle with gonadotrophin-releasing hormone analogues.

Management centres on the avoidance of provoking factors, and the provision of an 'emergency protocol' to administer oral carbohydrates (glucose polymer) or intravenous dextrose with electrolytes to terminate an acute attack. In severe cases, intravenous haem arginate inhibits the haem biosynthesis pathway, thereby reducing the production of toxic metabolites. However, it is an irritant and frequently causes local phlebitis. Recently, RNA interference therapy has been shown to inhibit ALA synthesis and reduce the rate of acute porphyria attacks in severely affected patients.

Cutaneous porphyrias

The cutaneous manifestations of porphyria cutanea tarda, erythropoetic porphyria, variegate porphyria and hereditary coproporphyria are discussed in more detail in Chapter 26. It should be noted, however, that variegate porphyria and hereditary coproporphyria can have both neurovisceral and cutaneous features.

Multiple Choice Questions

19.1. A pregnant woman with phenylketonuria (PKU) attends a routine obstetric appointment, worried about the risk of her unborn baby inheriting the same condition. What is the risk of the fetus also having PKU?

A. 1 in 4
B. 1 in 2
C. Only a risk for male offspring
D. ~1/50
E. No risk

Answer: D.

PKU is autosomal recessive, and only results in disease when two faulty copies of the affected gene are inherited. A mother with PKU will always pass on one copy to her offspring – who will therefore be a carrier. However, the fetus would only be affected if, by chance, her partner was also a carrier, and passed on their affected gene (1 in 2 chance). Population carrier rates are estimated at ~1/50 so the risk of the fetus being affected by PKU remains low. However, in some countries this population carrier frequency would allow access to pre-natal testing.

More importantly, the fetus is at significant risk from high phenylalanine levels in the mother, who should follow a strictly managed low-phenylalanine diet in order to avoid maternal PKU syndrome.

19.2. A 35-year-old man attends the nephrology clinic with proteinuria. What features would be suspicious for a diagnosis of Fabry disease?

A. Pain in hands and feet
B. Peri-umbilical skin rash
C. Mother had stroke aged 56
D. LVH on echocardiogram
E. All of the above

Answer: E.

Acroparaesthesia (burning pain in hands and feet) and angiokeratomas (small, red, raised spots often around the genitals and umbilicus) are features of classical Fabry disease, often present from childhood or adolescence. Cardiomyopathy begins to develop in mid-life. Women with Fabry disease have a variable presentation, but can present with young stroke.

19.3. A 59-year-old man presents for cardiovascular risk assessment, but he has not fasted for the blood collection that was to be performed during his appointment. Which of the following plasma lipid or lipoprotein levels is most likely to be significantly affected by his recent consumption of food?

A. HDL cholesterol
B. Lipoprotein (a)
C. Calculated LDL cholesterol
D. Non-HDL cholesterol
E. Total cholesterol

Answer: C.

Calculated LDL cholesterol is correct because the calculation includes the triglyceride level, which increases following food consumption. The effect of food consumption on the other measurements is small by comparison, especially in relative terms.

19.4. The same 59-year-old man returns with a set of fasting results that include: total cholesterol 6.7 mmol/L (260 mg/dL), fasting triglyceride 3.3 mmol/L (290 mg/dL), HDL cholesterol 0.9 mmol/L (35 mg/dL), calculated LDL cholesterol 4.3 mmol/L (167 mg/dL), non-HDL cholesterol 5.8 mmol/L (225 mg/dL) and fasting serum glucose 6.9 mmol/L (124 mg/dL). The best indicator of the metabolic component of his cardiovascular risk is his level of:

A. HDL cholesterol
B. Non-HDL cholesterol
C. Fasting plasma glucose
D. Calculated LDL cholesterol
E. Total cholesterol

Answer: B.

Non-HDL cholesterol is correct because it allows for the presence of small dense LDL and other atherogenic lipoproteins. This is particularly relevant in hypertriglyceridaemia, with or without accompanying elevation of fasting plasma glucose. It is more strongly associated with CVD in studies where comparison has been made with the other alternatives.

19.5. The same 59-year-old man fails to improve his lipid profile following diet and exercise advice, and treatment is deemed necessary. Which of the following medications may have a detrimental effect on the triglyceride component of his lipid profile?

A. Rosuvastatin
B. Ezetimibe
C. An anti-PCSK9 monoclonal antibody
D. Niacin
E. Cholestyramine

Answer: E.

Cholestyramine reduces re-circulation of bile acids, down-regulates the FXR receptor and stimulates the replacement of the bile acids by conversion of cholesterol via 7 alpha-hydroxylase. The response to the down-regulation of FXR includes increased synthesis and secretion of triglyceride and VLDL. The other agents have neutral or favourable effects on triglyceride levels.

19.6. The same 59-year-old man commences atorvastatin 20 mg at night. His follow-up lipid profile and glucose reveal: total cholesterol 3.7 mmol/L (144 mg/dL), fasting triglyceride 1.1 mmol/L (97 mg/dL), HDL cholesterol 1.1 mmol/L (43 mg/dL), calculated LDL cholesterol 2.1 mmol/L (81 mg/dL), non-HDL cholesterol 2.6 mmol/L (101 mg/dL) and fasting serum glucose 8.9 mmol/L (160 mg/dL). A subsequent glucose tolerance test is diagnostic of new onset type 2 diabetes. The onset of diabetes and the use of statins is:

A. A completely unrelated phenomenon
B. More likely in those with pre-existing impaired fasting glucose
C. A contraindication to statin use due to CVD risk associated with type 2 diabetes
D. Unrelated to the dose or potency of the statin
E. Inconsistent with the fact that fasting triglyceride has improved

Answer: B.

Type 2 diabetes following statin therapy is likely in those with pre-existing impaired fasting glucose. It is proportional to the dose and potency of the statin, but the CVD benefit of the response clearly outweighs the

CVD risk of the diabetes. Statins modestly improve triglyceride, even in the presence of diabetes.

19.7. A 24-year-old man presents for assessment of his lipid profile because severe hypercholesterolaemia was detected as part of his life insurance application. His LDL cholesterol was 8.2 mmol/L (318 mg/dL) and his mother's level is thought to be even higher. Which of the following is true?

A. Genetic testing for familial hypercholesterolaemia (FH) should be performed on his original blood sample as an add-on test
B. In his case, the severity of his LDL cholesterol elevation invalidates the use of population-based absolute risk calculators
C. The main advantage of genetic diagnosis in FH is that it can be used to guide the selection of first-line therapy
D. The very high level of LDL cholesterol makes his continuation or cessation of smoking irrelevant from the CVD point of view
E. A non-elevated level of LDL cholesterol earlier in life is possible because the metabolic changes associated with FH emerge after childhood

Answer: B.

LDL is above the 99th percentile in most cases of FH, so population studies do not have sufficient power to estimate the increase in CVD risk. Genetic testing requires explanation and counselling, but it cannot guide treatment. Smoking amplifies CVD risk in FH. FH is manifest from birth.

19.8. The same 24-year-old patient undertakes genetic testing, which yields a variant of unknown significance in the LDL receptor gene. Which of the following is true?

A. This result explains the increase in LDL cholesterol level in the patient and his mother
B. This result can be used to screen his siblings for familial hypercholesterolaemia (FH)
C. This result means that there are some cholesterol-lowering drugs that will not work in this patient
D. Genetic testing is guaranteed to find the cause of FH in every case
E. The patient should have been counselled before the test was performed in case he had any questions, concerns or misconceptions, e.g. the need to disclose results for life insurance purposes

Answer: E.

Insurance requirements vary between jurisdictions and there are many ethical and clinical issues that need to be considered. The test may not explain the results in the patient or his mother and it may not be conclusive for screening of siblings. Genetic diagnosis is only achieved in about 80% of cases with clinical FH, and it rarely informs about the effectiveness of therapy.

± Retrosternal extension, tracheal compression

Solitary nodule (p. 701)
Adenoma, cyst or carcinoma

Cervical lymphadenopathy
Suggests carcinoma

Hormones are chemical messengers critical for maintaining homeostasis, regulating responses to environmental challenges, controlling growth and reproduction. Endocrinology concerns the synthesis, secretion and action of hormones. Endocrine disease may result directly from pathology within endocrine glands, and indirectly from disrupted hormone signalling. This chapter describes the principles of endocrinology before discussing the physiology and pathology of each gland in turn.

An overview of endocrinology

Functional anatomy and physiology

Most endocrine glands are controlled by hormones released from the anterior pituitary gland, although some, such as the parathyroid glands and pancreas, respond directly to metabolic signals. Hormone secretion from the anterior pituitary is controlled in turn by messengers produced in the hypothalamus and released into the hypothalamo-hypophyseal portal system, which drains directly down the pituitary stalk (Fig. 20.1). Posterior pituitary hormones are synthesised in the hypothalamus and transported down nerve axons, to be released from the posterior pituitary. Hormone release in the hypothalamus and pituitary is regulated by numerous neuropeptides and by feedback control by hormones produced by the target glands (thyroid, adrenal cortex and gonads). These integrated endocrine systems are called ‘axes’ and are listed in Figure 20.2.

A wide variety of molecules can act as hormones. Small peptides such as insulin, glycoproteins such as thyroid-stimulating hormone, and amines such as noradrenaline (norepinephrine) bind to specific receptors on the membrane of their target cells. Activation of these receptors triggers a cascade of intracellular signalling to affect cell function. Steroid (for example cortisol) and thyroid hormones cross the cell membrane and exert their effects predominantly by binding to intracellular receptors forming complexes that affect the transcriptional activity of target genes.

The classical model of endocrine function involves hormones synthesised in endocrine glands, which are released into the circulation and act at distal sites (as in Fig. 20.1). Hormone activity is also regulated by a number of ‘fine-tuning’ physiological processes: (1) hormones may be activated or deactivated locally at their target organ (local deiodinases activate and deactivate thyroid hormones); (2) circulating peptide hormones, such as insulin, have a short half-life due to degradation by peptidases thereby limiting the risk of hormone activity when it is no longer required; (3) hormones may be rendered inactive by binding to large proteins circulating in the bloodstream, leaving a small pool of circulating active ‘free’ hormone (thyroid hormone is almost entirely bound to carrier proteins). Some hormones can act in a paracrine fashion

Fig. 20.2 The principal endocrine ‘axes’. Some major endocrine glands are not controlled by the pituitary. These include the parathyroid glands (regulated by calcium concentrations, p. 717), the adrenal zona glomerulosa (regulated by the renin–angiotensin system, p. 721) and the endocrine pancreas (p. 733). Italics show negative regulation. (ACTH = adrenocorticotrophic hormone; CRH = corticotrophin-releasing hormone; FSH = follicle-stimulating hormone; GH = growth hormone; GHRH = growth hormone-releasing hormone; GnRH = gonadotrophin-releasing hormone; IGF-1 = insulin-like growth factor-1; IGF-BP3 = IGF-binding protein-3; LH = luteinising hormone; T3 = triiodothyronine; T4 = thyroxine; TRH = thyrotrophin-releasing hormone; TSH = thyroid-stimulating hormone; vasopressin = antidiuretic hormone (ADH))

to affect adjacent cells, or act in an autocrine way to affect behaviour of the cell that produced the hormone.

Endocrine pathology

For each endocrine axis or major gland, diseases can be classified as shown in Box 20.1. Pathology arising within the gland is often called 'primary' disease (e.g. primary hypothyroidism resulting from Hashimoto thyroiditis), while abnormal stimulation of the gland is often called 'secondary' disease (e.g. secondary hypothyroidism due to thyroid-stimulating hormone deficiency in patients with pituitary tumours). Some pathological processes can affect multiple endocrine glands; these may have a genetic basis (such as the multiple endocrine neoplasia (MEN) syndromes) or be a consequence of therapy for another disease (such as following systemic anti-cancer treatment and/or radiotherapy).

Investigation of endocrine disease

As chemical messengers, most hormones can be measured in samples of bodily fluids, commonly in blood, urine and saliva. Physiological hormone secretion can be highly variable and thus the timing and context of a sample may impact significantly on the interpretation of results; for example, a low cortisol value may be normal at 2300 hrs, but indicate adrenal insufficiency if assessed at 0800 hrs. Furthermore, some hormones are labile and have specific requirements for sample processing (for example, collection into particular tubes, transport on ice, rapid processing). Local protocols for hormone measurement should be followed carefully.

For some hormones, dynamic tests may be required to identify disrupted secretion; suppression tests are used to assess for hypersecretion (for example, dexamethasone suppression testing for excessive cortisol secretion); and stimulation tests are required where there is concern about insufficiency (for example, ACTH stimulation testing [also known as short Synacthen, corticotrophin, cosyntropin or tetracosactide stimulation test] for adrenal insufficiency). The choice of stimulus can help to determine the level of the endocrine axis affected; whilst the ACTH stimulation test will assess primarily adrenal responsiveness, an insulin tolerance test (inducing hypoglycaemia) will assess appropriate hypothalamus, pituitary and adrenal response to stress. Intra- and inter-individual variation in hormone levels means that some tests may have poor sensitivity and specificity; an understanding of the accuracy of the test being interpreted is thus important.

The context in which a hormone has been measured will affect its concentration, with important implications for interpretation of results. For example, parathyroid hormone levels may be reported within the reference range for a patient with hypercalcaemia; in this context one would expect suppressed parathyroid hormone (PTH) levels; thus, levels are 'inappropriately normal' and suggestive of hyperparathyroidism. The principles of investigation are shown in Box 20.2. The choice of test is often pragmatic, taking local access to reliable sampling facilities and laboratory measurements into account.

20.1 Classification of endocrine disease

Hormone excess
- Primary gland hypersecretion
- Secondary to excess gland stimulation

Hormone deficiency
- Primary gland failure
- Secondary to deficient trophic hormone

Hormone hypersensitivity
- Failure of inactivation of hormone
- Target organ over-activity/hypersensitivity

Hormone resistance
- Failure of activation by hormone
- Target organ resistance

Non-functioning tumours
- Benign
- Malignant

Presenting problems in endocrine disease

Endocrine diseases present in many ways to clinicians in different disciplines. The classical syndromes associated with disorders of individual glands are described in the following sections. However, patients often present with non-specific symptoms (Box 20.3) or are seemingly asymptomatic with only biochemical abnormalities. Endocrine diseases are also encountered within the differential diagnosis of common presentations discussed in other chapters of this book, including electrolyte

20.2 Principles of endocrine investigation

Timing of measurement
- Release of many hormones is rhythmical (pulsatile, circadian or monthly), random measurement may be invalid and specifically timed, sequential or dynamic tests may be required

Choice of dynamic biochemical test
- If hormone deficiency is suspected, choose a stimulation test
- If hormone excess is suspected, choose a suppression test
- The more tests there are to choose from, the less likely it is that any single test is infallible, so avoid interpreting one result in isolation

Imaging
- 'Functional' as well as conventional 'structural' imaging can be performed as secretory endocrine cells often take up labelled substrates, e.g. radio-labelled iodine or octreotide
- Most endocrine glands have a high prevalence of 'incidentalomas', so do not scan unless the biochemistry confirms endocrine dysfunction or the primary problem is a tumour

Biopsy
- Many endocrine tumours are difficult to classify histologically (e.g. adrenal carcinoma and adenoma)

20.3 Examples of non-specific presentations of endocrine disease

Symptom	Most likely endocrine disorder(s)
Lethargy and depression	Hypothyroidism, diabetes mellitus, hyperparathyroidism, hypogonadism, adrenal insufficiency, Cushing syndrome
Weight gain	Hypothyroidism, Cushing syndrome
Weight loss	Thyrotoxicosis, adrenal insufficiency, diabetes mellitus
Polyuria and polydipsia	Diabetes mellitus, arginine vasopressin resistance or insufficiency, hyperparathyroidism, hypokalaemia (Conn syndrome)
Heat intolerance*	Thyrotoxicosis
Palpitation	Thyrotoxicosis, phaeochromocytoma
Headache	Acromegaly, pituitary tumour, phaeochromocytoma
Muscle weakness (usually proximal)	Thyrotoxicosis, Cushing syndrome, hypokalaemia (e.g. Conn syndrome), hyperparathyroidism, hypogonadism
Coarsening of features	Acromegaly, hypothyroidism
Sweating*	Thyrotoxicosis, hypogonadism, hypoglycaemia, carcinoid syndrome, phaeochromocytoma

*Heat intolerance and sweating are common features of menopause.

abnormalities (Ch. 19), hypertension (Ch. 16), obesity (Ch. 5) and osteoporosis (Ch. 25). The non-specific presentation of some endocrine disorders means diagnosis relies on astute clinical observation and so it is important to be familiar with their key features.

The thyroid gland

Thyroid disease has an incidence of 2.6 cases per 1000 per year in European populations with the rate 5 times higher in females than males. The incidence is twice as high in populations deficient in iodine. Diseases of the thyroid are summarised in Box 20.4. Thyroid hormones regulate cellular differentiation and metabolism in virtually all nucleated cells, meaning disorders of thyroid function have diverse manifestations. Structural disease of the thyroid gland, such as goitre or thyroid nodules, may not necessarily affect thyroid function.

Functional anatomy, physiology and investigations

Thyroid physiology is illustrated in Figure 20.3. Parafollicular C cells secrete calcitonin, which reduces plasma calcium but is seemingly redundant in humans. Follicular cells synthesise thyroid hormones; they secrete thyroglobulin (Tg), a scaffold protein, and transport iodide into the thyroid colloid. Here, thyroid peroxidase catalyses the iodination of tyrosine residues, forming triiodothyronine (T3) and the prohormone thyroxine (T4). Iodide is essential for thyroid hormone synthesis.

The thyroid secretes predominantly T4 and a small amount of T3; approximately 85% of T3 is produced peripherally from T4 by deiodinase enzymes that regulate localised thyroid hormone activity. T4 has a much longer half-life in blood than T3 (approximately 1 week compared with approximately 18 hours).

T3 and T4 circulate in plasma almost entirely (>99%) protein-bound, predominantly to thyroxine-binding globulin (TBG) but also to albumin and transthyretin. Only unbound or free hormones are transported into cells to activate the thyroid receptor. Historically, laboratories used assays that measured total T4 and T3; however, it is now common to measure free T4 and free T3. The advantage of free hormone measurements is that they are not influenced by changes in the concentration of binding proteins. For example, TBG levels are increased by oestrogen (such as in the combined oral contraceptive pill), which results in raised total T3 and T4, whilst free thyroid hormone levels remain normal.

Production of T3 and T4 in the thyroid gland is stimulated by thyroid-stimulating hormone (TSH). TSH is a glycoprotein released from the thyrotroph cells of the anterior pituitary primarily in response to the hypothalamic tripeptide, thyrotrophin-releasing hormone (TRH). A circadian rhythm of TSH secretion can be demonstrated with a peak at about midnight and trough in the afternoon. However, variation in TSH (and free T3) secretion is modest, meaning thyroid function can be assessed reliably from blood drawn at any time of day.

20.4 Classification of thyroid disease

	Primary	Secondary
Hormone excess	Graves disease Multinodular goitre Adenoma Subacute thyroiditis	TSHoma
Hormone deficiency	Hashimoto thyroiditis Atrophic hypothyroidism	Hypopituitarism
Hormone hypersensitivity	–	
Hormone resistance	Thyroid hormone resistance syndrome 5′-monodeiodinase deficiency	
Non-functioning tumours	Differentiated carcinoma Medullary carcinoma Lymphoma	

T3 inhibits TRH and TSH production in the hypothalamus and pituitary; when plasma concentrations of T3 and T4 are raised in patients with thyrotoxicosis, TSH secretion should be suppressed. Conversely, in hypothyroidism due to thyroid gland dysfunction, low T3 and T4 should be associated with high circulating TSH levels. The relationship between TSH and T4 is classically described as inverse log-linear (Fig. 20.4), such that small changes in TSH levels reciprocate larger changes in free T4. For this reason, TSH is usually regarded as the most useful investigation of thyroid function, especially in the context of assessing replacement.

Discrepant thyroid function tests, where TSH and thyroid hormones do not reciprocate as expected, most commonly occur due to problems with hormone measurement, but may indicate less common pathology. For example, in patients with pituitary disease, TSH may be inappropriately low or 'normal' in the context of low free T4 levels (see Box 20.5 and Box 20.51). Further, there can be a lag of several weeks in the thyrotroph response to changes to thyroid hormone levels; for example, levothyroxine therapy will raise T4 and T3 levels within approximately 2 weeks, but it can take 4–6 weeks for the TSH to reach a steady state. Heterophilic antibodies (host antibodies with affinity to the animal antibodies used in immunoassays) can interfere with the TSH assay and cause a spurious high or low measurement. Common patterns of abnormal thyroid function test results and their interpretation are shown in Box 20.5.

Other investigations of thyroid disease include the measurement of antibodies targeting the TSH receptor (TRAb) or other thyroid antigens (see Box 20.8), radioisotope imaging, fine needle aspiration biopsy and ultrasound. Their use is described below.

Presenting problems in thyroid disease

The most common presentations are hyperthyroidism (thyrotoxicosis), hypothyroidism and enlargement of the thyroid (goitre or thyroid nodule). Increasingly, thyroid dysfunction is identified in patients who are asymptomatic or who have relatively non-specific symptoms such as fatigue or changes to weight.

Thyrotoxicosis

Thyrotoxicosis describes a state in which the patient exhibits clinical features arising from elevated circulating levels of thyroid hormone. The most common causes are Graves disease, multinodular goitre, autonomously functioning thyroid nodules (toxic adenoma) and thyroiditis (Box 20.6).

Clinical assessment

The clinical manifestations of thyrotoxicosis are shown in Box 20.7, and an approach to differential diagnosis is given in Figure 20.5. The most common symptoms are weight loss with a normal or increased appetite (although around 5% patients may exhibit weight gain), heat intolerance, palpitations, tremor and irritability. Tachycardia, palmar erythema and lid lag are common clinical signs. Not all patients have a palpable goitre, but experienced clinicians may discriminate the diffuse soft goitre of Graves disease from the irregular enlargement of a multinodular goitre. All causes of thyrotoxicosis can cause lid retraction and lid lag, due to potentiation of sympathetic innervation of the levator palpebrae muscles, but only Graves disease causes other features of ophthalmopathy, including periorbital oedema, conjunctival irritation, exophthalmos and diplopia. Pretibial myxoedema and the rare thyroid acropachy (a periosteal hypertrophy, indistinguishable from finger clubbing) are also specific to Graves disease (see p. 690).

Investigations

The first-line investigations are serum free T4 and TSH. If abnormal values are found, the tests should be repeated and the abnormality confirmed in view of the likely need for prolonged medical treatment or destructive

Fig. 20.3 Structure and function of the thyroid gland. (1) Thyroglobulin (Tg) is synthesised and secreted into the colloid of the follicle. (2) Inorganic iodide (I^-) is actively transported into the follicular cell ('trapping'). (3) Iodide is transported on to the colloidal surface by a transporter (pendrin, defective in Pendred syndrome, p. 709) and 'organified' by the thyroid peroxidase enzyme, which incorporates it into the amino acid tyrosine on the surface of Tg to form monoiodotyrosine (MIT) and diiodotyrosine (DIT). (4) Iodinated tyrosines couple to form triiodothyronine (T3) and thyroxine (T4). (5) Tg is endocytosed. (6) Tg is cleaved by proteolysis to free the iodinated tyrosine and thyroid hormones. (7) Iodinated tyrosine is dehalogenated to recycle the iodide. (8) T4 is converted to T3 by 5′-monodeiodinase. (CNS = central nervous system; TSH = thyroid-stimulating hormone)

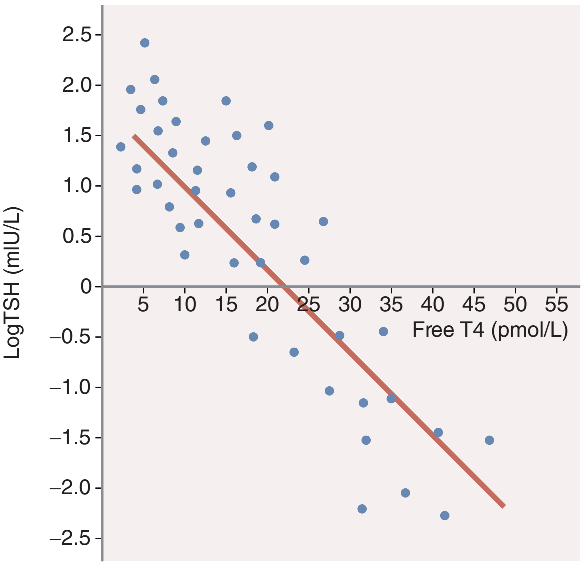

Fig. 20.4 The relationship between serum thyroid-stimulating hormone (TSH) and free T4. Due to the classic negative feedback loop between T4 and TSH, there is an inverse relationship between serum free T4 and the log of serum TSH. To convert pmol/L to ng/dL, divide by 12.87.

therapy. In most patients, serum T3 and T4 are both elevated; elevation of only T3 (T3 toxicosis) is seen in about 5% of presentations. Therefore, free T3 should be assessed in cases with suppressed TSH and normal free T4 levels (T4 usually being at the upper end of the reference range). Serum TSH is undetectable in primary thyrotoxicosis, but values can be raised (or inappropriately normal) in the extremely rare syndrome of secondary thyrotoxicosis caused by a TSH-producing pituitary adenoma, or where uncommon mutations in the thyroid hormone receptor cause thyroid hormone resistance. When biochemical thyrotoxicosis has been confirmed, measurement of TSH receptor antibodies (TRAb, elevated in Graves disease; Box 20.8) is recommended. Where TRAb assessment is not available, or is not detected, radioisotope scanning may help with diagnosis, as shown in Figure 20.5. Other non-specific laboratory abnormalities are common (Box 20.9). An electrocardiogram (ECG) may demonstrate sinus tachycardia and around 5%–10% patients may have atrial fibrillation.

Radio-iodine uptake tests measure the proportion of isotope that is trapped in the whole gland, but have been largely superseded by technetium-99m (^{99m}Tc) scintigraphy scans, which are quicker to perform with a lower dose of radioactivity and provide a higher-resolution image. In low-uptake thyrotoxicosis, the cause is usually a transient thyroiditis; an increase in global uptake is consistent with Graves disease, whilst localised uptake may be demonstrated in toxic nodular disease.

Occasionally, patients induce 'factitious thyrotoxicosis' by consuming excessive amounts of a thyroid hormone preparation, most often

20.5 How to interpret thyroid function test results

TSH	T4	T3	Most likely interpretation(s)
Undetectable	Raised	Raised	Primary thyrotoxicosis
Undetectable or low	Raised	Normal	Over-treatment of hypothyroidism with levothyroxine Factitious thyrotoxicosis
Undetectable	Normal[1]	Raised	Primary T3 toxicosis
Undetectable	Normal[1]	Normal[1]	Subclinical thyrotoxicosis
Undetectable or low	Raised	Low or normal	Non-thyroidal illness Amiodarone therapy
Undetectable or low	Low	Raised	Over-treatment of hypothyroidism with liothyronine (T3)
Undetectable	Low	Low	Secondary hypothyroidism[4] Transient thyroiditis in evolution
Normal	Low	Low[2]	Secondary hypothyroidism[4]
Mildly elevated 5–20 mIU/L	Low	Low[2]	Primary hypothyroidism Secondary hypothyroidism[4]
Elevated > 20 mIU/L	Low	Low[2]	Primary hypothyroidism
Mildly elevated 5–20 mIU/L	Normal[3]	Normal[2]	Subclinical hypothyroidism
Elevated 20–500 mIU/L	Normal	Normal	Artefact Heterophilic antibodies (host antibodies with affinity to the animal antibodies used in TSH assays)
Elevated	Raised	Raised	Non-adherence to levothyroxine replacement – recent 'loading' dose Secondary thyrotoxicosis[4] Thyroid hormone resistance

[1] Usually upper part of reference range.
[2] T3 is not a sensitive indicator of hypothyroidism and should not be requested.
[3] Usually lower part of reference range.
[4] i.e. Secondary to pituitary or hypothalamic disease. Note that TSH assays may report detectable TSH.
(TSH = thyroid-stimulating hormone)

20.6 Causes of thyrotoxicosis and their relative frequencies

Cause	Frequency[1] (%)
Graves disease	76
Multinodular goitre	14
Solitary thyroid adenoma	5
Thyroiditis	
Subacute (de Quervain)[2]	3
Post-partum[2]	0.5
Iodide-induced	
Drugs (amiodarone)[2]	1
Radiographic contrast media[2]	–
Iodine supplementation programme[2]	–
Extrathyroidal source of thyroid hormone	
Factitious thyrotoxicosis[2]	0.2
Struma ovarii[2,3]	–
TSH-induced	
TSH-secreting pituitary adenoma	0.2
Choriocarcinoma and hydatidiform mole[4]	–
Follicular carcinoma ± metastases	0.1

[1] In a series of 2087 patients presenting to the Royal Infirmary of Edinburgh over a 10-year period.
[2] Characterised by negligible radioisotope uptake.
[3] i.e. Ovarian teratoma containing thyroid tissue.
[4] Human chorionic gonadotrophin has thyroid-stimulating activity.
(TSH = thyroid-stimulating hormone)

levothyroxine. Exogenous levothyroxine suppresses pituitary TSH secretion and thus thyroid activity. Thyroglobulin production and release of endogenous thyroid hormones are reduced. The T4:T3 ratio (typically 30:1 in conventional thyrotoxicosis) is increased to above 70:1 because circulating T3 in factitious thyrotoxicosis is derived exclusively from the peripheral deiodination of T4. The combination of negligible iodine uptake, high T4:T3 ratio and a low or undetectable thyroglobulin is diagnostic.

Management

Definitive treatment of thyrotoxicosis depends on the underlying cause and may include antithyroid drugs, radioactive iodine or surgery. A non-selective β-adrenoceptor antagonist (β-blocker), such as propranolol (80–16 mg in 4 divided doses), will alleviate but not abolish symptoms in most patients within 24–48 hours. Beta-blockers should not be used for long-term treatment of thyrotoxicosis, but are invaluable in the short term while patients are awaiting diagnosis and treatment. Verapamil may be used as an alternative to β-blockers, e.g. in patients with asthma, but usually is only effective in improving tachycardia and is less helpful managing other systemic symptoms of thyrotoxicosis.

Atrial fibrillation in thyrotoxicosis

Atrial fibrillation occurs in about 5%–10% of patients with thyrotoxicosis. The incidence is higher in men and increases with age, such that almost half of all males with thyrotoxicosis over the age of 60 are affected. Moreover, subclinical thyrotoxicosis (see p. 701) is a risk factor for atrial fibrillation. Characteristically, the ventricular rate is little influenced by digoxin (likely due to increased clearance) but responds to the addition of a β-blocker. Thromboembolic vascular complications are particularly common in thyrotoxic atrial fibrillation, so anticoagulation is required unless contraindicated. Once thyroid hormone and TSH concentrations have returned to normal, atrial fibrillation will spontaneously revert to sinus rhythm in about 50% of patients; cardioversion should be considered in the remainder.

Thyrotoxic crisis ('thyroid storm')

This is a rare but life-threatening complication of thyrotoxicosis with mortality rates of 8%–25%. The most prominent signs are fever, agitation, delirium, tachycardia or atrial fibrillation and, in the older patient, cardiac failure. Thyrotoxic crisis is a medical emergency. It is precipitated most commonly

20.7 Clinical features of thyroid dysfunction

Thyrotoxicosis		Hypothyroidism	
Symptoms	**Signs**	**Symptoms**	**Signs**
Common			
Weight loss despite normal or increased appetite Heat intolerance, sweating Palpitations, tremor Dyspnoea, fatigue Irritability, emotional lability	Weight loss Tremor Palmar erythema Sinus tachycardia Lid retraction, lid lag	Weight gain Cold intolerance Fatigue, somnolence Dry skin Dry hair Menorrhagia	Weight gain
Less common			
Osteoporosis (fracture, loss of height) Diarrhoea, steatorrhoea Angina Ankle swelling Anxiety, psychosis Muscle weakness Periodic paralysis (predominantly in Chinese and other Asian groups) Pruritus, alopecia Amenorrhoea/oligomenorrhoea Infertility, spontaneous abortion Loss of libido, impotence Excessive lacrimation	Goitre with bruit[1] Atrial fibrillation[2] Systolic hypertension/ increased pulse pressure Cardiac failure[2] Hyper-reflexia Ill-sustained clonus Proximal myopathy Bulbar myopathy[2]	Constipation Hoarseness Carpal tunnel syndrome Alopecia Aches and pains Muscle stiffness Deafness Depression Infertility	Hoarse voice Facial features: Purplish lips Malar flush Periorbital oedema Loss of lateral eyebrows Anaemia Carotenaemia Erythema ab igne Bradycardia, hypertension Delayed relaxation of reflexes Dermal myxoedema
Rare			
Vomiting Apathy Anorexia Exacerbation of asthma	Gynaecomastia Spider naevi Onycholysis Pigmentation	Psychosis (myxoedema madness) Galactorrhoea Impotence	Ileus, ascites Pericardial and pleural effusions Cerebellar ataxia Myotonia

[1] In Graves disease only.
[2] Features found particularly in older patients.

by infection in a patient with unrecognised or inadequately treated thyrotoxicosis. It may also develop in patients with uncontrolled thyrotoxicosis shortly after thyroid manipulation during thyroidectomy or within a few days of iodine-131 (^{131}I) therapy, when acute radiation damage may lead to a transient rise in serum thyroid hormone levels. Urgent specialist endocrine input should be sought in cases of suspected 'thyroid storm', both to confirm the diagnosis and provide advice on appropriate treatment.

Patients should be rehydrated. Beta-blockade using propranolol, either orally (40–80 mg 4 times daily) or intravenously (0.5–2 mg, slow bolus) should be initiated; close monitoring may be needed for patients with congestive heart failure. Oral propylthiouracil (PTU) (200–250 mg every 4 hours) should be given to inhibit the synthesis of new thyroid hormone. PTU is preferred to carbimazole (20 mg every 6 hours) as it also inhibits the conversion of T4 to T3. PTU and propranolol can be administered by nasogastric tube if necessary; however, IV treatment may be necessary due to reduced gastrointestinal absorption. Both glucocorticoids (hydrocortisone 100 mg IV every 8 hours) and iodine reduce the conversion of T4 to active T3. Iodine (saturated potassium iodide solution/Lugol's solution) 0.25 mL every 6 hours orally or sodium ipodate, a radiographic contrast medium (500 mg per day orally), should restore serum T3 levels to normal in 48–72 hours. Administration 1 hour after PTU or carbimazole should limit the risk of stimulating thyroid hormone release (p. 706). After 10–14 days the patient can usually be maintained on carbimazole alone.

Hyperthyroidism in old age

Some of the diagnostic and management challenges of hyperthyroidism in older people are highlighted in Box 20.12.

Hypothyroidism

Hypothyroidism has a prevalence of 0.5%–5% in populations replete in iodine and may approach 10% in populations with endemic iodine deficiency. Autoimmune disease (Hashimoto thyroiditis), thyroid failure following ^{131}I or surgical treatment of thyrotoxicosis account for over 90% of cases, except in areas where iodine deficiency is endemic (Box 20.10). Women are affected approximately six times more frequently than men.

Clinical assessment

The clinical presentation depends on the duration and severity of the hypothyroidism. Those in whom complete thyroid failure has developed insidiously over months or years may present with many of the clinical features listed in Box 20.7. A consequence of prolonged hypothyroidism is the infiltration of many body tissues by the mucopolysaccharides hyaluronic acid and chondroitin sulphate, resulting in a low-pitched voice, poor hearing, slurred speech due to a large tongue, and compression of the median nerve at the wrist (carpal tunnel syndrome). Infiltration of the dermis gives rise to non-pitting oedema (myxoedema), predominantly in the skin of the hands, feet and eyelids. The resultant periorbital puffiness is often striking and may be combined with facial pallor due to vasoconstriction and anaemia, or a lemon-yellow tint to the skin caused by carotenaemia, along with purplish lips and malar flush. Most cases of hypothyroidism are not clinically obvious and thyroid function testing should be considered in individuals complaining of non-specific symptoms such as tiredness, weight gain, depression or carpal tunnel syndrome.

The key discriminatory features in the history and examination are highlighted in Figure 20.6. Care must be taken to identify patients with transient hypothyroidism, in whom life-long levothyroxine therapy is inappropriate. This may occur during the first 6 months after ^{131}I treatment of Graves disease, in the post-thyrotoxic phase of subacute thyroiditis and in post-partum thyroiditis. In these conditions, levothyroxine treatment is not always necessary, as the patient may be asymptomatic during the short period of thyroid failure.

Fig. 20.5 Establishing the differential diagnosis in thyrotoxicosis. [1]Thyroid-stimulating hormone (TSH) receptor antibodies are very rare in patients without autoimmune thyroid disease and occur in ~95% of patients with Graves disease; a positive test is confirmatory, but a negative test does not exclude Graves disease. Other thyroid antibodies (e.g. anti-peroxidase and anti-thyroglobulin antibodies) are unhelpful in the differential diagnosis since they occur frequently in the population and are found with several of the disorders that cause thyrotoxicosis. [2]Graves ophthalmopathy refers to clinical features of exophthalmos and periorbital and conjunctival oedema, not simply the lid lag and lid retraction that can occur in all forms of thyrotoxicosis. [3]Scintigraphy is not necessary in most cases of drug-induced thyrotoxicosis. [4]Technetium-99m (^{99m}Tc) pertechnetate scans of patients with thyrotoxicosis. In low-uptake thyrotoxicosis, most commonly due to a viral, post-partum or iodine-induced thyroiditis, there is negligible isotope detected in the region of the thyroid, although uptake is apparent in nearby salivary glands (not shown here). In a toxic adenoma there is lack of uptake of isotope by the rest of the thyroid gland due to suppression of serum TSH. In multinodular goitre there is relatively low, patchy uptake within the nodules; such an appearance is not always associated with a palpable thyroid. In Graves disease there is diffuse uptake of isotope.

i 20.8 Prevalence of thyroid autoantibodies (%)

	Antibodies to:		
	Thyroid peroxidase[1]	Thyroglobulin	TSH receptor[2]
Normal population	8–27	5–20	< 1
Graves disease	50–80	50–70	> 95
Autoimmune hypothyroidism	90–100	80–90	10–20
Multinodular goitre	~30–40	~30–40	< 1
Transient thyroiditis	~30–40	~30–40	< 1

[1] Thyroid peroxidase (TPO) antibodies are the principal component of what was previously measured as thyroid 'microsomal' antibodies.
[2] Thyroid-stimulating hormone receptor antibodies (TRAb) can be agonists (stimulatory, causing Graves thyrotoxicosis) or antagonists ('blocking', causing hypothyroidism).

Investigations

In the majority of cases, hypothyroidism results from an intrinsic disorder of the thyroid gland (primary hypothyroidism). In this situation, serum T4 is low and TSH is elevated, usually in excess of 20 mIU/L. Measurements of serum T3 are unhelpful since they do not discriminate reliably between euthyroidism and hypothyroidism. Measurement of thyroid peroxidase antibodies is helpful but further investigations are rarely required (see Fig. 20.6). Secondary hypothyroidism (where both TSH and free T4 levels are low) is rare and is caused by failure of TSH secretion in an individual with hypothalamic or anterior pituitary disease. Other non-specific laboratory abnormalities are shown in Box 20.9. In severe, prolonged hypothyroidism, the ECG classically demonstrates sinus bradycardia with low-voltage complexes and may show prolongation of the QRS complex and T-wave flattening or inversion.

20.9 Non-specific laboratory abnormalities associated with thyroid dysfunction*

Thyrotoxicosis

- Serum enzymes: raised alanine aminotransferase, γ-glutamyl transferase (GGT), and alkaline phosphatase from liver and bone
- Raised bilirubin
- Mild hypercalcaemia
- Glycosuria: associated diabetes mellitus, 'lag storage' glycosuria

Hypothyroidism

- Serum enzymes: raised creatine kinase, aspartate aminotransferase, lactate dehydrogenase (LDH)
- Hypercholesterolaemia
- Anaemia: normochromic normocytic or macrocytic
- Hyponatraemia

*These abnormalities are not useful in differential diagnosis, so the tests should be avoided and any further investigation undertaken only if abnormalities persist when the patient is euthyroid.

20.10 Causes of hypothyroidism

Causes	Anti-TPO antibodies[1]	Goitre[2]

Consider rare causes and refer to specialist⁴

Fig. 20.6 An approach to adults with suspected primary hypothyroidism. This scheme ignores congenital causes of hypothyroidism (see Box 20.10), such as thyroid aplasia and dyshormonogenesis (associated with nerve deafness in Pendred syndrome, p. 709), which are usually diagnosed in childhood. [1]Immunoreactive thyroid-stimulating hormone (TSH) may be detected at normal or even modestly elevated levels in patients with pituitary failure; unless T4 is only marginally low, TSH should be > 20 mIU/L to confirm the diagnosis of primary hypothyroidism. [2]The usual abnormality in 'non-thyroidal illness' is a low TSH but any pattern can occur. [3]Thyroid peroxidase (TPO) antibodies are highly sensitive but not very specific for autoimmune thyroid disease (see Boxes 20.8 and 20.10). [4]Specialist advice is most appropriate where indicated. Secondary hypothyroidism is rare, but is suggested by deficiency of pituitary hormones or by clinical features of pituitary tumour such as headache or visual field defect (p. 734). Rare causes of hypothyroidism with goitre include dyshormonogenesis and infiltration of the thyroid (see Box 20.10).

Management

Treatment is with levothyroxine replacement. The average replacement dose of levothyroxine is 1.6 µg/kg (100 µg in a 70 kg adult). In healthy younger adults, it is safe to commence an estimated full dose. In older individuals, and those with a history of cardiovascular disease, it is customary to start with a low dose of 25–50 µg per day for 3 weeks before increasing to the estimated full dose. Levothyroxine has a half-life of 7 days and should be taken as a single daily dose. Ten weeks should pass before repeating thyroid function tests and adjusting the dose as TSH takes several weeks to reach a steady state. Symptomatic improvement usually takes 2–3 weeks. Reduction in weight and periorbital puffiness occurs quickly, but the restoration of skin and hair texture and resolution of any effusions may take 3–6 months. As illustrated in Figure 20.6, most patients do not require specialist review but will need life-long levothyroxine therapy.

The dose of levothyroxine should be adjusted to maintain serum TSH within the reference range. To achieve this, serum T4 often needs to be in the upper part of the reference range because the T3 required for receptor activation is derived exclusively from conversion of T4 within the target tissues, without the usual contribution from thyroid secretion. Some physicians advocate combined replacement with T4 (levothyroxine) and T3 (liothyronine) or preparations of animal thyroid extract, but these approaches remain controversial and are not supported by robust evidence. Some patients remain symptomatic despite normalisation of TSH and may wish to take extra levothyroxine, suppressing their TSH. However, a suppressed TSH is a risk factor for osteoporosis and atrial fibrillation (see below; subclinical thyrotoxicosis), so this approach cannot be recommended.

It is important to measure thyroid function every 1–2 years once the dose of levothyroxine is stabilised to assess adherence and allow adjustment for changes in levothyroxine requirements (Box 20.11). Some patients have a persistent elevation of serum TSH despite an ostensibly adequate replacement dose of levothyroxine; most commonly, this is a consequence of suboptimal adherence to therapy. There may be differences in bioavailability between the numerous generic preparations of levothyroxine, and if an individual is experiencing marked changes in serum TSH despite optimal adherence, the prescription of a branded preparation of levothyroxine could be considered. There is some limited evidence that suggests levothyroxine absorption may be better when the drug is taken before bed. In some individuals with variable adherence, levothyroxine is taken diligently or even in excess for a few days prior to a clinic visit, resulting in the seemingly anomalous combination of a high serum T4 and high TSH (see Box 20.5).

20.11 Situations in which an adjustment of the dose of levothyroxine may be necessary

Increased dose required

Pregnancy or oestrogen therapy
- Increases concentration of serum thyroxine-binding globulin

Use of other medication
- Increase T4 clearance: phenobarbital, phenytoin, carbamazepine, rifampicin, sertraline*, chloroquine*
- Interfere with intestinal T4 absorption: colestyramine, sucralfate, aluminum hydroxide, ferrous sulphate, dietary fibre supplements, calcium carbonate

After surgical or ^{131}I ablation of Graves disease
- Reduces thyroid secretion with time

Malabsorption

Decreased dose required

Ageing
- Decreases T4 clearance

Graves disease developing in patient with long-standing primary hypothyroidism
- Switch from production of blocking to stimulating TSH receptor antibodies

*Mechanism not fully established.

Levothyroxine replacement in ischaemic heart disease

Hypothyroidism and ischaemic heart disease are common comorbidities. Although angina may remain unchanged in severity or paradoxically disappear with restoration of metabolic rate, exacerbation of myocardial ischaemia, infarction and sudden death are recognised complications of levothyroxine replacement, even using doses as low as 25 µg per day. In patients with known ischaemic heart disease, thyroid hormone replacement should be introduced at low dose and increased very slowly under specialist supervision. Coronary intervention may be required if angina is exacerbated by levothyroxine replacement therapy.

Hypothyroidism in old age

Box 20.12 illustrates some of the diagnostic and management challenges of hypothyroidism in older people.

Hypothyroidism in pregnancy

Women with hypothyroidism usually require an increased dose of levothyroxine in pregnancy; inadequately treated hypothyroidism in pregnancy has been associated with impaired neurodevelopment in the fetus. This is discussed in more detail on page 1308 (see also Box 20.13).

Myxoedema coma

This is a very rare presentation of hypothyroidism in which there is a depressed level of consciousness (not always coma), usually in an older patient who appears myxoedematous. Body temperature may be as low as 25°C, convulsions are not uncommon and cerebrospinal fluid (CSF) pressure and protein content are raised. The mortality rate is 50% and survival depends on early recognition and treatment of hypothyroidism and other factors contributing to the altered consciousness level, such as medication, cardiac failure, infection, hyponatraemia and respiratory failure.

Myxoedema coma is a medical emergency and treatment must begin before biochemical confirmation of the diagnosis. Suspected cases should be treated with 200–400 µg levothyroxine followed by 1.6 µg/kg/day (with the dose reduced by 25% if the IV route is required). Liothyronine 2.5–10 µg every 8 hours may be needed alongside levothyroxine as there may be impaired deiodination in the context of myxoedema. Liothyronine 20 µg every 8 hours could be considered where IV levothyroxine is not available. In survivors, there is a rise in body temperature within 24 hours and, after 48–72 hours, it is usually possible to switch patients to oral levothyroxine in a dose of 1.6 µg/kg daily, with lower doses considered in patients vulnerable to coronary artery disease. Unless it is apparent that the patient has primary hypothyroidism, the thyroid failure should also be assumed to be secondary to hypothalamic or pituitary disease. Empirical treatment with hydrocortisone, pending the results of fT4, TSH and cortisol measurement is recommended (100 mg as intravenous bolus and then 200 mg/day, either as a continuous infusion or in 4 divided doses). Other measures include slow rewarming, cautious use of intravenous

20.12 The thyroid gland in old age

Thyrotoxicosis

- **Causes**: commonly due to multinodular goitre.
- **Clinical features**: apathy, anorexia, proximal myopathy, atrial fibrillation and cardiac failure predominate.
- **Non-thyroidal illness**: thyroid function tests are performed more frequently in older patients but interpretation may be altered by intercurrent illness.

Hypothyroidism

- **Clinical features**: non-specific features, such as physical and mental slowing, are often attributed to increasing age and the diagnosis is delayed.
- **Myxoedema coma**: more likely in older people.
- **Levothyroxine dose**: to avoid exacerbating latent or established heart disease, the starting dose should be 25–50 µg daily. Levothyroxine requirements fall with increasing age and few patients need more than 100 µg daily.
- **Other medication** (see Box 20.10): may interfere with absorption or metabolism of levothyroxine, necessitating an increase in dose.

20.13 Thyroid disease in pregnancy

Normal pregnancy

- **Trimester-specific reference ranges**: should be used to interpret thyroid function test results in pregnancy.

Iodine deficiency

- **Iodine requirements**: increased in pregnancy. The World Health Organization (WHO) recommends a minimum intake of 250 μg/day.
- **Iodine deficiency**: the major cause of preventable impaired cognitive development in children worldwide.

Hypothyroidism

- **Impaired cognitive development in the offspring**: may be associated with hypothyroidism that is not adequately treated.
- **Levothyroxine replacement therapy dose requirements**: increase by 30%–50% from early in pregnancy. Monitoring to maintain TSH results within the trimester-specific reference range is recommended in early pregnancy and at least once in each trimester.

Thyrotoxicosis

- **Gestational thyrotoxicosis**: associated with multiple pregnancies and hyperemesis gravidarum. Transient and usually does not require antithyroid drug treatment.
- **Graves disease**: the most common cause of sustained thyrotoxicosis in pregnancy.
- **Antithyroid drugs**: propylthiouracil should be used in the first trimester, with carbimazole substituted in the second and third trimesters.

Post-partum thyroiditis

- **Screening**: not recommended for every woman, but thyroid function should be tested 4–6 weeks post partum in those with a personal history of thyroid disease, goitre or other autoimmune disease including type 1 diabetes, in those known to have positive antithyroid peroxidase antibodies, or when there is clinical suspicion of thyroid dysfunction.

fluids, broad-spectrum antibiotics and mechanical ventilation or high-flow oxygen.

Symptoms of hypothyroidism with normal thyroid function tests

The classic symptoms of hypothyroidism are, by their very nature, non-specific (see Box 20.3). There is a wide differential diagnosis for symptoms such as fatigue, weight gain and low mood. As has been noted, outside the context of pituitary and hypothalamic disease, serum TSH is an excellent measure of an individual's thyroid hormone status. However, some individuals believe that they have hypothyroidism despite normal serum TSH concentrations. They require reassurance that their symptoms are being taken seriously and that organic disease has been carefully considered; if their symptoms persist, referral to a team specialising in medically unexplained symptoms should be considered.

Asymptomatic abnormal thyroid function tests

One of the most common problems in medical practice is how to manage patients with abnormal thyroid function tests who have no obvious signs or symptoms of thyroid disease. These can be divided into three categories.

Subclinical thyrotoxicosis

Serum TSH is undetectable and serum T3 and T4 are at the upper end of the reference range. This combination is most often found in older patients with multinodular goitre. These patients are at increased risk of atrial fibrillation and osteoporosis; therapy, either with ^{131}I or low-dose thionamide should be considered. Otherwise, annual review is essential, as the conversion rate to overt thyrotoxicosis is 5% each year.

Subclinical hypothyroidism

Serum TSH is raised and serum T3 and T4 concentrations are at the lower end of the reference range. This may persist for many years, although there is a risk of progression to overt thyroid failure, particularly if antibodies to thyroid peroxidase are present or if the TSH rises above 10 mIU/L. In patients with non-specific symptoms, a trial of levothyroxine therapy may be appropriate. In those with positive autoantibodies or a TSH greater than 10 mIU/L, it is better to treat the thyroid failure early rather than risk loss to follow-up and subsequent presentation with profound hypothyroidism. Levothyroxine should be initiated and titrated as for hypothyroidism.

Non-thyroidal illness ('sick euthyroidism')

This typically presents with a low serum TSH, raised T4 and normal or low T3 in a patient with systemic illness who does not have clinical evidence of thyroid disease. These abnormalities are caused by decreased peripheral conversion of T4 to T3 (with conversion instead to reverse T3), altered levels of binding proteins and their affinity for thyroid hormones, and often reduced secretion of TSH. During convalescence, serum TSH concentrations may increase to levels found in primary hypothyroidism. Treatment is generally not required. As thyroid function tests are difficult to interpret in patients with non-thyroidal illness, it is wise to avoid performing thyroid function tests unless there is clinical evidence of concomitant thyroid disease. If an abnormal result is found, treatment should only be initiated with specialist advice and the diagnosis should be re-evaluated after recovery.

Thyroid lump or swelling

A lump or swelling in the thyroid gland can be a source of considerable anxiety for patients. There are numerous causes but, broadly speaking, a thyroid swelling is either a solitary nodule, a multinodular goitre or a diffuse goitre (Box 20.14; see p. 690).

Nodular thyroid disease is more common in women and occurs in approximately 30% of the adult female population. Most thyroid nodules are impalpable, but may be identified when imaging of the neck is performed for another reason. Palpable thyroid nodules occur in 4%–8% of adult women and 1%–2% of adult men, and classically present when the individual (or their friend or relative) notices a lump in the neck. Multinodular goitre and solitary nodules sometimes present with acute painful enlargement due to haemorrhage into a nodule.

Patients with thyroid nodules often worry that they have cancer, but only 5%–10% of thyroid nodules are malignant. A nodule presenting in childhood or adolescence, particularly if there is a history of head and neck irradiation, or presentation in an older patient should heighten suspicion of a primary thyroid malignancy. The presence of cervical lymphadenopathy also increases the likelihood of malignancy. Rarely, a secondary deposit from a renal, breast or lung carcinoma presents as a painful, rapidly

20.14 Causes of thyroid enlargement

Diffuse goitre

- Simple goitre
- Hashimoto thyroiditis[1]
- Graves disease
- Drugs: iodine, amiodarone, lithium
- Iodine deficiency (endemic goitre)[1]
- Suppurative thyroiditis[2]
- Transient thyroiditis[2]
- Dyshormonogenesis[1]
- Infiltrative: amyloidosis, sarcoidosis etc.
- Riedel thyroiditis[2]

Multinodular goitre

Solitary nodule

- Colloid cyst
- Hyperplastic nodule
- Follicular adenoma
- Papillary carcinoma
- Follicular carcinoma
- Medullary cell carcinoma
- Anaplastic carcinoma
- Lymphoma
- Metastasis

---

[1] Goitre likely to shrink with levothyroxine therapy.

[2] Usually tender.

growing, solitary thyroid nodule. Thyroid nodules incidentally identified on FDG PET scanning have an approximately 33% chance of being malignant.

Clinical assessment and investigations

Swellings in the anterior part of the neck most commonly originate in the thyroid and this can be confirmed by demonstrating that the swelling moves on swallowing. There is a broad differential diagnosis of anterior neck swellings, which includes lymphadenopathy, branchial cysts, dermoid cysts and thyroglossal duct cysts (the latter are classically located in the midline and move on protrusion of the tongue).

Free T3, T4 and TSH should be measured in all patients with a goitre or solitary thyroid nodule. The finding of biochemical thyrotoxicosis or hypothyroidism (both of which may be subclinical) should lead to investigations, as already described in Box 20.5 and Figures 20.5 and 20.6.

Thyroid scintigraphy

Thyroid scintigraphy with ^{99m}Tc should be performed in an individual with a low serum TSH and a nodular thyroid to confirm the presence of an autonomously functioning ('hot') nodule (see Fig. 20.5). In such circumstances, further evaluation is not necessary. 'Cold' nodules on scintigraphy have a higher likelihood of malignancy, although the majority are benign.

Thyroid/neck ultrasound

If thyroid function tests are normal, an ultrasound scan will differentiate thyroid lumps from other causes of neck swelling. Ultrasound can establish whether there is generalised or localised swelling of the thyroid. Inflammatory disorders causing a diffuse goitre, such as Graves disease and Hashimoto thyroiditis, demonstrate a diffuse pattern of hypoechogenicity and, in the case of Graves disease, increased thyroid blood flow may be seen on colour-flow Doppler (although ultrasound need not form part of the routine investigation of Graves disease). The presence of thyroid autoantibodies will support the diagnosis of Graves disease or Hashimoto thyroiditis, while their absence in a younger patient with a diffuse goitre and normal thyroid function suggests a diagnosis of 'simple goitre'.

Ultrasound can readily determine the size and number of nodules within the thyroid and can distinguish solid nodules from those with a cystic element. It is used increasingly as the key investigation in defining the risk of malignancy in a nodule and a variety of different grading systems are in use. The size of a nodule is not predictive of malignancy, but hypoechogenicity, intranodular vascularity, the presence of microcalcification and irregular or lobulated margins are associated with increased risk. Purely cystic and 'spongiform'-appearing nodules are highly likely to be benign. Each nodule within a multinodular goitre has the same risk of malignancy as a solitary nodule. Thyroid ultrasonography is a highly specialised investigation and the accurate stratification of risk of malignancy of a thyroid nodule requires skill and expertise.

Fine needle aspiration cytology

Fine needle aspiration cytology is recommended for thyroid nodules that are suspicious for malignancy or are radiologically indeterminate. Fine needle aspiration of a thyroid nodule can be performed in the outpatient clinic, usually under ultrasound guidance. Aspiration may be therapeutic for a cyst, although recurrence on more than one occasion is an indication for surgery or alcohol ablation. Fine needle aspiration cytology cannot differentiate between a follicular adenoma and a follicular carcinoma, and in 10%–20% of cases an inadequate specimen is obtained.

Management

Nodules with a benign appearance on ultrasound may be observed in an ultrasound surveillance programme; when the suspicion of malignancy is very low, the patient may be reassured and discharged. Surgery or radiofrequency ablation may be considered for large, symptomatic nodules. In regions with borderline low iodine intake, there is evidence that levothyroxine therapy, in doses that suppress serum TSH, may reduce the size of some nodules. This should not be routine practice in iodine-sufficient populations.

Nodules that are suspicious for malignancy are treated by surgical excision, by either lobectomy or thyroidectomy. Nodules that are radiologically and/or cytologically indeterminate are more of a management challenge and are often surgically resected. Molecular techniques may, in the future, improve the diagnostic accuracy of thyroid cytology and allow a more conservative strategy for individuals with an indeterminate biopsy. Nodules in which malignancy is confirmed by formal histology are treated as described on page 706.

A diffuse or multinodular goitre may require surgical treatment for cosmetic reasons or if there is compression of local structures (resulting in stridor or dysphagia). ^{131}I therapy can also reduce the size of a multinodular goitre. Levothyroxine therapy may shrink the goitre of Hashimoto disease, particularly if serum TSH is elevated.

Autoimmune thyroid disease

Thyroid diseases are amongst the most prevalent autoimmune diseases and are associated with other organ-specific autoimmune diseases. Autoantibodies may produce inflammation and destruction of thyroid tissue, resulting in hypothyroidism, goitre (in Hashimoto thyroiditis) and sometimes even transient thyrotoxicosis ('Hashitoxicosis'), or they may stimulate the TSH receptor to cause thyrotoxicosis (in Graves disease). There is overlap between these conditions, since some patients have multiple autoantibodies.

Graves disease

Graves disease can occur at any age but is unusual before puberty and most commonly affects women aged 30–50 years. The most common manifestation is thyrotoxicosis with or without a diffuse goitre. The clinical features and differential diagnosis are described on page 694. Graves disease also causes ophthalmopathy and, rarely, pretibial myxoedema (p. 705). These extrathyroidal features usually occur in thyrotoxic patients, but can arise in the absence of thyroid dysfunction.

Graves thyrotoxicosis

Pathophysiology

Thyrotoxicosis results from the production of IgG antibodies directed against the TSH receptors on thyroid follicular cells, which stimulate thyroid hormone production and proliferation of follicular cells, leading to goitre in many patients. These antibodies are termed thyroid-stimulating immunoglobulins (TSI) or TSH receptor antibodies (TRAb) and can be detected in the serum of > 95% of patients with Graves disease. The titre of TRAb in the serum is presumed to fluctuate, accounting for the natural history of Graves thyrotoxicosis (Fig. 20.7). Thyroid failure seen in some

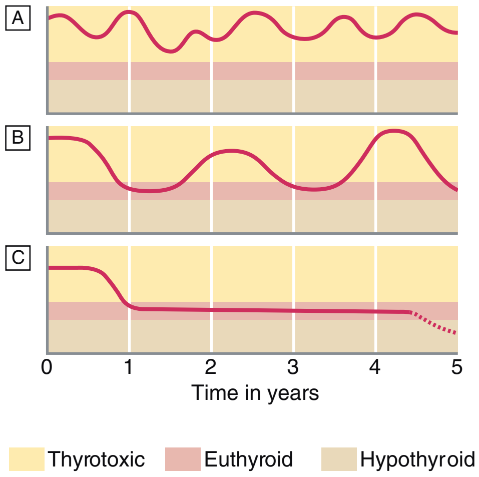

Fig. 20.7 Natural history of the thyrotoxicosis of Graves disease. **A** and **B** The majority (60%) of patients have either prolonged periods of thyrotoxicosis of fluctuating severity, or periods of alternating relapse and remission. **C** It is the minority who experience a single short-lived episode followed by prolonged remission and, in some cases, by the eventual onset of hypothyroidism.

patients may result from the presence of blocking antibodies against the TSH receptor and from tissue destruction by cell-mediated immunity.

Graves disease has a strong genetic component. There is 20%–40% concordance for thyrotoxicosis between monozygotic twins, but only 5% concordance between dizygotic twins. Genome-wide association studies have identified several genes associated with susceptibility. These include *HLA-DRβ-Arg74*, *CTLA4*, *PTPN22*, *TSHR*, *CD25* and *CD40*. Many of these loci have been implicated in the pathogenesis of other autoimmune diseases.

In most cases the environmental trigger for Graves disease is not apparent. In regions of iodine deficiency, iodine supplementation can precipitate thyrotoxicosis in those with pre-existing subclinical Graves disease. Smoking is associated with an approximately twofold risk of Graves thyrotoxicosis and approximately sevenfold risk of the development of ophthalmopathy.

Management

Symptoms of thyrotoxicosis respond to β-blockade but definitive treatment requires control of thyroid hormone secretion. The different options are compared in Box 20.15. Some clinicians adopt an empirical approach of prescribing a course of antithyroid drug therapy and then recommending ^{131}I or surgery if relapse occurs. However, ^{131}I is also used extensively as a first-line therapy, given the high risk of relapse following a course of antithyroid drugs (> 60%). Observational studies have linked therapeutic ^{131}I with increased incidence of some malignancies, particularly of the thyroid and gastrointestinal tract, but results are inconsistent; the association may be with Graves disease rather than its therapy, and the magnitude of the effect, if any, is small. Experience from the disaster at the Chernobyl nuclear power plant in 1986 suggests that younger people are more sensitive to radiation-induced thyroid cancer.

Antithyroid drugs The most commonly used are carbimazole and its active metabolite, methimazole (not available in the UK). Propylthiouracil is equally effective. These drugs reduce the synthesis of new thyroid hormones by inhibiting the iodination of tyrosine (see Fig. 20.3). Carbimazole may also have an immunosuppressive action, leading to a reduction in serum TRAb concentrations, but this does not significantly influence the natural history of the thyrotoxicosis.

Antithyroid drugs are typically introduced at high doses (carbimazole 20–40 mg daily or propylthiouracil 200–400 mg daily), although lower doses are reasonable in individuals with only modest elevation of T4 and T3. Usually, this results in subjective improvement within 10–14 days and renders the patient clinically and biochemically euthyroid at 6–8 weeks. At this point, the dose can be down-titrated to maintain T4 and TSH within their reference range. In most patients, carbimazole is continued at 5–20 mg per day for 12–18 months in the hope that remission will occur. 50%–80% of patients with Graves disease will subsequently relapse, usually within 2 years of stopping treatment. Risk factors for relapse include younger age, male sex, presence of a goitre and higher TRAb titres at both diagnosis and cessation of antithyroid therapy. Rarely, T4 and TSH levels fluctuate between those of thyrotoxicosis and hypothyroidism at successive review appointments, despite good drug adherence, presumably due to rapidly changing concentrations of TRAb. In these patients, satisfactory control can be achieved by blocking thyroid hormone synthesis with carbimazole 20–40 mg daily and adding levothyroxine 1.6 µg/kg daily as replacement therapy (a 'block and replace' regimen).

Antithyroid drugs can have adverse effects. The most common is a rash. Agranulocytosis is a rare but potentially serious complication (1–2 per 1000) that cannot be predicted by routine measurement of white blood cell count, but which is generally reversible on stopping treatment. Patients should be warned to stop the drug and seek medical advice immediately should a severe sore throat, mouth ulcers or fever develop while on treatment. Carbimazole crosses the placenta and has a small risk of inducing congenital malformations including aplasia cutis, a localised defect in skin development (it should be avoided during the first trimester of pregnancy). Propylthiouracil is associated with a small risk of hepatotoxicity, which, in some instances, has resulted in liver failure requiring liver transplantation, and even in death. It should therefore be considered second-line therapy to carbimazole, used only during pregnancy or if an adverse reaction to carbimazole has occurred, and patients should be monitored for hepatotoxicity.

Thyroid surgery Patients should be rendered euthyroid with antithyroid drugs before surgery. Oral potassium iodide, ~50–100 mg (e.g. 1–2 drops [0.05–0.1 mL] saturated solution of potassium iodide) 3 times daily, is often added for 10 days before surgery to limit perioperative thyroid hormone release and reduce the size and vascularity of the gland, making surgery technically easier. The optimal surgical approach is a 'near-total' thyroidectomy, leaving behind only a small portion of gland adjacent to the recurrent laryngeal nerves. This strategy results in permanent hypothyroidism and is probably associated with a higher risk of hypoparathyroidism, compared to 'subtotal' thyroidectomy, but maximises the potential for cure of thyrotoxicosis.

Radioactive iodine ^{131}I is administered orally as a single dose and is trapped and organified in the thyroid (see Fig. 20.3). ^{131}I emits both β and γ radiation and, although it decays within a few weeks, it has long-lasting

20.15 Comparison of treatments for the thyrotoxicosis of Graves disease

Management	Common indications	Contraindications	Disadvantages/complications
Antithyroid drugs (carbimazole, propylthiouracil)	First episode in patients < 40 years	Breastfeeding[1]	Hypersensitivity rash 2% Agranulocytosis 0.2% Hepatotoxicity (with propylthiouracil) – very rare but potentially fatal > 50% relapse rate usually within 2 years of stopping drug
Thyroidectomy	Large goitre Poor drug adherence, especially in young patients Recurrent thyrotoxicosis after course of antithyroid drugs in young patients	Previous thyroid surgery Dependence on voice, e.g. singer, lecturer[2]	Hypothyroidism (~25%) Transient hypocalcaemia (10%) Permanent hypoparathyroidism (1%) Recurrent laryngeal nerve palsy[2] (1%)
Radio-iodine	Patients > 40 years[3] Recurrence following surgery irrespective of age Other serious comorbidity	Pregnancy or planned pregnancy within 6 months of treatment Active Graves ophthalmopathy[4]	Hypothyroidism: ~40% in first year, 80% after 15 years Most likely treatment to result in exacerbation of ophthalmopathy[4]

[1] Antithyroid drugs, particularly carbimazole, pass into breast milk. Risks/benefits should be considered with a specialist and as low a dose as possible chosen if necessary.

[2] It is not only vocal cord palsy due to recurrent laryngeal nerve damage that alters the voice following thyroid surgery; the superior laryngeal nerves are frequently transected and this results in minor changes in voice quality.

[3] In many institutions, ^{131}I is used more liberally and is prescribed for much younger patients.

[4] The extent to which radio-iodine exacerbates ophthalmopathy is controversial and practice varies; some use prednisolone to reduce this risk.

inhibitory effects on survival and replication of follicular cells. In most centres, approximately 400–600 MBq (approximately 10–15 mCi) is administered. This regimen is effective in 75% of patients within 4–12 weeks. Following treatment, symptoms can be controlled by β-blockade or, in more severe cases, by carbimazole. Carbimazole reduces the efficacy of ^{131}I therapy because it prevents organification of ^{131}I in the gland, and so should be avoided until 48 hours after ^{131}I administration. If thyrotoxicosis persists after 6 months, a further dose of ^{131}I can be given. If successful, in the context of Graves disease, ^{131}I treatment will likely render the patient hypothyroid. Due to the difficulty predicting thyroid dysfunction following ^{131}I therapy, and the risk of delay diagnosing hypothyroidism, some physicians advocate initiation of 'block and replace' treatment for 6 months following ^{131}I, with subsequent withdrawal of thionamide. ^{131}I is usually avoided in patients with Graves ophthalmopathy and evidence of significant active orbital inflammation. It can be administered with caution in those with mild or 'burnt-out' eye disease, when it is customary to cover the treatment with a 6-week tapering course of oral prednisolone. In women of reproductive age, pregnancy must be excluded before administration of ^{131}I and avoided for at least 6 months thereafter. Men are also advised to use strict contraceptive measures for at least 4 months after receiving ^{131}I, to avoid the possibility of conceiving with sperm that have been exposed to radiation.

Thyrotoxicosis in pregnancy Thyrotoxicosis in pregnancy may be associated with significant maternal and fetal morbidity. Management is specialised and is discussed on page 1308 (see also Box 20.13).

Thyrotoxicosis in adolescence Thyrotoxicosis can occasionally occur in adolescence and is almost always due to Graves disease. The presentation may be atypical and management challenging, as summarised in Box 20.16.

Graves ophthalmopathy

This condition is immunologically mediated, with the TSH receptor identified as the main autoantigen. Cytokine-mediated proliferation of fibroblasts that secrete hydrophilic glycosaminoglycans occurs in the orbit and dermis. The resulting increase in interstitial fluid content, combined with a chronic inflammatory cell infiltrate, causes marked swelling and ultimately fibrosis of the extraocular muscles (Fig. 20.8) and a rise in retrobulbar pressure. The eye is displaced forwards (proptosis, exophthalmos) and in severe cases there is optic nerve compression.

Ophthalmopathy, like thyrotoxicosis (see Fig. 20.7), typically follows an episodic course and it is helpful to distinguish patients with active inflammation (periorbital oedema and conjunctival inflammation with changing orbital signs) from those in whom the inflammation has 'burnt out'. Eye disease is detectable in up to 50% of thyrotoxic patients at presentation (although moderate to severe in only 5%), but active ocular inflammation may occur before or after thyrotoxic episodes (exophthalmic Graves disease). Ophthalmopathy is more common in men and cigarette smokers. It may be exacerbated by ^{131}I and poor control of thyroid function, especially hypothyroidism. The most frequent presenting symptoms are related to increased exposure of the cornea, resulting from proptosis and lid retraction. There may be excessive lacrimation made worse by wind and bright light, a 'gritty' sensation in the eye and pain due to conjunctivitis or corneal ulceration. In addition, there may be reduction of visual acuity and/or visual fields because of corneal oedema or optic nerve compression. Other signs of optic nerve compression include reduced colour vision and a relative afferent pupillary defect (see p. 691). If the extraocular muscles are involved and do not act in concert, diplopia results.

20.16 Thyrotoxicosis in adolescence

- **Presentation**: may present with a deterioration in school performance or symptoms suggestive of attention deficit hyperactivity disorder.
- **Antithyroid drug therapy**: prolonged courses may be required because remission rates following an 18-month course of therapy are much lower than in adults.
- **Adherence**: adherence to antithyroid drug therapy is often suboptimal, resulting in poor disease control that may adversely affect performance at school.
- **Radio-iodine therapy**: usually avoided in adolescents because of concerns about risk of future malignancy.

Most patients require no treatment other than reassurance. Smoking cessation should be strongly encouraged. Methylcellulose eye drops and gel counter the gritty discomfort of dry eyes, and tinted glasses or side shields reduce the excessive lacrimation triggered by sun or wind. In patients with mild Graves ophthalmopathy, oral selenium (100 μg twice daily for 6 months) improves quality of life, reduces ocular involvement and slows progression of disease. Moderate to severe ophthalmopathy is optimally managed by an expert multidisciplinary service. More severe inflammatory episodes are treated with glucocorticoids (e.g. pulsed intravenous methylprednisolone) and immunosuppressive therapies (e.g. rituximab and tocilizumab); the insulin-like growth factor-1 (IGF-1) receptor inhibitor teprotumumab may be required in moderate to severe ophthalmopathy. Orbital radiotherapy may also be considered. Loss of visual acuity is an indication for urgent surgical decompression of the orbit. In 'burnt-out' disease, surgery to the extraocular muscles, and later the eyelids, may improve diplopia, conjunctival exposure and cosmetic appearance.

Pretibial myxoedema

This infiltrative dermopathy occurs in fewer than 5% of patients with Graves disease and has similar pathological features as occur in the orbit. It takes the form of raised pink-coloured or purplish plaques on the anterior aspect of the leg, extending on to the dorsum of the foot; less commonly, the face and arms are affected (see p. 690). The lesions may be itchy and the skin may have a 'peau d'orange' appearance with growth of coarse hair. Treatment is rarely required but in severe cases topical glucocorticoids may be helpful.

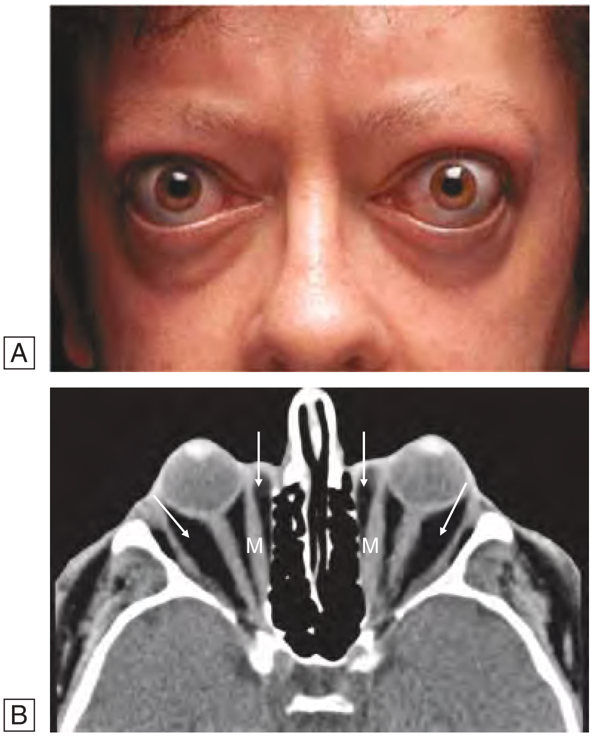

Fig. 20.8 Graves disease. **A** Bilateral ophthalmopathy in a 42-year-old man. The main symptoms were diplopia in all directions of gaze and reduced visual acuity in the left eye. The periorbital swelling is due to retrobulbar fat prolapsing into the eyelids, and increased interstitial fluid as a result of raised intraorbital pressure. **B** Axial CT of the orbits, showing bilateral increased intraorbital fat (arrows), proptosis and bilateral enlarged medial recti muscles (M).
